# Foreword

---

It is a special pleasure to provide this Foreword for the lucky readers of the third edition of this classic handbook. The first two editions of the handbook significantly impacted the chemical senses at large, and there is no reason to believe that this will also not be the case for the third edition. Importantly, the third edition has been expanded to cover topics beyond those of its predecessors.

Describing a system in the brain “from molecules to behavior” is one of the grand goals of contemporary neuroscience. This new edition makes clear how the chemosenses – smell and taste – are systems par excellence for achieving this goal. To begin with, the stimuli are themselves molecules, and even in the case of salt and sour, ions. The Handbook covers leading work on how chemosensory receptors are produced by gene expression, and how each type of molecule or ion interacts with its receptor. The combined responses of the receptor cells represent the stimuli as spatial and temporal patterns. These patterned responses are subjected to central processing in the brain centers that transform the neural images created in the sensory domain to smell and taste objects in the central domain. This creates the neural basis of conscious smell and taste perception all the way up to the cerebral cortex, as the Handbook describes.

In addition to acting separately, the taste and smell systems act in concert during eating to give rise to the perception of flavor. The Handbook documents the physiological underpinnings of this process and reveals how flavor and food preferences are shaped from before birth into old age. Clearly, as emphasized in the Handbook, the neural basis of flavor is a rapidly growing field with critical implications for public health policies such as curbing the tendencies of people to eat too much of the foods they crave – tendencies that lead to overeating, obesity, and related disorders.

The editor, Richard Doty, is an expert in both normal and disordered taste and smell, and the Handbook is thus especially strong in disorders to which smell and taste are related. An important example is in neurodegenerative disorders such as Alzheimer’s and Parkinson’s disease, where the first signs may be decreased smell sensitivity.

Disordered chemosensation may be primary, as well as secondary, elements of disease states elsewhere in the body, and their study have begun to shed light on the etiology of a number of diseases, including some forms of cancer. Altered taste and smell are now recognized as being more prevalent than previously thought and chemosensory testing has begun to be more common in a number of doctors’ offices and medical centers. Clearly, chemosensory research has led, and continues to lead, to many practical applications in public health, as the Handbook emphasizes.

The third edition of the Handbook has been expanded to emphasize the important role that the chemical senses play in the national economy. This includes the importance of aromas in cosmetics and perfumes, as well as in determining the flavors of virtually all processed foods. This new edition of the Handbook covers these subjects eloquently, as well as topics such as problems of smell pollution in the environment and chemosensory properties of drinking water.

In addition to these mainstream topics, the Handbook also highlights many little known facts about these fascinating senses. These include the nasal cycle and chemoreception in one-cell organisms, in birds, in dogs, and in insects. Other topics include how taste aversions arise and the role of the frequently overlooked vomeronasal organ in the behavior of a wide range of vertebrates. It provides an excellent introduction into the new field of chemesthesia – a field developing as a result of the discovery of isolated taste cells along the lining of the stomach, esophagus, and intestines that continue to sense our food unconsciously long after its ingestion. Taste and smell thus offer up many surprises about what controls our lives, and the Handbook will continue to be the first place to go to learn about them.

New Haven, Connecticut, USA

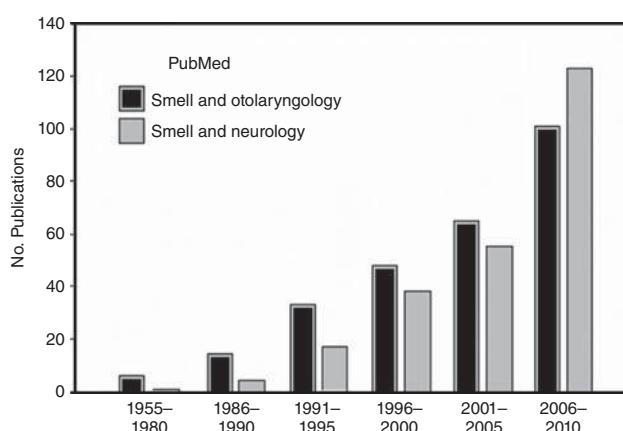

# Preface

---

This third edition of the *Handbook of Olfaction and Gustation* represents the largest collection of basic, clinical, and applied knowledge on the chemical senses ever compiled in one volume. Since the publication of the second edition a decade ago, many more advances in chemosensory science have occurred, most remarkably in neuroscience, molecular biology, and neurology. A year after the publication of the second edition, the 2004 Nobel Prize in Medicine or Physiology was awarded to Linda Buck and Richard Axel for their discovery of the gene family responsible for expression of the olfactory receptors. This punctuated the fact that the chemical senses had by that time become a key element of modern neuroscience, in part as a result of their unique transduction processes and integral association with stem cell activity and regenerative capacities. Multiple taste receptor proteins and mechanisms have since been identified, particularly for bitter-tasting agents, and taste receptors have now been found to be distributed throughout the alimentary tract, the upper and lower respiratory tracts, and elsewhere. The importance of olfaction in a variety of clinical fields has grown, largely as a consequence of the continued proliferation of commercially available clinical olfactory tests and the discovery that decreased smell function is one of the earliest signs of such neurodegenerative diseases as Alzheimer's disease and Parkinson's disease. The geometric growth of interest in olfaction in neurology and otorhinolaryngology is illustrated in the above figure, a growth that is paralleled in a number of other clinical specialties. Note that in every half decade since 1986, more publications have occurred than in the entire preceding quarter century.

It is important to emphasize that biology, neuroscience, and the clinical specialties are not the only fields where the chemical senses are current centers of focus. The food and beverage industries are increasing,

at great cost, research efforts to enhance the flavor of their products and, importantly, to maintain such flavor in light of developing government regulations to minimize the amount of salt, sugar, and other ingredients in their products. The energy industry is now required, by law, to test many of their workers for the ability to smell, making this sensory system of direct interest to this entire industry. Continued interest in olfaction by marketers of perfumes and personal care products goes without saying.

In keeping with previous editions, the third edition of the *Handbook* continues to emphasize history and perspective in its presentations. Also, in keeping with prior editions, in many cases several authors with divergent experience within each of the topic areas have formed collaborations to provide unique and compelling contributions. Compared to earlier editions, more emphasis has been placed on the genetics of olfaction and taste, as well as central nervous system integration of sensory processing. A number of new chapters have been added

to incorporate findings from a wider range of species, including birds, fish, and invertebrates, as well as ones that address chemosensory research perspectives within the food, beverage, perfume, personal care, and water industries. To make way for these new chapters and to reduce redundancy and minimize the inevitable increase in the number of volume pages, several previous chapters from the second edition have been combined or omitted.

I am particularly indebted to the contributors for providing such excellent chapters, as well to those who volunteered to be section editors. I thank the staff of Wiley-Liss for their professionalism and suggestions for making the volume the highest quality possible.

## Introduction and Historical Perspective

RICHARD L. DOTY

### 1.1 INTRODUCTION

All environmental nutrients and airborne chemicals required for life enter our bodies by the nose and mouth. The senses of taste and smell monitor the intake of such materials, not only warning us of environmental hazards, but determining, in large part, the flavor of our foods and beverages, largely fulfilling our need for nutrients. These senses are very acute; for example, the human olfactory system can distinguish among thousands of airborne chemicals, often at concentrations below the detection limits of the most sophisticated analytical instruments (Takagi, 1989). Furthermore, these senses are the most ubiquitous in the animal kingdom, being present in one form or another in nearly all air-, water-, and land-dwelling creatures. Even bacteria and protozoa have specialized mechanisms for sensing environmental chemicals – mechanisms whose understanding may be of considerable value in explaining their modes of infection and reproduction (Jennings, 1906; Russo and Koshland, 1983; van Houten, 2000).

While the scientific study of the chemical senses is of relatively recent vintage, the important role of these senses in the everyday life of humans undoubtedly extends far into prehistoric times. For example, some spices and condiments, including salt and pepper, likely date back to the beginnings of rudimentary cooking, and a number of their benefits presumably were noted soon after the discovery of fire. The release of odors from plant products by combustion was likely an early observation, the memory of which is preserved in the modern word *perfume*, which is derived from the Latin *per* meaning “through” and *fumus* meaning “smoke.” Fire, with its dangerous and magical connotations, must have become associated early on with religious activities, and pleasant-smelling smoke was likely sent into the heavens in rituals designed to please

or appease the gods, as documented in later civilizations, such as the early Hebrews. Importantly, food and drink became linked to numerous social and religious events, including those that celebrated birth, the attainment of adulthood, graduation to the status of hunter or warrior, and the passing of a soul to a better life.

In this chapter I provide a brief historical overview of the important role that tastes and odors have played in the lives of human beings throughout millennia and key observations from the last four centuries that have helped to form the context of modern chemosensory research. Recent developments, which are described in detail in other contributions to the *Handbook*, are briefly mentioned to whet the reader’s appetite for what is to follow. Although an attempt has been made to identify, rather specifically, major milestones in chemosensory science since the Renaissance, some important ones have undoubtedly been left out, and it is not possible to mention, much less discuss, even a small fraction of the many studies of this period that have contributed to our current fund of knowledge. Hopefully the material that is presented provides some insight into the basis for the present Zeitgeist. The interested reader is referred elsewhere for additional perspectives on the history of chemosensory science (e.g., Bartoshuk, 1978, 1988; Beauchamp, 2009; Beidler, 1971a, b; Boring, 1942; Cain, 1978; Cloquet, 1821; Corbin, 1986; Doty, 1976; Douek, 1974; Farb and Armelagos, 1980; Farbman, 1992; Frank, 2000; Garrett, 1998; Gloor, 1997; Harper et al., 1968; Harrington and Rosario, 1992; Jenner, 2011; Johnston et al., 1970; Jones and Jones, 1953; Luciani, 1917; McBurney and Gent, 1979; McCartney, 1968; Miller, 1988; Moulton and Beidler, 1967; Moulton et al., 1975; Myktytowycz, 1986; Nagel, 1905; Ottoson, 1963; Pangborn and Trabue, 1967; Parker, 1922; Pfaff, 1985; Piesse, 1879;

## 1.2 A BRIEF HISTORY OF PERFUME AND SPICE USE

The relatively rich history of a number of ancient civilizations, particularly those of Egypt, Greece, Persia, and the Roman Empire, provides us with examples of how perfumes and spices have been intricately woven into the fabric of various societies. Thousands of years before Christ, fragrant oils were widely used throughout the Middle East to provide skin care and protection from the hot and dry environment, and at least as early as 2000 BCE, spices and fragrances were added to wine, as documented by an inscription on a cuneiform text known as the *Enuma elish* (Heidel, 1949). During the greater part of the 7th to 5th Centuries BCE, Rhodian potters developed vast quantities of perfume bottles in the form of animals, birds, and human heads and busts that were shipped throughout the mediterranean area (Figure 1.1). In Egypt, incense and fragrant substances played a key role in religious rites and ceremonies, including elaborate burial customs, and whole sections of towns were inhabited by men whose sole profession was to embalm the deceased. As revealed in the general body of religious texts collectively termed the “Book of the Dead” (a number of which predate 3000 BCE; Budge, 1960), the Egyptians performed funeral ceremonies at which prayers and recitations of formulae

(including ritualistic repeated burning of various types of incense) were made, and where the sharing of meat and drink offerings by the attendees occurred. Such acts were believed to endow the departed with the power to resist corruption from the darkness and from evil spirits that could prevent passage into the next life, as well as to seal the mystic union of the friends and loved ones with the dead and with the chosen god of the deceased. The prayers of the priests were believed to be carried via incense into heaven and to the ears of Osiris and other gods who presided over the worlds of the dead (Budge, 1960).

As noted in detail by Piesse (1879), the ancient Greeks and Romans used perfumes extensively, keeping their clothes in scented chests and incorporating scent bags to add fragrance to the air. Indeed, a different scent was often applied to each part of the body; mint was preferred for the arms; palm oil for the face and breasts; marjoram extract for the hair and eyebrows; and essence of ivy for the knees and neck. At their feasts, Greek and Roman aristocrats adorned themselves with flowers and scented waxes and added the fragrance of violets, roses, and other flowers to their wines. As would be expected, perfume shops were abundant in these societies, serving as meeting places for persons of all walks of life (Morfit, 1847). In Grecian mythology, the invention of perfumes was ascribed to the Immortals. Men learned of them from the indiscretion of Aeone, one of the nymphs of Venus; Helen of Troy acquired her beauty from a secret perfume, whose formula was revealed by Venus. Homer (8th century BCE) reports that whenever the Olympian gods honored mortals by visiting them, an ambrosial odor was left, evidence of their divine nature (Piesse, 1879). Interestingly, bad odors were a key element of a number of myths, including that of Jason and the Argonauts (Burket, 1970). As a result of having been smitten with the wrath of Aphrodite, the women of Lemnos developed a foul odor, which drove their husbands to seek refuge in the arms of Thracian slave girls. The women were so enraged by their husbands’ actions that one evening they slew not only their husbands, but all the men of the island. Thereafter, Lemnos was a community of women without men, ruled by the virgin queen Hypsiple, until the day when Jason and the Argo arrived, which ended the period of celibacy and returned the island to heterosexual life.

Perfumes were not universally approved of in ancient Greece. Socrates, for example, objected to them altogether, noting, “There is the same smell in a gentleman and a slave, when both are perfumed,” and he believed that the only odors worth cultivating were those that arose from honorable toil and the “smell of gentility” (Morfit, 1847). Nevertheless, the use of perfumes became so prevalent in ancient Greece that laws were passed in Athens in the 6th century BCE to restrain their use. Despite this prohibition, however, their use grew unabated, and the Greeks added greatly to the

**Figure 1.1** Example of a horse head perfume bottle manufactured in Rhodes circa 580 BCE. © Heritage Images (Image ID: 2-605-015).

stock of fragrant plants from the East that made up the core of the perfume industry.

Perfume and incense had religious significance to the followers of Zoroaster, the Persian religious leader of the 6th century BCE, who offered prayers before altars containing sacred fires to which wood and perfumes were added five times each day (Piesse, 1879). It is noteworthy that, to this day, sandalwood fuels the sacred fires of the Parsees (modern Zoroastrians) in India and that similar rituals were required of the early Hebrews, as indicated by the following instructions from God to Moses (Exodus 30:1, 7–9, 34–38; King James version):

And thou shalt make an altar to burn incense upon: of shittim wood shalt thou make it. And Aaron shall burn thereon sweet incense every morning: when he dresseth the lamps, he shall burn incense upon it [the altar]. And when Aaron lighteth the lamps at even, he shall burn incense upon it, a perpetual incense before the Lord throughout your generations. Ye shall offer no strange incense thereon, nor burnt sacrifice, nor meat offering; neither shall ye pour drink offering thereon.

And the Lord said unto Moses, take unto thee three sweet spices, stacte, and onycha, and galbanum; these sweet spices with pure frankincense; of each shall there be a light weight. And thou shalt make it a perfume <or incense>, a confection after the art of the apothecary, tempered together, pure and holy: And thou shalt beat some of it very small, and put of it before the testimony in the tabernacle of the congregation, where I will meet with thee: it shall be unto you most holy. And as for the perfume which thou shalt make, ye shall not make to yourselves according to the composition thereof: it shall be unto thee holy for the Lord. Whosoever shall make like unto that, to smell thereto, shall even be cut off from his people.

Given such instructions from God and the Christian emphasis on cleansing the soul of evil spirits, as well as the fact that Christ himself, after his crucifixion, had been embalmed in pleasant-smelling myrrh, aloe, and spices (John 19: 39–40), it is perhaps not surprising that bad smells came to signify the unholy at various times in Christian history. Indeed, St. Philip Neri reportedly found the stench emanating from heretics so great that he had to turn his head (Summers, 1926).

One of the more interesting, and tragic, uses of bad smells was to identify witches and warlocks in Europe in the late 1500s. Remy, a distinguished appointee of Charles III to the Provosts of Nancy (a court that judged all criminal cases for some 72 villages in the Nancy region of France), wrote the following in his classic 1595 monograph *Demonolatry*:

In the Holy Scriptures the Devil is constantly referred to as Behemoth, that is to say, “the impure animal and the unclean spirit” (see S. Gregory, in *Memorabilia, Matthew XII, Mark I and V, Job XI*). It is not only because the Devil is, as all his actions and purposes show, impure in his nature and character that we should consider this name to be aptly applied to him; but also because he takes immoderate delight in external filth and uncleanness. For often he makes his abode in dead bodies; and if he occupies a living body, or even if he forms himself a body out of the air or condensation of vapours, his presence therein is always betrayed by some notable foul and noisome stench. The gifts of the Demon are also fashioned from ordure and dung, and his banquets from the flesh of beasts that have died . . . for the most part [he] has for his servants filthy old hags whose age and poverty serve but to enhance their foulness; and these . . . he instructs in all impurity and uncleanness . . . Above all he cautions them not to wash their hands, as it is the habit of other men to do in the morning; for he tells them that to do so constitutes a sure obstruction to his incantations. This is the case whether it is the witches themselves who wash their hands, as we learn from the answer freely given to her examiners by Alexia Galaea of Betoncourt at Mirecourt in December 1584, and by countless others whose names I have not now by me; or whether it is the intended victims of their witchcraft who wash their hands, as was stated by Claude Fellet (Mersuay, February 1587) and Catharina Latomia (Haraucourt, February 1587).

In contrast to the detection of witches and warlocks by stench was the verification of sainthood by a pleasant odor, the so-called “odor of sanctity.” If a saint had been an impostor, a nauseating smell, rather than a delectable one, was present upon exhumation of his body (Rothkrug, 1981). This concept bears a striking resemblance to the Greek myths of the pleasant odors left by the Olympian gods who visited mortals and may well stem from the same tradition.

It should be noted, however, that cleanliness was not always the vogue for Christianity, as described by McLaughlin (1971) in a series of interesting accounts from the Middle Ages. Thus, in their repudiation of Roman values and their desire to avoid lust and sins of the flesh, early Christians often went unbathed. Every sensation offensive to humans was believed acceptable to God, and the custom of bathing the limbs and anointing them with oil was condemned. Monks shaved their hair, wrapped their heads in cowls to avoid seeing profane objects, and kept legs naked except in the extreme of winter. St. Jerome criticized a number of his followers for being too clean,

and St. Benedict, a key administrator of the early church, pronounced solemnly that “to those that are well, and especially to the young, bathing shall seldom be permitted.” St. Agnes reportedly had never washed throughout her life, and a pilgrim to Jerusalem in the 4th century is said to have boasted that her face had gone unwashed for 18 years so as not to disturb the holy water used at her baptism.

During the Middle Ages, perfumery and the widespread use of spices and flavoring agents was little known in Europe, being practiced mainly by Arabs in the East. Marco Polo, visiting the China of Kublai Khan (1216–1295), noted that pleasantly perfumed silk paper money was used for exchange within Khan’s kingdom (Boorstin, 1985). The dearth of smell in Europe was to change dramatically, however, as a major element of the Renaissance was the relentless search for perfumes and spices, a number of which were more valuable than silver or gold. The quest was not only for aesthetic enjoyment; some of these agents made it possible, much like cooking itself, to exploit a wider and more diverse range of foodstuffs, including ones that otherwise were unsafe or had little gastronomic appeal. In this regard, it is of interest that at the siege of Rome in 408 BCE, Alaric, the victorious king of the Goths, demanded 3000 pounds of pepper as ransom for the city, and when the Genoese captured Caesarea in 1101 BCE, each soldier received two pounds of pepper as his share of the spoils (Verrill, 1940).

Perfume was introduced, at least in a widespread sense, to medieval Europe by the crusaders. After the downfall of the Roman Empire, the perfume industry moved to the Eastern Roman Empire, and Constantinople became the perfume center of the world. Reportedly, Avicenna (CE 980–1036), the great Arab scientist, philosopher, and physician, discovered a way to extract and maintain the fragrances of plants and invented rose water (Takagi, 1989). In 1190, King Philip II (Philip Augustus, r. 1180–1223) of France granted the first charter to a perfume maker. King Charles V (Charles the Wise, r. 1364–1380) subsequently planted large fields of flowers in France to obtain perfume materials, and Charles VIII (r. 1483–1498) was reportedly the first French monarch to appoint a court perfumer. The soil, climate, and location of southern France made it a natural place for the cultivation of flowers for the perfume industry, which gained world supremacy from the late 1700s – supremacy that has continued to the present time (Vivino, 1960).

According to Piesse (1879), perfumes lost their popularity in England for more than a century prior to the Victorian era, unlike the case in France, Italy, and Spain. Related to this loss of popularity was an act, introduced into the English parliament in 1770, that warned women of the use of scents and other materials in the seduction of men (Piesse, 1879, p. 20):

That all women, of whatever age, rank, profession, or degree, whether virgins, maids, or widows, that shall, from and after such Act, impose upon, seduce or betray into matrimony, any of his Majesty’s subjects, by the scents, paints, cosmetic washes, artificial teeth, false hair, Spanish wool, iron stays, hoops, high-heeled shoes, and bolstered hips, shall incur the penalty of the law now in force against witchcraft and the like misdemeanors, and that the marriage, upon conviction, shall stand null and void.

The influences of such attempts to ban perfumes in England were short-lived, as perfume vendors thrived, although the state taxed them and required them, in 1786, to have licenses. By 1800 approximately 40 companies were making perfumes in London. Importantly, in the 19th century the revolution that occurred in organic chemistry ensured the continuance of perfume manufacturing in Britain; the first important successful synthetic odorant, coumarin, was prepared in 1863 by the British chemist Sir William Henry Perkin (Vivino, 1960).

Interestingly, for some time the odor of coffee, when first introduced into London, was viewed as offensive. Thus, a formal complaint was lodged in 1657 by the inhabitants of the parish of St. Dustant’s in West London against a barber, James Farr, “for making & Selling of a Drinke called Coffee whereby in making the same he annoyeth his neighbors by evill smells” (Jenner, 2011). As with perfume manufacturing, however, such concerns were relatively short-lived. Thus, in 1708 the English historian Edward Hatton pointed out, in relation to the Farr incident, “who would then have thought London would ever have had nearly 3000 such Nusances, and that Coffee would have been (as now) so much Drank by the best of Quality, and Physicians” (Jenner, p. 30).

### 1.3 THE CHEMICAL SENSES AND EARLY MEDICINE

The close association between odors, spices, and medicine was undoubtedly forged long before recorded history and was likely fostered not only by stenches associated with plagues and death, but by the utility of essential oils and spices in warding off insects and microbes. Indeed, one reason why perfumes and spices were major objects of international trade in the ancient world was their medicinal properties (van der Veen and Morales, 2014). According to Morris (1984), such properties may have been as important to early civilizations as the development of the X-ray or discovery of penicillin was to our own, as modern studies confirm that numerous essential oils and spices are very effective in controlling pathogens, including *Staphylococcus* and tuberculosis bacilli. Apparently

this observation first came to the attention of European scientists in the latter half of the 19th century, when the perfumery workers at Grasse, France, were found to have a much lower rate of cholera and tuberculosis than the rest of the European population. As noted by Morris (1984, p. 15):

Essential oils have shown startling fungitoxic properties. Oil of clove is toxic to specific growths, and oil of geranium is effective against a broad range of fungi. *Cymbopogon* grasses, an Indian genus of aromatic grasses, have been found effective against *Heuninthsoprium oryzae*, a source of food poisoning, *Aspergillus niger*, a cause of seborrheic dermatitis of the scalp, *Absidia ramosa*, a cause of otitis, and *Trichoderma viride*, another cause of dermatitis. Man has long guessed that these oils that the plant secreted to protect itself from insect, fungal, and microbial dangers could serve him as well. Thus it is that the story of perfumery is intimately linked to the story of pharmacy. Our ancestors could not formulate the germ theory of disease, but they assumed that whatever smelled clean and healthy must be of use in hygiene.<sup>1</sup>

The history of hygiene and public health is closely associated with the view that bad odors were the source, indeed often the cause, of diseases and pestilence. Places of filth and stench were, in fact, associated with a higher incidence of diseases. The stenches that developed in the cities of Europe during the Middle Ages are unimaginable to us today. Conditions were so bad that, for example, the monks of White Friars in London's Fleet Street complained that the smell from the Fleet River overcame all the frankincense burnt at their altars and killed many of their brethren (McLaughlin, 1971). Such problems were the backdrop of the spread of the plague epidemics that traversed Europe and England in the 12th to the 17th

<sup>1</sup>Billing and Sherman (1998) provide empirical support for the hypothesis that the amount of spice in foodstuffs from various world cuisines is better explained on the basis of their antibacterial than their sensory properties. These investigators quantified the frequency of use of 43 spices in the meat-based cuisines of 136 countries for which traditional cookbooks could be found. A total of 4578 recipes from 93 cookbooks was examined, along with information on the temperature and precipitation in each country, the ranges of spice plants, and the antibacterial properties of each spice. As mean annual temperatures (an index of relative spoilage rates of unrefrigerated foods) increased, the proportion of recipes containing spices, number of spices per recipe, total number of spices used, and use of the most potent antibacterial spices all increased, both within and among countries. The estimated fraction of bacterial species inhibited per recipe in each country was positively correlated with annual temperature. Although alternative hypotheses were considered (e.g., that spices provide macronutrients, disguise the taste and smell of spoiled foods, or increase perspiration and thus evaporative cooling), the data did not support any of these alternatives.

centuries. As chronicled by Corbin's (1986) fascinating account of the history of hygiene and odors in 18th-century France, health administration of that era was based on a catalog of noxious odors. Indeed, authorities sought to locate the networks of miasmas by "mapping the flux of smells that made up the olfactory texture of the city" (p. 55). The desire to localize odors and to eliminate them in an effort to ward off diseases may well have been one reason why so many odor classification schemes arose during the 18th century, including those of von Haller (1756), Linnaeus (1765), Lorry (1784/85), and Fourcroy (1798).

Throughout this period, as well as in earlier times, infection was believed to be stemmed by wearing a perfume or by burning aromatic pellets in special perfume pans, thereby masking the odors that were considered unhealthy. Lemery's *Pharmacopee universelle* (1697) cataloged the therapeutic value of aromatics and perfumes and suggested the prescription of "apoplectic balms" because "what is pleasing to the nose, being composed of volatile, subtle, and penetrating parts, not only affects the olfactory nerve, but is spread through the whole brain and can deplete its pituita and other overcourse humors, increasing the movement of animal spirits" (Corbin, 1986, p. 62). During outbreaks of the plague, defenses included the burning of incense, juniper, laurel leaves, cypress, pine, balm, rosemary, and lavender, although, if effective, they were only marginally so. Various plague waters, to be poured on handkerchiefs or into pomanders, were invented, including the original eau de cologne. Unpleasant agents were also believed to keep away the plague, and the members of many households crouched over their privies inhaling the fumes in attempts to avert the disaster (McLaughlin, 1971). Specialized plague Physicians wore garmets designed to protect them from the odors emanating from plague victims who were touched by long canes, some of which were hollow to allow for listening to the heart (Figure 1.2). Even in the late 1800s, smells were associated with illnesses, as exemplified by the belief that decaying organic matter in swamps produced malaria (mal = bad, aira = air). This theory, apparently initially proposed by Varro (116-28 BCE) and Palladius (4th century CE), was brought to the more modern stage by Morton (1697) and Lancisi (1717), but was largely abandoned after the French physician Alphonse Laveran (1881) described the responsible parasite and Sir Ronald Ross (1923) demonstrated, a few years later, its transmission by the female anopheline mosquito.

In the history of medicine, both odors and tastes have been used at various times in the diagnosis of diseases (Doty, 1981; Whittle et al., 2007). Even today, diabetes is diagnosed in some areas of the world on the basis of the patient's acetone-like breath and sweet-tasting urine, although, in general, the use of odor and taste in diagnosis has become a lost art. In addition, certain smells and tastes were known to elicit symptoms of some diseases,

**Figure 1.2** Picture of a plague doctor in his protective garb. This costume was invented in France in 1619. It was comprised of a heavy overcoat rubbed in beeswax, glass eye openings, and a beak-like extension which contained scents, such as ambergris, camphor, cloves, mint, and rose petals, to breathe through in an effort to protect the wearer from miasmatic bad air. A cane pointer was used to touch the patient. Courtesy of the Wellcome Library, London.

including epilepsy and hysteria. A classic example is reported by the Roman historian Caius Plinius Caecilius Secundus (Pliny) in his *Historia Naturalis* (circa 50 CE), where sulfur and burning bitumen (asphalt) were noted to induce seizures (Bailey, 1932), a phenomenon that has also been noted in more modern times (West and Doty, 1995). Alum (alumen), which contained aluminum, was used as a deodorant in the Roman empire, predating the use of aluminum salts as deodorants in the United States in the 1880s, as evidenced by the following quotation of Pliny, which extols its values (Bailey, 1932, p. 103):

...Liquid alumen has astringent, hardening, and corrosive properties. Mixed with honey, it heals sores in the mouth, pustules, and itchy eruptions. In the latter case, the treatment is applied in a bath to which honey and alumen have been added in the

proportion of two to one. Alumen diminishes offensive odours of the axilla, and reduces sweating in general.

To my knowledge, there are no pre-Renaissance treatises on chemosensory dysfunction, *per se*, although descriptions of loss of olfactory function are found in the writings of the ancient Greeks and Romans, as well as in the Bible. In 2 Samuel 19:31–37, a story is told about an 80-year-old man who complained to the king that his ability to taste (or smell) had faded, along with his hearing. Theophrastus noted, in the 3rd century BCE, the following (Stratton, 1917, p. 84):

. . . it is silly to assert that those who have the keenest sense of smell inhale most; for if the organ is not in health or is, for any cause, not unobstructed, more breathing is to no avail. It often happens that man has suffered injury [to the organ] and has no sensation at all.

Although the early Greeks routinely used surgical intervention for the treatment of polyps and other intranasal obstructive problems (for review, see Wright, 1914), the first description of the use of surgery to specifically correct anosmia was apparently made during the Renaissance by Forestus (1591; cited in Lederer, 1959):

If it [anosmia] is from ethmoidal obstruction, or from the humor discharged from a catarrh, the latter must first be cured. If from the flesh growing from within the nose . . . it is to be cured by the surgeons by operative procedures, either with a cutting instrument, or cautery, or snare.

Claudius Galenus (Galen; 130–200 CE), whose writings had a major impact on Western medicine in general, attributed anosmia to obstruction of the foramina within the cribriform plate (an attribution made by a number of early Greeks, including Plato and Hippocrates). He correctly described the role of the nose in warming and filtering the air and alluded to empirical studies noting the permeability of the dura matter around the cribriform plate to both water and air (Wright, 1914). He believed that the organ for smell was located in the ventricles of the brain and that particles responsible for olfactory sensations passed through the foramina of the cribriform plate during inhalation. As discussed in more detail later in this chapter, this compelling idea continued until the 18th century, when light microscopy revealed that the nasal secretions came from secretory cells within the epithelium. In terms of taste, he posited that the lingual nerve communicated gustatory sensations, in accord with modern perspectives (see Chapters 29 and 32).

## 1.4 THE RENAISSANCE AND THE BIRTH OF MODERN STUDIES OF TASTE AND SMELL

As is evidenced throughout the volume, major advances have been made in the last quarter century in understanding the senses of taste and smell – advances that follow on the footsteps of a long tradition of scientific observations stemming from treatises written in the 16th century. Indeed, the sense of smell did not escape the attention of Leonardo da Vinci (1452–1519), who, in the *Codex Atlanticus*, presented nine diagrams next to one another in which he compared the behavior of light, the force of a blow, sound, magnetism, and odor (Riti, 1974). Cardinal Gasparao Contarini (1482–1542), an alchemist, wrote about the elements and their combinations in five brief volumes published posthumously in 1548 by Ioannes Gaignaeus. The last of these was dedicated to flavors, odors, and colors. Contarini believed that there were eight flavors or tastes and argued that cooking food or preserving fruit can produce flavors not found in nature. He felt the sense of smell was imperfect and noted that the names of flavors are often employed to explain the variety of odors. Andrea Vesalius devoted one and a half large pages to the sense of smell in his classic anatomy treatise *De Humani Corporis Fabrica* (1543), although he failed to observe the olfactory fila. In 1581, Fernel listed nine types of basic taste qualities, including the seven of Aristotle and Galen (sweet, bitter, sour, salty, astringent, pungent, harsh) and “fatty” and “insipid,” the latter apparently reflecting the lack of other taste qualities (Bartoshuk, 1978). During this period, *Two Books on Taste, Sweet and Bitter* was published by Laurence Gyrrlus (1566), conceivably being the first work solely devoted to taste. In 1609, Casserius described the detailed structure of the tongue, and Malpighi (1664), Casserius, 1609 and Bellini (1665) associated the sense of taste with lingual papillae. Taste buds were first identified on the barbels and skin of fishes by Leydig (1851), and later were described in mammals (Loven, 1868; Schwalbe, 1868). In 1587, Iohannes Camerarius presented a thesis to the University of Marburg entitled “*Themata Physica de Odorum Natura et Affectionibus*.” In this work, he discussed odor classification, the relationship between taste and smell, a mechanism for explaining the function of olfaction, the ability of smelling in water, and the effect of heat from the sun on odors (Kenneth, 1928).

In 1673 Robert Boyle wrote an article on “Nature, Properties, and Effects of Effluvia” in which he provides vivid and accurate observations on such topics as olfaction in birds, odor tracking in dogs, and the physical nature of the materials released from various odor sources. In his 1675 paper, “*Experiments and Observations About the Mechanical Production of Odours*,” he addresses some simple issues of odorant mixtures and observes that the

quality and intensity of odors can be related. He provides, in his “*Experiments and Considerations About the Profity of Bodies*” (1684), perhaps the first description of intravascular olfaction or taste (i.e., the smelling or tasting of substances that are initially blood-borne):

One of the noblest instances I ever met with of the porosity of the internal membranes of the human body, was afforded to me by that British nobleman, of whom our famous Harvey tells a memorable, not to say matchless story. This gentleman, having in his youth by an accident, which that doctor relates, had a great and lasting perforation made in his thorax, at which the motion of his heart could be directly perceived, did not only out-live the accident, but grew a strong and somewhat corpulent man; and so robust, as well as gallant, that he afterwards was a soldier, and had the honour to command a body of an army for the King.

This earl of Mount-Alexander . . . gave me the opportunity of looking into his thorax, and of discerning there the motions of the cone, as they call it, or mucro of the heart . . . Having then made several inquiries fit for my purpose, his lordship told me, that, when he did, as he was wont to due from time to time, (though not every day) inject with a syringe some actually warm medicated liquor into his thorax, to cleanse and cherish the parts, he should quickly and plainly find in his mouth the taste and smell of the drugs, wherewith the liquor had been impregnated. And I further learned, that, whereas he constantly wore, upon the unclosed part of his chest, a silken quilt fluffed with aromatic and odoriferous powders, to defend the neighboring parts and keep them warm; when he came, as he used to do after several weeks, to employ a new quilt, the fragrant effluvia of it would mingle with his breath in expiration, and very sensibly perfume it, not, as I declared I suspected, upon the score of the pleasing exhalations, that might get up between his clothes and his body, but that got into the organs of respiration, and came out with his breath at his mouth, as was confirmed to me by a grave and judicious statesman, that happened to be then present, and knew this general very well.

Another early depiction of what seems to be an example of intravascular olfaction is described by Cloquet (1821). Cloquet notes that Dupuytren, a famous surgeon of the time, performed an ad hoc experiment in which he injected an odorous fluid into a vein of a dog. Soon thereafter, the dog began running around sniffing.

Unfortunately, many of the studies and observations of the period from the 1500s to the mid-1800s confused taste with flavor (which is largely dependent on the sense of smell), thereby obscuring the clear focus needed for

optimal scientific progress. In these periods, research on gustation was much more limited in scope than that on olfaction, although notable advances were made in taste research, including (1) the discovery that dissimilar metals, when placed on the tongue, produced an “electric taste” sensation (Sulzer, 1752; Volta, 1792), (2) the observation that taste sensations are localized to papillae (Malpighi, 1664; Bell, 1803), (3) the identification of the chorda tympani as the nerve that mediates taste in the anterior tongue (Bellingeri, 1818; see Bartoshuk, 1978), and (4) the demonstration that different regions of the oral cavity are differentially sensitive to different taste qualities (Horn, 1825). As noted above, the observation that taste buds exist within the papillae of the mammalian tongue and depend on an intact nerve supply came in the latter half of the 19th century (see Chapter 29; Loven, 1868; Merkel, 1880; Schwabe, 1867; Vintschgau and Hönigschmied, 1877), as did the painstaking mapping of the sensitivity of individual papillae to stimuli representing the four basic taste qualities (Öhrwall, 1891; Kiesow, 1894).

One reason for the comparatively greater interest in olfaction than taste during the post-Renaissance period stemmed from the compelling, albeit erroneous, conceptual framework in which olfactory functioning, disease, and nasal secretions were viewed. For smelling to occur, odorous bodies had to enter the brain via the foramina of the cribriform plate – the same foramina through which body humors flowed to produce nasal mucus. From this perspective, blockage or alterations in this passageway (e.g., by the changes in the viscosity of the humors) were closely related to diseases that caused (1) anosmia, (2) running noses, (3) high fever, and (4) general ill feeling. There is no doubt that the major conceptual chemosensory advance of this period, indeed perhaps of the entire modern era, was refutation of this ancient concept. The compelling nature of this theory and its adaptation to a more modern era is illustrated by Descartes’ (1644) description of how olfaction works (Haldane and Ross, 1955, p. 292):

... two nerves or appendages to the brain, for they do not go beyond the skull, are moved by the corporeal particles separated and flying in the air – not indeed by any particles whatsoever, but only by those which, when drawn into the nostrils, are subtle and lively enough to enter the pores of the bones which we call the spongy, and thus to reach the nerves. And from the diverse motions of these particles, the diverse sensations of smell arise.

Interestingly, convincing evidence for this notion continued to be amassed during this period, as the following quotation from Thomas Willis (1681, p. 100) indicates:

The Sieve-like Bone in divers Animals is variously perforated for the manifold necessity and difference

of smelling. A Process from the Dura Mater and manifold nervous Fibres pass through every one of its holes, and besmear the inside of the Nostrils. But as the impressions of sensible things, or sensible Species, confined as it were by the undulation or waving of the animal Spirits, ascend through the passages of these bodies stretched out from the Organ towards the Sensory; so the humidities watring the same bodies, for as much as some they may be more superfluous than usual, may distil into the Nostrils through the same ways. For indeed such humors as are perpetually to be sent away from the brain, ought so copiously to be poured upon the Organs of Smelling, as we shall shew hereafter, when we shall speak particularly of the smelling Nerves; in the mean time, that there is such a way of Excretion opening into the Nostrils, some observations, taken of sick people troubled with Cephalick diseases, do further perswade.

... A Virgin living in this City, was afflicted a long time with a most cruel Headach, and in the midst of her pain much and thin yellow Serum daily flowed out from her Nostrils; the last Winter this Excretion stopped for some time, and then the sick party growing worse in the Head, fell into cruel Convulsions, with stupidity; and within three days dyed Apoplectical. Her Head being opened, that kind of yellow Latex overflowed the deeper turnings and windings of the Brain and its interior Cavity or Ventricles ... I could here bring many other reasons, which might seen to perswade, that the Ventricles of the Brain, of the Cavity made by the complicature or folding up of its border, is a mere sink of the excrementitious Humor; and that the humors there congested, are purged out by the Nose and Palate.

The idea of movement of humors from the brain to the nasal cavity was most likely supported by other types of evidence as well. For example, demonstrations that dyes (e.g., Indian ink), after injection into the subarachnoid space or the cerebral spinal fluid, travel to the nasal mucosa via the cribriform plate were made in the 19th century, and there is no reason to believe that such information was not available in earlier times (see Jackson et al., 1979, for review).

It is not clear who deserves the credit for identifying the olfactory nerves in the upper nasal cavity, although, according to Wright (1914), the 7th-century Greek physician Theophilis gave one of the better anatomical accounts of their distribution, despite the potential political ramifications of going against Galen’s dictates. Graziadei (1971) credits Massa, in 1536, as having first demonstrated the olfactory nerves in humans, and Scarpa, in 1789, as having shown that the fine fila olfactoria actually end in the *regio olfactoria* (note, however, Scarpa’s 1785 article). Wright

(1914), on the other hand, notes that the Italian Anatomist Alessandro Achillini, who died in 1512, had described their intranasal distribution.

Regardless of who is responsible for their first description, there was considerable disagreement, which spanned over a century and a half, among authorities as to whether the processes that extended from the olfactory bulbs into the nasal cavity were, in fact, nerves. Indeed, even after they were generally accepted as nerves, debate lasted into the 1840s as to whether they mediated smell sensations. Francois Magendie (1824) was the primary proponent of the idea that such sensations were mediated via the trigeminal nerve, whereas Sir Charles Bell believed that the olfactory nerves subserved such sensations (Shaw, 1833). As late as 1860, experiments appeared in the literature that addressed this point (e.g., Schiff, 1860), although the more authoritative general physiology and medical textbooks from the 1820s to the 1850s correctly noted that the olfactory nerve mediates qualitative odor sensations and the trigeminal nerve somatosensory sensations (e.g., Good, 1822; Kirkes, 1849).

Schneider (1655) and Lower (1670) are generally credited as being the first to show that nasal secretions arise from glands, rather than being secreted through the cribriform plate. However, a century earlier Berenger del Carpi, who taught surgery at Bologna (1502–1527), broke the Hippocratic and Galenic tradition and denied that fluids passed through these foramina, suggesting that they actually passed through the sphenoid sinus (Wright, 1914). The evidence that nasal secretions came from glands, rather than through the cribriform plate, was clearly an important observation in the history of medicine. Collectively, the aforementioned studies placed the first nails in the coffin of the theory propagated largely by Galen that the cribriform plate is pervious to odors and that the sense of smell lies within the ventricles of the brain. Other major studies before 1890, a number of which are now considered classic, contributed the remaining nails to this coffin and include, in chronological order, those by Hunter (1786), Sömmerring (1809), Todd and Bowman (1847), Schultze (1856, 1863), Ecker (1856), Eckhard (1858), Clarke (1861), Hoffman (1866), Martin (1873), Krause (1876), von Brunn (1875, 1880, 1889, 1892), Sidky (1877), Exner (1878), Ehrlich (1886), and Cajal (1889).

An important 17th century discovery was that exocrine glands were responsible for the saliva of the oral cavity, a finding that preceded the aforementioned discovery that similar glands were responsible for nasal secretions. This discovery resulted from the identification of the ducts of the submandibular and parotid glands by Wharton in 1656 and Stensen (Latinized to Nicolaus Stenonis) in 1661, respectively. In 1677, de Graaf employed chronic salivary fistula for collecting saliva from conscious dogs. He and Bordeu (1751) recognized that smell and taste of food, as

well as its mastication, increased salivary flow, preceding the classic and defining studies of Pavlov of this phenomenon in the early 1900s. However, investigators at that time did not pay much attention to the neural innervation of the salivary glands, largely due to the belief that saliva arose solely from the small arteries by the opening of pores, being then filtered by the acini (Haller, 1744). This “particle and pore theory” continued until Carl Ludwig discovered, in 1850, that electrical stimulation of the chorda-lingual nerve induced considerable flow of saliva from the submandibular gland in the dog. Ludwig also found that the secretory pressure in the submandibular duct could exceed the arterial pressure, a finding that disproved the particle and pore theory. Claude Bernard followed up Ludwig’s discovery by studying reflex salivation and the role of the medulla in altering such salivation, introducing the concept of the salivary reflex arc in 1856.

Since these early studies saliva has been found to serve numerous functions, including ones related to digestion, lubrication, protection of oral tissues, and thermoregulation. In 1963, McBurney and Pfaffmann demonstrated, in a human psychophysical study, that salivary constituents (namely sodium and chloride) could affect taste sensitivity to NaCl. This important study led to the realization that saliva is not only a solvent for tastants, but forms the external milieu of the taste receptors. Their study evolved from previous speculations that lowered sodium content of the blood, such as occurs after adrenalectomy, might directly lower the threshold sensitivity of the salt receptors (e.g., Young 1949). Previously Richter and MacLean (1939) had raised the possibility that the taste threshold might be determined by the salt content of saliva. After McBurney and Pfaffmann’s research, the effects of salivary constituents on taste function became the focus of numerous human psychophysical and animal electrophysiological studies. These studies led to the realization that saliva affects not only the perception of salty tasting stimuli, but also the taste of stimuli that induce the other classic taste qualities, as well as fatty tastes and tactile sensations such as astringency (Spielman, 1990; Matsuo, 2000; Bradley and Beidler, 2003).

The studies by Schultze of the olfactory neuroepithelium (1856, 1863) deserve special mention. Despite the lack of modern stains and fixatives, Schultze painstakingly provided the first comprehensive accurate description and drawings of the olfactory receptor cells and supporting cells (Zippel, 1993). He clearly identified the cilia. As noted in his 1856 paper, “... each of the various fiber cells, lying on a refracting knoblet, bears six to ten of these long hairlets which, under resting conditions, appear bristly and extend freely to the nostril air” (Zippel, p. 67). Schultze noted species differences in cilia and identified the non-ciliated supporting cells, as well as basal cells near the lamina propria. Moreover, he noted the irregularities

in the epithelium – irregularities that were further defined by von Brunn in his 1880 and 1882 papers as follows, “... the olfactory region can be compared to a continent which has a sometimes greater, sometimes lesser density of large lakes, extends into peninsulas and splits and contains numerous islands” (Zippel, p. 71). The basal cells were named by Krause (1876). Evidence that the receptor cells arise from the periphery and grow towards the bulb was provided by His (1889).

It is of interest that many of these olfactory studies were performed in an era when the human sense of smell was not highly regarded as important to many notables, a stigma that remains today. For example, Charles Darwin, who might have been expected to champion an exploration of human olfactory studies, indicated the following in 1871 (p. 32):

‘... <human olfaction> is of extremely slight service, if any, even to savages, in whom it is generally more highly developed than in the civilised races. It does not warn them of danger, nor guide them to their food; nor does it prevent the Esquimaux from sleeping in the most fetid atmosphere, nor many savages from eating half-putrid meat’.

Darwin’s negative perspective on human olfaction was foreshadowed nearly a century earlier by Immanuel Kant, the renowned German philosopher, who stated in 1798:

‘To which organic sense do we owe the least and which seems to be the most dispensable? The sense of smell. It does not pay us to cultivate it or to refine it in order to gain enjoyment; this sense can pick up more objects of aversion than of pleasure (especially in crowded places) and, besides, the pleasure coming from the sense of smell cannot be other than fleeting or transitory’.

Leading 19th century physicians similarly denigrated the human sense of smell. In 1870, Notta pointed out that smell dysfunction did not represent a life-threatening infliction (Notta, 1870) and three years later Legg indicated, in *The Lancet*, that smell loss “barely amounts to a discomfort” (Legg, 1873). In 1881, Althaus, also writing in *The Lancet* (p. 771), stated the following (p. 771):

if Prince Bismarck and M. Gabetta were to become suddenly blind and deaf, the destinies of Europe would no doubt be changed; while if these two men were to lose their smell and taste, things would probably go on much in the same manner as they do now.

Leading comparative anatomy of the late 19th century fueled, to some degree, the argument that the human sense of smell is not very important and that olfaction is largely

a primitive element of the brain. Broca (1878), using the rhinal fissure as a dividing line, separated the brain into a basal (rhinencephalon) and a superior (pallium) portion. Animals with a large basal region were termed “osmotic” and were assumed to have a keen sense of smell. Those with a small basal brain region were termed “anosmatic” and were assumed to have little or no smell function (Schiller, 1997). Broca extended this concept into human mental development, concluding that the basal, i.e., limbic, part of the brain represented the emotional “brute,” whereas the newer cerebral lobes represented the development of intelligence.<sup>2</sup> In 1890, Turner further refined Broca’s schemata by dividing animals into three groups, described as follows (p. 106):

1. Macrosmatic, where the organs of smell are largely developed, a condition which is found, for example, in the Ungulata, the proper Carnivora and indeed in the majority of mammals.
2. Microsmatic, where the olfactory apparatus is relatively feeble, as in the Pinnipedia, the Whalebone Whales, Apes, and Man.
3. Anosmatic, where the organs of smell are apparently entirely absent, as in the Dolphins, and it may be in the Toothed Whales generally, though, as regards some genera of Odontoceti, we still require further information.

That being said, considerable efforts were made in the 19th century to quantify human smell and taste function, particularly in Germany where Hermann von Helmholtz’s student, Wilhelm Wundt, founded the first experimental psychology laboratory in 1879. Indeed, the dawn of human chemosensory psychophysics occurred in the mid-to-late 19th century, as illustrated by studies in which specific taste qualities were painstakingly mapped on the tongue by Öhrwall (1891) and Kiesow (1894). Although Boring (1942) credits Fischer and Penzoldt (1886) as having measured the first absolute threshold to an odorant, Valentin, in 1848, described a procedure that assessed olfactory sensitivity that predated even Fechner’s development of formal threshold methodology by a dozen years. Zwaardemaker (1925), who invented the important draw-tube olfactometer (Chapter 11) and who performed sophisticated studies on a wide range of topics, including adaptation and cross-adaptation, credited Passy (1892) as having made an important step in the development of olfactometry. In essence, Passy dissolved a given amount of odorant in alcohol in a 1:10 ratio. This new solution was then again diluted in such a ratio, and this was repeated

<sup>2</sup>This dichotomy was rejuvenated by subsequent investigators, including Maclean’s triune brain in which sectors of the brain were divided into the reptilian, paleomammalian (limbic system), and neomammalian (neocortex) complexes (Maclean, 1990).

over and over to provide a series of dilution steps. For testing, a small amount of solution at each concentration was placed in liter bottles which were heated slightly to evaporate the alcohol. Such bottles were then sampled from highest concentration to lowest concentration until no smell was discernible to the subject. Zwaardemaker, however, expressed concern that the alcohol diluent used by Passy might influence the perception of the test odorant. This potential problem was eliminated to a large degree in the successive dilution series described by Toulouse and Vaschide (1899) and Proetz (1924), where water and mineral oil, respectively, served as the diluents.

From the clinical perspective, the more scholarly physicians of the 18th and 19th centuries were very much aware of the major types of olfactory disorders that we recognize today. Good (1822), for example, classified disorders of olfaction into the following categories: *Parosmia acris* (acute smell), *Parosmia obtusa* (obtuse or distorted smell), and *Parosmia expers* (anosmia or lack of smell). Good (1822, pp. 260–261) notes the following regarding *Parosmia obtusa*:

The evil is here so small that a remedy is seldom sought for in idiopathic cases; and in sympathetic affections, as when it proceeds from catarrhs or fevers, it usually, though not always, ceases with the cessation of the primary disease. It is found also as a symptom of hysteria, syncope, and several species of cephalaea, during which the nostrils are capable of inhaling very pungent, aromatic, and volatile errhines, with no other effect than that of a pleasing and refreshing excitement.

Where the sense of smell is naturally weak, or continues so after catarrhs or other acute diseases, many of our cephalic snuffs may be reasonably prescribed, and will often succeed in removing the hebetude. The best are those fond of the natural order verticillatae, as rosemary, lavender, and marjoram; if a little more stimulus be wanted, these may be intermixed with a proportion of the teucrium *Marum*; to which, if necessary, a small quantity of asarum may also be added: but pungent errhines will be sure to increase instead of diminishing the defect.

Good's observations concerning *Parosmia expers* were as follows:

This species is in many instances a sequel of the preceding [*Parosmis obtusa*]; for whatever causes operate in producing the former, when carried to an extreme or continued for a long period, may also lay a foundation for the latter. But as it often occurs by itself, and without any such introduction, it is entitled to be treated separately. It offers us the two following varieties:

Organica. Organic want of smell. From natural deficit, or accidental lesion, injurious to the structure of the organ.

Paralytica. Paralytic want of smell. From local palsy.

The FIRST VARIETY occurs from a connate destitution of olfactory nerves, or other structural defect; or from external injuries of various kinds; and is often found as a sequel in ozaenas, fistula lachrymalis, syphilis, small-pox, and porphyra. The SECOND is produced by neglected and long continued coryzas, and a persevering indulgence in highly acrid sternutatories.

Among the more detailed and vivid descriptions of cases of anosmia in the 19th century literature are those of Ogle (1870). He describes in detail three cases of anosmia due to head injury in which taste function was intact, a case of anosmia associated with facial palsy, a viral-induced case of anosmia, a case of anosmia due to obstruction, and three cases of unilateral olfactory loss that were related to aphasia, agraphia, and seizure attributable to brain lesions. The olfactory losses due to head injury were believed to be caused by the shearing of the olfactory filaments at the level of the cribriform plate from movement of the brain produced by the blow. In this explanation of the problem, Ogle notes (p. 266) that "the anterior brain rests directly upon the bones of the skull, and is not separated from them as is the case elsewhere by the interposition of cerebro-spinal fluid."

## 1.5 THE MODERN ERA: 20th AND 21st CENTURY ADVANCES

The major progress in the field of chemosensory research that has taken place in the 20th and 21st centuries has largely been due to contemporaneous technical advances in other fields of science. Included among such advances, which are not mutually exclusive, are (1) the invention of sensitive methods for recording minute electrical potentials from the nervous system, including measurements taken from the scalp (e.g., electroencephalography) and recordings from single cells and isolated components of cell membranes, (2) development and refinement of statistical methodologies and experimental designs, such as those employed in epidemiology and pharmacology, (3) development of novel and sensitive psychophysical techniques, (4) the invention of new histological stains and radically novel histological procedures, such as those that utilize autoradiography, immunohistochemistry, and various tracing agents, (5) the development of biochemical techniques for assessing endocrine and neurotransmitter receptor events, including radioimmunochemistry, (6) the

continued development and refinement of microimaging systems, including the electron microscope, (7) advances in tissue preparation procedures that optimize such imaging technology, such as osmium preparations and freeze fracture techniques, (8) the invention of computerized tomography (CT), magnetic resonance imaging (MRI), and other noninvasive imaging tools useful for evaluating the structure of the brain *in vivo*, (9) the development of functional imaging techniques, such as positron emission tomography (PET), single photon emission computed tomography (SPECT), and functional MRI (fMRI), and (10) innumerable advances in biology, including the development of the fields of animal behavior and, importantly, molecular biology and molecular genetics, where, for example, recombinant DNA techniques and gene manipulations have made it possible to identify and confirm the roles of many proteins involved in olfactory and gustatory function.

Obviously, in this introduction it is only possible to mention a few of the many important observations made in the last hundred and fifty years or so that have contributed to the present research climate. The areas selected for exposition were chosen, in part, on the basis of the amount of chemosensory research they have generated and are continuing to generate. These and other important events or areas of research are mentioned in more detail throughout the *Handbook*.

### 1.5.1 Electrophysiological Studies

A major 20th-century milestone that had a significant impact on modern chemosensory science was the development of means for electrophysiologically recording nerve impulses from the brain, including the olfactory and gustatory receptors and pathways. Although crude electrical recordings were obtained from the olfactory system in the late 19th century (e.g., Saveliev, 1892; Garten, 1900), the sophisticated equipment necessary for reliable recordings, including sensitive electrodes, was not available until well into the 20th century (e.g., the oscilloscope was invented in 1922; Erlanger and Gasser, 1937). The earliest extracellular recordings of single-cell gustatory primary afferent nerve activity were made by Zotterman (1935) and Pfaffmann (1941), the latter of whom was working in Lord Adrian's laboratory at the time. Kimura and Beidler (1961) and Tateda and Beidler (1964) were the first to record from single cells within the taste bud. Recordings of olfactory nerve fiber bundles were made by Beidler and Tucker (1955); recordings of single-cell olfactory receptor activity from extracellular electrodes were obtained by Hodgson et al. (1955) and Gesteland et al. (1963, 1965). The first evidence for between species differences in single-cell neural firing was presented by Beidler et al. (1955) and Pfaffmann (1955), a point that was later exploited by Frank

(1973) in the use of the hamster as a model for species, such as the human, that exhibit salient responsiveness to sweet-tasting stimuli.

These observations were harbingers for the more recent discoveries of the receptors that largely defined their afferent activity. Other manifestations of this advance in technology include (1) the recording of multicellular summated potentials at the levels of the vertebrate olfactory mucosa [the electro-olfactogram (EOG); Hosoya and Yoshida, 1937; Ottoson, 1956] and insect antenna (the electroantennogram; Schneider, 1957a, b), (2) recording of transduction currents in isolated olfactory receptor cells (e.g., Kurahashi and Shibuya, 1987; Firestein and Werblin, 1989), (3) measurement of ion channel activity in restricted patches of olfactory or taste cell membranes (Nakamura and Gold, 1987; Kinnamon et al., 1988); (4) topographic analysis of responses within the olfactory epithelium and olfactory bulb (e.g., Kauer and Moulton, 1974; Kubie and Moulton, 1980; Levetan and MacLeod, 1966; Mackay-Sim et al., 1982; Mozell, 1964, 1966; Moulton, 1976), (5) the application of voltage-sensitive dyes for recording electrical changes in chemosensory neural tissue (Kauer, 1988), (6) the recording of olfactory- and taste-evoked potentials in higher brain regions (e.g., Funakoshi and Kawamura, 1968, 1971; Kobal and Hummel, 1988; Kobal and Plattig, 1978; Plattig, 1968/1969), and (7) electrophysiological mapping, in animals, of local, as well as more global, olfactory, and gustatory brain circuits (e.g., Emmers et al., 1962; Getchell and Shepherd, 1975; Komisaruk and Beyer, 1972; Mori and Takagi, 1978; Motokizawa, 1974; Nicoll, 1971; Norgren, 1970; Pfaffmann et al., 1961; Rall et al., 1966; Scott and Pfaffmann, 1972; Shepherd, 1971, 1972; Tanabe et al., 1973, 1975).

The first studies to directly stimulate sectors of the human brain in conscious patients so as to map brain centers associated with taste and smell were those of Foerster (1936) and Penfield and Faulk (1955). These neurosurgeons identified key cortical regions associated with taste and somatosensory perception. Subsequently, numerous anatomical and electrophysiological studies in nonhuman primates confirmed that the primary "gustatory cortex" is located within the insular cortex and parietal operculum and that these regions contain cells sensitive to both gustatory and somatosensory inputs (e.g., Benjamin and Burton, 1968; Ogawa et al., 1989) (see Chapters 32 and 35).

### 1.5.2 Studies of Receptor Function

Remarkable progress has been made in the last 30 years in identifying the initial events that occur when odorant or tastant molecules activate receptor cells, as is evidenced by the studies reviewed in detail in Chapters 5, 6, 30,

31, and 40–42. A number of these studies have been performed solely at the molecular genetic or biochemical level, but many others have used electrophysiological measures, sometimes in combination with biochemical ones, to address conductance changes that occur in the cell membrane following receptor activation, including activation of single channels. Major technical advances have made it possible to identify the olfactory and gustatory receptors, establish the involved second messengers and ion channels, and to understand phylogenetic associations and likely patterns of evolution. In olfaction, the discovery of a protein termed olfactory marker protein, which is expressed in mature olfactory receptor cells of a range of species, has proved invaluable to the study of olfactory transduction and the anatomy of the olfactory pathways (Margolis, 1972; Farbman and Margolis, 1980). Another protein, alpha-gusducin, has proved similarly useful in understanding taste transduction (McLaughlin et al., 1992a,b).

Soluble proteins have been identified within the olfactory mucus that may play multiple roles, most notably assisting in the transport of hydrophobic molecules to receptor regions or in stimulus removal and/or deactivation (Lee et al., 1987; Pevsner et al., 1988a, b; Schmale et al., 1990). Such “odorant binding proteins” are also found in insects, where they have been said to represent “a major evolutionary adaptation regarding the terrestrialization of the olfactory system, converting hydrophobic odorants into hydrophilic ones by increasing their aqueous solubility” (Vogt et al., 1991, p. 74). The role of mucus and saliva in early elements of olfactory and gustatory transduction are described in Chapters 3 and 28.

It is now appreciated that the interaction of stimulus molecules with the receptor membrane opens or closes, directly or indirectly (i.e., via second-messenger systems), membrane channels, resulting in a change in the flux of ions and alteration of the cell’s resting potential (see Chapters 5, 6, 30, 31, 40–42). Taste receptor cells possess a number of ion channels identical to some of those found in neurons (i.e., voltage-gated  $\text{Na}^+$ ,  $\text{Ca}^{2+}$ , and  $\text{K}^+$  channels, as well as  $\text{Ca}^{2+}$ -mediated cation channels and amiloride-sensitive  $\text{Na}^+$  channels) and release a neurotransmitter that activates the first-order taste neuron (Roper, 1989). In the case of olfaction, the receptor cell is the first-order neuron, so changes in membrane potential, if of sufficient magnitude, produce the action potentials. Bronshtein and Minor (1977) provided the first scientific evidence that these interactions occur on the olfactory cilia, an observation supported by subsequent workers (e.g., Rhein and Cagan, 1980, 1983; Lowe and Gold, 1991; Menco, 1991; see Chapters 3–7). In taste, such interactions occur on microvillae associated with apical portions of the taste receptor cell (Avenet and Lindemann, 1987, 1990; Heck et al., 1984), a region whose importance was apparently first stressed by Renqvist in

1919 (see Kinnamon and Cummings, 1992). Although occluding junctions among cells in the apical region of the taste bud restrict most stimuli to that region, molecules of low molecular weight may permeate these junctions (Holland and Zampighi, 1991). Interestingly, actin filaments are found around the taste pore, suggesting that taste buds may contract or expand, possibly in response to the type of taste stimulus that they encounter (Ohishi et al., 2000). Until the application of electron microscopy to taste buds in the 1950s (de Lorenzo, 1958; Engström and Rytzner, 1956a, b), taste buds were believed to contain cilia, not microvillae.

In the 1980s and 1990s, a number of important findings led to a fuller understanding of the initial events in olfactory transduction. A calcium sensitive enzyme adenylyl cyclase (type III), which is usually coupled to a G-protein, was found to be highly active in olfactory cilia (Kurihara and Koyama, 1972; Pace et al., 1985). Several laboratories found that odorants increase, in a dose-related manner, intracellular cyclic adenosine 3',5'-monophosphate (cAMP) in olfactory receptor cells, triggering the opening of cAMP-gated cation channels (Bruch and Teeter, 1989; Nakamura and Gold, 1987; Pace et al., 1985; Pace and Lancet, 1986; Sklar et al., 1986). In addition to cAMP, cGMP was found to play a likely role in the modulation of the sensitivity of olfactory receptor neurons, such as during adaptation (Leinders-Zufall et al., 1996). A positive correlation was noted between an odorant’s ability to activate adenylyl cyclase in a frog ciliary preparation and both the magnitude of the EOG response it produces in frog epithelia (Lowe et al., 1989) and its perceived odor intensity to humans (Doty et al., 1990), suggesting a gross association between the amount of adenylyl cyclase activated and the intensity of odor perception.

In 1989, Jones and Reed (1989) isolated a guanine nucleotide-binding protein (G-protein) in olfactory cilia, thereby lending strong support to the view that odorant receptors are G protein-coupled receptors. This protein had 88% sequence identity to conventional  $G_s$  and was termed  $G_{\alpha_{olf}}$  or  $G_{\alpha_{olf}}$ . Although G-proteins other than  $G_{\alpha_{olf}}$  (e.g.,  $G_{i2}$  and  $G_o$ ) have been identified in olfactory receptor cells, they appear not to be involved in early transduction events, presumably assisting in such processes as axonal signal propagation, axon sorting, and target innervations (Wekesa and Anholt, 1999).

In 1991, the identification of the primary receptor family responsible for vertebrate olfactory transduction was made by Buck and Axel (1991). This work was the basis for the 2004 Nobel Prize in Medicine or Physiology. Under the assumption that olfactory receptors have elements in common with a large superfamily of surface receptors that evidence seven transmembrane domains and linkage to G-proteins and second-messenger systems, these investigators synthesized oligonucleotides that coded for conserved

(i.e., nearly invariant) amino acid sequences found among receptors from sensory systems other than olfaction. These oligonucleotides were then used as molecular probes. Eighteen clones were found that coded for proteins with seven transmembrane domains within olfactory tissue, but not within brain, retina, or various non-neuronal tissues. The variability in the amino acid sequences was found to be in regions of the molecule believed to be important in the binding of ligands in other receptor proteins with seven transmembrane domains. Based on this information, it was concluded that a large number of diverse receptors were involved in olfactory transduction and that such receptors comprised a very large multigene family that “encodes seven transmembrane domain proteins whose expression is restricted to the olfactory epithelium.”<sup>3</sup>

Subsequent work has found that the number of functional olfactory receptors varies among species, being nearly 2000 in the African elephant, over 1000 in murine rodents, and around 400 in humans and chimpanzees (Glusman et al., 2001; Zozulya et al., 2001; Young and Trask, 2002; Zhang and Firestein, 2002; Niimura et al., 2014). The number of genes appears to be influenced by the environment to which a given species is adapted. In the mid-1990s, it was found that each receptor gene is expressed in only a small percentage of neurons (Ressler et al., 1994) and that a given neuron expresses only one allele of a single receptor gene (Malnic et al., 1999; Lombardas et al., 2006), although this generalization does not apply to all vertebrates (e.g., fish; see Chapter 23). It was also found that neurons that express the same odorant receptor gene converge on the same glomeruli (Ressler et al., 1994; Mombaerts et al., 1999). Such findings, along with those from other studies (e.g., Johnson and Leon, 2000), have largely clarified the topographic relationships between olfactory receptor cells and the olfactory bulb – relationships that were incompletely and only grossly known from earlier anatomical and physiological studies (e.g., Adrian, 1953; Le Gross Clark, 1951; Døving and Pinching, 1973).

It is important to note that the gene family encoding insect olfactory receptors likely evolved independently from that encoding vertebrate olfactory receptors. This is reflected by the fact that genes of these two families lack sequence homology (Wistrand et al., 2006). One major difference between the two families was discovered in *Drosophila*, where a “chaperone” receptor (*Or83b*), unlike other olfactory receptors, was found to be expressed in

<sup>3</sup>It is now known that receptor-encoding complement DNA can be expressed in some non-neuronal cells, which, when stimulated with appropriate ligands, generate second-messenger responses (e.g., Raming et al., 1993). The same receptor genes described by Buck and Axel (1991) have now been identified in tissues far removed from the olfactory cilia, including sperm (Parmentier et al., 1992) and the heart (Hillier et al., 1996).

all olfactory receptor neurons. Instead of binding volatile ligands, this receptor forms dimers with other olfactory receptors, resulting in ligand-detecting receptor complexes that enhance receptor sensitivity (Benton et al., 2006; Larsson et al., 2004; Neuhaus et al., 2005).

Trace amine-associated receptors (TAARs), a specific family of G-protein coupled receptors, have been identified that function as chemosensory receptors for several volatile amines in mice (Liberles and Buck, 2006) and a range of other vertebrate species (Hashiguchi and Nishida, 2007). TAARs are expressed in the olfactory epithelium, being most abundant in fish and less abundant in tetrapods. Humans express only five putatively functional TAARs, in contrast to zebrafish, who express 109 such TAARs (Hashiguchi and Nishida, 2007). The function of these receptors is yet to be determined, although amines are found among a number of biological secretions in rodents.

As described in detail in Chapter 5, the olfactory-specific receptor guanylyl cyclase D (GC-D, *Gucy2d*) was cloned in the mouse by Fulle et al. (1995). Less than 0.1% of the bipolar olfactory receptor neurons express the GC-D transcript, and these neurons appear to be randomly dispersed among the classic olfactory receptor neurons. Their axons project to unique glomeruli that form a “necklace-like” structure in the caudal olfactory bulb. The function of these unique neurons, which mainly employ cGMP as their second messenger, is poorly understood, although there is evidence that they detect natriuretic peptides from the urine of conspecifics, as well as atmospheric CO<sub>2</sub> (Hu et al., 2007).

A number of olfactory, taste, and vomeronasal organ receptors have now been deorphanized (Glatz and Bailey-Hill, 2011; Krautwurst et al., 1998; Malnic et al., 1999; Touhara, 2007; Touhara et al., 1999; Wetzel et al., 2001; Zhao et al., 1998; for invertebrates, see Carlson, 2001). For example, Zhao et al. (1998) used an adenovirus-mediated gene transfer procedure to increase the expression of a specific receptor gene in an increased number of receptor neurons in the rat olfactory epithelium, demonstrating ligand-specific increases in EOG amplitude. Krautwurst et al. (1998) employed a polymerase chain reaction (PCR) strategy to generate an olfactory receptor library from which cloned receptors were screened for odorant-induced responsiveness to a panel of odorants, as measured by an assay sensitive to intracellular Ca<sup>2+</sup> changes. Several receptor types with ligand specificity were found, including one differentially sensitive to the (–) and (+) stereoisomers of citronella. More recently, Saito et al. (2009) deorphanized 10 human and 52 mouse olfactory receptors. Some were broadly tuned to a range of odorants (“generalists”) whereas others were narrowly tuned (“specialists”) to a small number of structurally related odorants.

An explosion in the identification of taste receptor genes has occurred in the last decade. Nearly 50 taste receptor genes have been identified and more than 2,000 genes have been associated with primate taste buds (Hevezsi et al., 2009). Receptors on three main classes of taste cells have been defined. Type I cells, which are involved in neurotransmitter clearance and ion redistribution and transport, mediate salty taste sensations via specialized  $\text{Na}^+$  channels (Chaudhari and Roper, 2010). Type II cells harbor G-protein-coupled receptors that produce sweet, umami (monosodium glutamate-like), and bitter sensations, the latter being mediated by a family of ~30 such receptors. Type III cells have been found to have specialized proton channels for hydrogen ions and mediate sour sensations (Chang, Waters, and Liman, 2010). Of considerable importance is the discovery that sweet receptor genes are compromised in a wide range of vertebrate species, including bats, horses, cats, chickens, zebra finches, and the western clawed frog (Li et al., 2005; Zhao et al., 2010), as are bitter and umami receptors for dolphins (Feng et al., 2014) (see Chapter 43). During the early part of the 21st century the sequencing and functional expression of umami human taste receptors for glutamate were made, solidifying the concept that umami represents a fifth taste quality (Chaudhari, Landin and Roper, 2000; Nelson et al., 2002; Li et al., 2002). Kikunae Ikeda (1909) was the first to identify glutamic acid as the agent associated with the umami taste, a word derived from the Japanese adjective Umai, meaning delicious (Lindemann, Ogiwara and Ninomiya, 2002).

It has now become apparent that both bitter and sweet taste-related receptors, heretofore believed to occur only in taste buds, are present elsewhere in the body, most notably in the alimentary and respiratory tracts. In pioneering work, Hofer and Drenckhahn (1998), Hofer et al. (1996) discovered that  $\alpha$ -gustducin, the taste-specific G-protein  $\alpha$ -subunit, is expressed in so-called brush cells within the rat stomach, duodenum, and the pancreatic duct system. Such cells, which were first described in the trachea by Rhodin and Dalham in 1956, have been found in olfactory epithelium (where they are termed microvillar cells; Okano et al., 1967; Moran et al., 1982), lung (Meyrick and Reid, 1968), pancreas (Nakagawa et al., 2009), gall bladder (Luciano and Reale, 1979), and, in nonhumans, the vomeronasal organ (Adams, 1978). Although they have no direct contact with neurons, brush cells are rich in nitric oxide (NO) synthase. NO defends against xenobiotic organisms, protects the mucosa from acid-induced lesions, and, in the case of the gastrointestinal tract, stimulates vagal and splanchnic afferent neurons. NO further acts on nearby cells, including enteroendocrine cells, absorptive or secretory epithelial cells, mucosal blood vessels, and cells of the immune system (Hofer et al., 1998).

Wu et al. (2002) were the first to identify members of the T2R family of bitter receptors within the gastrointestinal tract and in enteroendocrine cell lines. Sweet taste receptors of the T1R family were first found in the intestinal tract and the STC-1 enteroendocrine cell line by Dyer et al. (2005). Mace et al. (2007) found that all members of the T1R family were expressed in Paneth and other cells in rat jejunum and were involved in the stimulation of glucose absorption. That same year, Margolskee et al. (2007) and Jang et al. (2007) demonstrated that T1R3 receptors and gustducin play decisive roles in the sensing and transport of dietary sugars from the intestinal lumen into absorptive enterocytes via a sodium-dependent glucose transporter and in regulation of hormone release from gut enteroendocrine cells. Shah et al. (2009) identified a number of T2R bitter receptors in the motile cilia of the human airway that responded to bitter compounds by increasing their beat frequency. Recently, Lee et al. (2012) demonstrated that the T2R38 taste receptor is expressed in human upper respiratory epithelia and responds to acyl-monoserine lactone quorum-sensing molecules secreted by *Pseudomonas aeruginosa* and other gram-negative bacteria. Importantly, they found that differences in T2R38 functionality, as related to TAS2R38 genotype, correlated with susceptibility to upper respiratory infections in humans.

### 1.5.3 Studies of the Olfactory Pathways in Transport of Agents from the Nose to the Brain

A very important empirical observation, made in the first half of the 20th century, was that the olfactory nerve can serve as a conduit for the movement of viruses and exogenous agents from the nasal cavity into the brain (see Chapters 19 and 20). This route is direct, since the olfactory neurons lack a synapse between the receptive element and the afferent path. The existence of this pathway for viral infection of the brain has been recognized for some time, as evidenced by a number of studies from the 1920s and 1930s (see Clark, 1929; Hurst, 1936). For example, mice intraperitoneally inoculated with louping ill virus showed the first signs of CNS localization of the virus in the olfactory bulbs. Mice whose olfactory mucosa was cauterized with sulfate were partly protected against such infection (Burnet and Lush, 1938). Poliomyelitis virus, placed in the noses of primates, travels to the olfactory bulbs via the axoplasm of the olfactory nerves, rather than along the nerve bundle sheaths (Bodian and Howe, 1941a, b). In a pioneering paper, Armstrong and Harrison (1935) reported that monkeys could be protected against intranasal inoculations of poliomyelitis virus by previous lavage of the nose with solutions of alum or picric acid (or both). Subsequent studies (e.g., Schultz and Gebhardt, 1936) found that zinc sulfate gave a longer-lasting and higher

degree of protection from poliomyelitis, leading to the prophylactic spraying of noses of children with this agent during poliomyelitis outbreaks in the late 1930s (Peet et al., 1937; Schultz and Gebhardt, 1937; Tisdall et al., 1937). Unfortunately, such spraying produced long-lasting, presumably permanent, anosmia in some individuals (Tisdall et al., 1938).

Related to the observation that the olfactory nerves are a major carrier of viruses is the fact that the receptive elements of the olfactory system are exposed, to a large degree, to the vagaries of the external environment, making them susceptible to damage from bacteria, viruses, toxins, and other foreign agents. As reviewed in detail in Chapters 3 and 19, numerous studies have demonstrated that the olfactory mucosa is rich in enzymes that likely minimize the deleterious influences and uptake of most xenobiotic agents into the olfactory receptor cells, including cytochromes P-450, flavin-containing monooxygenase, and aldehyde dehydrogenases and carboxylesterases.

#### **1.5.4 The Discovery that Taste Buds and Olfactory Receptor Cells Regenerate**

Another important 20th-century development is the discovery that the gustatory and olfactory receptor cells regenerate periodically. Beidler and Smallman (1965) provided the first scientific demonstration that the sensory cells of the taste bud are in a dynamic state of flux and are constantly being renewed, with the more recently formed cells of the periphery migrating centrally to act as receptors for very limited periods of time. The observation that olfactory receptor cells, which are derived from ectoderm and which serve as the first-order neurons, can regenerate after they are damaged was first noted in mice by Nagahara (1940) and later confirmed in primates by Schultz (1960). This observation is particularly significant, in that it is in conflict with the long held notion that neurons in the adult animal are irreplaceable and suggests that the olfactory system may contain the key to producing neural regeneration in a variety of neural systems (Farbman, 1992). However, questions remain as to why metaplastic respiratory epithelium often invades the region of the damaged olfactory epithelium and, when such metaplasia occurs, the epithelium in that region may never convert to olfactory epithelium. Recent studies, in which the olfactory epithelia of rodents were exposed to airborne or systemically administered toxic agents, may shed some light on this question. Thus, the type of repair seems to correlate with the degree or extent of the initial epithelial damage (Keenan et al., 1990). For example, when the basilar layer of the mucosa is completely damaged, then metaplastic replacement with a respiratory-like epithelium occurs. When the damage is not marked or the toxic insult

is not sustained, regeneration, usually with fewer or irregularly arranged cells, occurs. It is currently believed that horizontal basal cells and globose basal cells near the basement membrane of the epithelium are responsible for the generation of all neuronal and non-neuronal cell types within the epithelium (Chapter 7).

Closely related to the discovery of regeneration within the olfactory epithelium is the important observation made by Andres (1966, 1969) that mitotic cells, young sensory cells, mature sensory cells, and dying cells coexist within the olfactory epithelium (see Farbman, 1992, for a review). This suggested to Andres the hypothesis that the olfactory receptor cells were continually being replaced. The notion that olfactory receptor cells were in a state of flux received subsequent support by others (Chapter 7; Moulton et al., 1970; Thornhill, 1970; Graziadei and Metcalf, 1971) and led to the idea that they are relatively short-lived. Hinds et al. (1984), however, found that a number of the olfactory receptor cells of mice reared in a pathogen-free environment survived for at least 12 months and hypothesized that olfactory nerve cell turnover involves recently formed or immature receptor cells that fail to establish synaptic connections with the olfactory bulb. This hypothesis implies that environmental agents play an important role in dictating which elements of the receptor sheet become replaced and that the rate of regeneration of the olfactory receptor cells is not genetically predetermined, as previously supposed (see Chapter 7). The observation that improvement in olfactory function after cessation of chronic cigarette smoking occurs over a period of years and is dose-related (Frye et al., 1990) suggests, under the assumption that the olfactory epithelium is involved, that either turnover of the olfactory epithelial cell complement takes a much longer time than previously supposed or growth of olfactory epithelium into damaged areas is relatively slow and dependent on the extent of prior trauma, or both.

The study of the regeneration of the olfactory neurons has been greatly enhanced by the ability to culture the olfactory mucosa *in vitro* (for review, see Mackay-Sim and Chuah, 2000). This was first demonstrated in the culture of olfactory organs from embryonic mice (Farbman, 1977) and used to show the importance of olfactory bulb in promoting differentiation of the olfactory sensory neurons (Chuah and Farbman, 1983). The next major development came with the investigations of dissociated cultures from embryonic and newborn rats (Calof and Chikaraishi, 1989; Pixley, 1992a). This allowed the growth factors regulating olfactory neurogenesis to be explored in the developing olfactory epithelium (DeHamer et al., 1994; Mahanthappa and Schwarting, 1993) and in the adult (MacDonald et al., 1996; Newman et al., 2000).

Interestingly, normal targeting of glomeruli by olfactory receptor axons has been demonstrated in mice lacking functional olfactory cycle nucleotide-gated channels

(Lin et al., 2000) and in mice lacking most intrabulbar GABAergic interneurons (Bulfone et al., 1998). Thus, establishment of the topographical map from the receptor cells to the glomeruli seems to require neither normal neural activity in these pathways nor cues provided by the major neural cell types of the bulb.

More recently, as described in detail in Chapter 7, considerable progress has been made in understanding the regulation of neurogenesis within the olfactory epithelium. Among the more important discoveries was the finding that horizontal basal cells are neural stem cells with the capacity to regenerate both neuronal and non-neuronal elements of the epithelium, including the olfactory receptor nerve precursors, globose basal cells (Leung et al., 2007).

Human olfactory neuronal progenitors have now been grown *in vitro* (Wolozin et al., 1992) and this has been exploited to study biochemical changes in Alzheimer's disease (Wolozin et al., 1993). Primary cultures of human olfactory mucosa (Féron et al., 1998; Murrell et al., 1996) have lead to investigations into the etiology of schizophrenia (Féron et al., 1999), and the *vitro* growth of olfactory ensheathing cells (Chuah and Au, 1991; Pixley, 1992b; Ramon-Cueto and Nieto-Sampedro, 1992). The latter glial cells assist sensory neuron regeneration (Doucette, 1984) and have, in fact, been employed in cell transplantation therapy for the damaged nervous system (Li et al., 1998; Lu et al., 2001; Ramon-Cueto et al., 2000; Ramon-Cueto and Nieto-Sampedro, 1994).

### 1.5.5 The Discovery that Some Olfactory Bulb Cells Regenerate

A long-held dogma regarding the nature of the CNS of vertebrates is now known to be false; namely, that the adult brain does not exhibit neurogenesis (for review, see Gross, 2000). Although early studies found mitotic figures within the walls of the lateral ventricle (e.g., Allen, 1912; Globus and Kuhlenbeck, 1944; Opalski, 1934; Rydberg, 1932), definitive evidence that such cells represented neurogenesis awaited the development of the tritiated thymidine technique, the electron microscope, and immunohistochemistry (Gross, 2000). In the 1960s, Altman and his associates published a series of classic studies based upon thymidine autoradiography that demonstrated neurogenesis in several brain regions of young and adult rats, including the olfactory bulb (Altman, 1969), the neocortex (Altman, 1963, 1966a,b), and the dentate gyrus of the hippocampus (Altman, 1963; Altman and Das, 1965). Regarding the olfactory bulb, proliferating cells were found within the subventricular zone lining segments of the lateral ventricles. These cells were found to reach the core of the olfactory bulb via the rostral migratory stream. Subsequent studies have confirmed and extended these observations (e.g., Luskin, 1993; Lois, Garcia-Verdugo

and Alvarez-Buylla, 1996; O'Rourke, 1996), noting that the precursor cells invade the granule and periglomerular layers of the bulb, where they differentiate into local interneurons. A major differentiation is into GABAergic granule cells – the most numerous cells of the bulb.

These stem-cell-related phenomena are of considerable significance, as they indicate that the plasticity of the olfactory system goes far beyond simply replacing damaged neuroepithelial cells, and that continual cell replacement may play an integral role in olfactory perception. It is now known, for example, that reducing the numbers of interneurons recently generated via this process impairs the ability of an animal to discriminate among odorants (Gheusi et al., 2000). Moreover, enriching the odorous environment of mice enhances such neurogenesis and improves odor memory (Rochefort et al., 2002). The degree to which such processes influence, or are influenced by, endocrine state and various social processes is not well known, although interestingly glucocorticoids decrease, and estrogens increase, the rate of such neurogenesis within the hippocampus (Gould and Tanapat, 1999; Tanapat et al., 1999).

### 1.5.6 Functional Imaging Studies

A significant and rapidly evolving modern development in the study of the chemical senses is that of functional imaging. It has long been known or suspected that brain circulation changes selectively with neuronal activity (e.g., Broca, 1879; Mosso, 1881, 1884; Roy and Sherrington, 1890; Fulton, 1928), but was not until the late 1950s and early 1960s, the development of the [<sup>131</sup>I]trifluoriodomethane ([<sup>131</sup>I]CF<sub>3</sub>I) method provided a potential and novel means for quantitatively examining the influences of sensory, cognitive, and motor processes on local blood flow within regions of the brain (Landau et al., 1955; Freygang and Sakoloff, 1958; Kety, 1960; Sakoloff, 1961). This early work led in the development of the [<sup>14</sup>C]2-deoxy-D-glucose (2-DG) autoradiographic method for determining regional glucose consumption in animals (Reivich et al., 1971; Kennedy et al., 1975; Sakoloff et al., 1977), and set the foundation for modern human functional imaging studies. Reivich et al. (1979) introduced the [<sup>18</sup>F] fluorodeoxyglucose method for assessing regional glucose metabolism, and Lassen et al. (1963) and Ingvar and Risberg (1965) subsequently developed and applied a procedure in which regional blood flow measurements could be established in humans by using scintillation detectors arrayed over the surface of the scalp. The refinement of such approaches led to the practical development of positron emission tomography (PET) (Ter-Pogossian et al., 1975; Hoffman et al., 1976), which was made possible by the earlier invention of X-ray computed tomography (CT) in 1973 (Hounsfield, 1973). The coincidence of these techniques provided the

capability of mapping the regions with increased blood flow or glucose metabolism to specific regions of the brain in three-dimensional coordinates.

Magnetic resonance imaging (MRI) technology emerged contemporaneously with the latter developments (e.g., Lauterbur, 1973). Based upon a set of earlier principles (Block, 1946; Fox and Raichle, 1986; Lauterbur, 1973; Pauling and Coryell, 1936), Ogawa et al. (1990) were able to demonstrate that changes in blood oxygenation could be detected, *in vivo*, with MRI, setting the stage for the development of functional MRI (fMRI). This phenomenon, known as the blood oxygen level dependent (BOLD) signal, reflects the fact that blood flow changes more than oxygen consumption does in an activated region, reflected by a reciprocal alteration in the amount of local deoxyhemoglobin that is present, thereby altering local magnetic field properties. Details of fMRI, as well as other imaging procedures, are presented in Chapters 13, 35, and 46.

The first study to employ functioning imaging in the chemical senses was that of Sharp et al. (1975). These investigators injected four rats intravenously with 2-DG and immediately placed them in a sealed glass jar containing glass wool saturated with pentyl acetate. After 45 minutes the animals were sacrificed, and sections of the bulbs were appropriately prepared and autoradiographed. Two regions of heightened optical density were noted bilaterally which tended to be centered in the glomerular layer, with variable spread into the external plexiform and olfactory nerve layers. Subsequent studies more clearly defined the regions of apparent activation (e.g., Sharp et al., 1977; Stewart et al., 1979), and resulted in the identification of a unique set of glomeruli in weanling rats responsive to odorants in their mothers' milk (Teicher et al., 1980).

The first published human olfactory PET study was that of Zatorre et al. (1992). These investigators found that odorants increased regional cerebral blood flow (rCBF) bilaterally in the piriform cortex, as well as unilaterally in the right orbitofrontal cortex. The first taste study employing PET was that of Small et al. (1997). Increased rCBF was noted, in response to citric acid, bilaterally within the caudolateral orbitofrontal cortex, and unilaterally within the right anteromedial temporal lobe and the right caudomedial orbitofrontal cortex. The first published fMRI report on olfaction was that of Yousem et al. (1997), who demonstrated (a) odor-induced activation of the orbitofrontal cortex (Brodmann area 11), with a mild right-sided predominance (in accord with the earlier PET study of Zatorre et al., 1992) and (b) unexpected cerebellar activation. Sobel et al. (1998a) noted that olfactory stimulation activated lateral and anterior orbito-frontal gyri of the frontal lobe, and that sniffing behavior, regardless of whether an odor is present, induces piriform cortex activation. These investigators, following up on the unexpected

observation of cerebellar activation by odorants, subsequently demonstrated concentration-dependent odorant activation in the posterior lateral cerebellar hemispheres, and activation from sniffing alone in the anterior cerebellum, most notably the central lobule (Sobel et al., 1998b). More recent advances are summarized in Chapters 13 and 35.

### 1.5.7 Optogenetics

Optogenetics is an emerging technology with potential for elucidating neural processes associated with smell and taste function. In this technology, which was pioneered by Deisseroth and his associates (e.g., Boyden et al., 2005), photoresponsive microbial proteins are genetically expressed in neurons whose action potentials can then be altered by exposure, *in vivo*, to various wavelengths of light delivered by fiber optics to the target neurons. Defined trains of spikes or synaptic events with millisecond-timescale temporal resolution can be induced by brief pulses of light.

To my knowledge, the first application of this technology to an element of the olfactory system, notably the piriform cortex, was by Choi et al. (2011). These investigators found that both appetitive and aversive behaviors could be classically conditioned in mice to light activation of small subsets of piriform neurons that expressed channelrhodopsin. Different sets of neurons could be independently conditioned to elicit distinct behaviors, suggesting that this cortex can produce learned behavioral outputs independent of sensory input. These findings have shed considerable light on the mechanisms by which the piriform cortex associates odors with behavioral responses.

### 1.5.8 The Animal Behavior Revolution

Another large area of research activity that must be mentioned as having had a profound impact on modern chemosensory research is that of animal behavior (see Chapters 19, 21–27). This field, which grew in geometric proportions after World War II, is a major contributor to chemosensory studies. In addition to providing detailed explications of the many rich and often complicated influences of chemical stimuli on wide range of invertebrate and vertebrate behaviors (including, in mammals, behaviors related to aggression, alarm, suckling and feeding, mating, predator-prey relationships, social status appraisal, territorial marking, and individual and species recognition), this field has provided important methodology for assessing olfactory, gustatory, and vomeronasal function in animals, including preference paradigms (e.g., Richter, 1939; Mainardi et al., 1965), classical conditioning paradigms (Pavlov, 1927), conditioned aversion paradigms (e.g., Garcia et al., 1955), habituation paradigms

(e.g., Krames, 1970), sniff rate analysis paradigms (e.g., Teichner, 1966), and operant conditioning paradigms using positive or negative reinforcers (Skinner, 1938). Furthermore, behavioral studies have been instrumental in the demonstration of the close association between neuroendocrine and chemoreception systems in both vertebrates and invertebrates, and are critical for demonstrating the effects of various gene manipulations on smell- or taste-mediated behaviors. A number of the chapters of this volume directly relate to this vast literature and, in some cases, provides means for assessing responses of animals to odorants (Chapters 21–27) and tastants (Chapters 38 & 41–44). The reader is referred to the many general reviews of this topic (Albone, 1984; Doty, 1974, 1975, 1976, 1980, 1986; Johnston, 2000; Johnston et al., 1970; Leon, 1983; Meredith, 1983; Mykytowycz, 1970; Slotnick, 1990; Smith, 1970; Stevens, 1975; Vandenbergh, 1983; Verendeev and Riley, 2012; Wysocki, 1979).

According to Stürckow (1970), the studies by Barrows (1907), von Frisch (1919), and Minnich (1921) were seminal for the development of studies of insect chemosensory behavior and physiology, even though earlier, more equivocal, studies had been performed (e.g., Hauser, 1880). Barrows (1907) devised the first insect olfactometer and found, in the pomice fly (*Drosophila ampelophila*), that different degrees of responding were obtained from different concentrations of chemical attractants. Von Frisch (1919) demonstrated that bees could be trained to fly to a fragrant odor using simple reinforcement and later found the location of the olfactory sensilla to be on the eight distal segments of the antennae (von Frisch, 1921, 1922). Minnich (1921, 1926, 1929) explored the responses of various body parts of butterflies, certain muscid flies, and the bee to taste solutions. For example, he found that they extended their proboscises when their tarsi or certain mouth parts were touched with a sugar solution. These and other studies led to electrophysiological studies of the chemoreceptive systems of insects by Dethier (1941), Boistel (1953), Boistel and Corabœuf (1953), Kaissling and Renner (1968), and Schneider (1955, 1957a, b).

A number of important studies, published in the 1950s, 1960s, and early 1970s, demonstrated a close association between olfaction, social behavior, and reproductive processes in rodents and other mammalian forms. Pioneering reports on this topic include those which showed that odors from male and female mice influence the timing of estrous cycles (Lee and Boot, 1955; Whitten, 1956; Whitten et al., 1968), that urine odor from unfamiliar male mice can block the pregnancy of female mice (Bruce, 1959; Bruce and Parrott, 1960), and that chemical stimuli can accelerate the onset of puberty in mice (Vandenbergh, 1969). Other important studies demonstrated that olfactory bulbectomy, anesthetization, or damage to the olfactory receptor region vomeronasal organ or nervus terminalis,

alone or in combination, can dramatically influence mating behavior, depending on the species involved (e.g., in the male or androgenized female hamster, anesthetization or damage of these systems can eliminate male copulatory behavior; Doty and Anisko, 1973; Doty et al., 1971; Murphy and Schneider, 1970; Powers and Winans, 1973, 1975; Winans and Powers, 1974). Such phenomena have been demonstrated to one degree or another in a wide variety of mammals and have important implications for animal ecology, husbandry, and perhaps even human behavior.

Other studies of this period that had a considerable impact on the field of mammalian social behavior include those that examined, in a systematic manner, sexual odor preferences in rodents. Godfrey (1958), for example, found that estrous female bank voles (*Clethrionomys*) preferred homospecific male odors over heterospecific male odors and that hybrids were discriminated against. Le Magnen (1952) demonstrated that adult male rats (*Rattus norvegicus*) prefer the odor of receptive females to nonreceptive ones, whereas prepubertal or castrated males do not (unless they have been injected with testosterone). Beach and Gilmore (1949) noted that sexually-active male dogs, but not a sexually-inactive male dog, preferred estrous to non-estrous urine. This and other work led to a number of carefully designed studies by Carr and his associates in the 1960s which sought to determine the influences of sexual behavior and gonadal hormones on measures of olfactory function. Carr and Caul (1962) demonstrated that both castrate and noncastrate male rats can be trained to discriminate between the odors of estrous and nonestrous females in a Y-maze test situation, implying that the preference phenomenon observed by Le Magnen (1952) was not due to castration-related influences on olfactory discrimination ability, per se. Carr et al. (1965) subsequently demonstrated the important role of sexual experience in producing strong preferences in male rats for estrous over diestrous odor and in female rats for noncastrate male odors over castrate male odors. These investigators also showed that sexually inexperienced females preferred male noncastrate odors if they were administered gonadal hormones that induced estrus.<sup>4</sup> These general findings have been observed in a wide range of species, although some species differences do exist and castration has been shown to mitigate the increase in detection performance of rats that follows repeated testing (Doty and Ferguson-Segall, 1989; for reviews, see Brown and Macdonald, 1985; Doty, 1974, 1976, 1986).

Animal behavior studies in the 1980s contributed significantly to the understanding of the function of

<sup>4</sup>In an unpublished M.A. thesis, Keesey (1962) found that sexually experienced, but not sexually inexperienced, male rats preferred the odor of female urine collected during proestrus than that collected during diestrus.

vomeronasal organ which was described histologically in many species in the 19th century, but whose function was unknown (for review of the early literature, see Wysocki, 1979). In the mouse, removal of the vomeronasal organ eliminates the surge in luteinizing hormone (LH) and subsequent increase in testosterone that ordinarily follows exposure of male mice to an anesthetized novel female mouse or her urine. However, this does not occur following exposure to an awake female mouse, suggesting several sensory cues can produce the LH surge (Coquelin et al., 1984; Wysocki et al., 1983). In both mice and hamsters, vomeronasal organ removal impairs male sexual behavior, particularly in animals that have had no prior adult contact with females (Meredith, 1986; Wysocki et al., 1986). In mice whose vomeronasal organs have been removed soon after birth, long-lasting influences on male sexual behavior in adulthood have been noted (Bean and Wysocki, 1985). Vomeronasal organ removal also greatly decreases aggression in male house mice, particularly those that have not had much fighting experience with other males (Bean, 1982; DaVanzo et al., 1983; Wysocki et al., 1986).

While there is now incontrovertible evidence that most adult humans have a rudimentary vomeronasal organ (VNO) whose opening is present at the base of the nasal chamber, no neural connection exists and the structure is generally considered vestigial (Doty, 2001; Smith and Bhatnagar, 2000; Bhatnagar and Meisami, 1998; Brown, 1979). The presence of a regressive human VNO fits into the general idea that humans have lost much chemosensory capacity, at least relative to many other mammals, over the course of evolution. However, aside from the VNO, the concept of lesser smell function has come under vigorous debate and some animal behavioral studies have suggested that the divide between humans and other mammals is not as great as often believed (Laska et al. 2000) (see Chapter 27). Contributing to this notion is a reassessment of the relationship between nasal cavity structure and both the size and density of the olfactory neuroepithelium of primates, throwing into question the classic distinction between macrosmatic and microsmatic mammals (Smith et al. 2004).

A significant event for the field of odor communication was the coining of the term “pheromone” in insects for “substances which are secreted to the outside by an individual and received by a second individual of the same species, in which they release a specific reaction, for example, a definite behavior or a developmental process” (Karlson and Lüscher, 1959, p. 55). The pheromone concept, which has permeated most areas of biology, has been applied by some workers to nearly any chemical involved in chemosensory communication. The term pheromone replaced an earlier term (ectohormone) and conjures up the idea that the social organization of animals is akin to the endocrine organization of an organism, with disparate

parts being influenced by chemicals that circulate within the social milieu. For many, but not all, insects, this term seems appropriate, given the high degree of stereotypic behavior and evidence for comparatively simple stimuli that induce behavioral or endocrinological changes. However, for many vertebrates, particularly mammals, this concept has questionable utility since it assumes simple associations between stimuli and responses which rarely, if ever, exist. As discussed in *The Great Pheromone Myth* (Doty, 2010), this concept suffers from a range of basic problems when applied to mammals. For example, it leads to the nominal fallacy, i.e., the tendency to confuse naming with explaining, and assumes that a few species-specific molecules of innate origin, largely impervious to learning and distinct from other types of stimuli, are the motive influences. Importantly, it inappropriately dichotomizes complex behaviors and stimuli into simple classes and fails to take into account the complexity of chemical stimuli and the influences of experience in determining their meaning. Despite possibly one or two such claims, no single chemical or set of chemicals has been identified in mammals that can be truly considered analogous to an insect pheromone. A number of phenomena in humans that have been attributed to pheromones, such as menstrual synchrony, have been found to be based upon statistical artifact, further denigrating the usefulness of this popular but flawed concept (Schank, 2006; Strassmann, 1997; Wilson, 1992).

Pioneering behavioral studies of mammalian taste function began in the 1930s, heralded by experiments that sought to explain so-called specific hungers, e.g., salt craving in patients with adrenal gland hypofunction. In seeking to determine whether alterations in taste function are responsible for increased NaCl intake of adrenalectomized rats, Richter (1936, 1939) developed the two-bottle taste test (see also Richter and Campbell, 1940). In this test, differential fluid intake from two bottles, one of which contains a tastant (e.g., a NaCl solution) and the other water alone, is recorded over a period of time. The lowest concentration of the tastant that produces a differential intake is taken as the threshold measure.

Although this behavioral procedure provided a means for measuring a preference threshold, postigestional factors may alter the behavioral response and such a threshold is conceptually different from a sensory threshold. Thus, a lack of preference between two solutions need not reflect an inability to discriminate between them [see Stevens (1975) for reviews of analogous procedures for olfaction]. Subsequent workers, including Carr (1952), Harriman and MacLeod (1953), Morrison (1967), and Morrison and Morrison (1966), utilized shock avoidance paradigms or operant conditioning paradigms that provided positive reinforcement to establish NaCl threshold values – values that were much lower than those obtained using Richter’s

procedure and which corresponded more closely to neural thresholds. Numerous modifications of behavioral procedures for assessing taste function in mammals have since been developed which incorporate general principles that evolved from these pioneering behavioral studies (e.g., Brosvic et al., 1985, 1989; Spector et al., 1990). Analogous procedures have been developed in olfaction (e.g., Bowers and Alexander, 1967; Braun et al., 1967; Braun and Marcus, 1969; Eayrs and Moulton, 1960; Goff, 1961; Henton, 1969; Moulton, 1960; Moulton and Eayrs, 1960; Pfaffmann et al., 1958; Slotnick and Katz, 1974; Slotnick and Ptak, 1977; Slotnick and Schellinck, 2002). Another noteworthy development in behavioral testing was that of the conditioned aversion paradigm (Garcia et al., 1955, 1974). In one variant of this technique, an animal is allowed to drink or smell a novel tastant or odorant and is then injected with an agent that produces nausea (e.g., lithium chloride). The animal quickly learns to avoid the novel stimulus as a result of a single aversive conditioning experience, even if the aversion occurs long after the presentation of the sensory stimulus. This procedure can be used to establish whether detection of a given stimulus is present and is particularly useful for assessing cross-reactivity of stimuli (i.e., the extent to which a stimulus has elements in common with other stimuli). One of the more novel applications of this technique was by Smotherman (1982), who demonstrated that the olfactory system of rats is functional in utero. In this study, unborn rat pups (gestation day 20) received in utero injections of apple juice and lithium chloride. After birth, these individuals showed evidence of having developed a conditioned aversion to the odor of apple juice (see Chapter 14).

### 1.5.9 Clinical Chemosensory Studies

Considerable progress in understanding chemosensory disorders has been made in the last few decades, as reviewed in detail in Chapters 16–20, 28, and 36–40. The proliferation of clinical studies has been fueled, in large part, by the development wide-spread commercial availability of standardized psychophysical tests of olfactory function that first occurred in the early 1980s (e.g., Doty et al., 1984a, Doty, 2000, 2001; Kobal et al., 1996; Hummel et al., 1997; for review, see Doty, 2007). It is now widely appreciated that smell loss is markedly depressed in elderly persons (Doty et al., 1984b), and that most common causes of permanent smell loss are (1) upper respiratory viral infections, (2) head trauma, and (3) nasal and sinus disease (e.g., Deems et al., 1991). Moreover, it appears that these disorders largely reflect damage to the olfactory neuroepithelium, as revealed by autopsy and biopsy studies (Douek et al., 1975; Hasegawa, Yamagishi and Nakano, 1986; Jafek et al., 1989, 1990; Moran et al., 1992). Most complaints of

taste loss reflect the loss of olfactory function, and flavor sensations are largely derived from retronasal stimulation of the olfactory system during active deglutition (Mozell et al., 1969; Burdach and Doty, 1987).

We now know that the olfactory system seems more susceptible to damage than the taste system, although damage to regional lingual afferents is particularly striking in old age (Matsuda and Doty, 1995), and taste sensitivity is directly related to the number of taste buds or papillae stimulated, regardless of whether stimulation is by chemicals or by electrical current (Doty et al., 2001; Miller et al., 2002; Zuniga et al., 1993). Moreover, it has become increasingly apparent that many medicines, including a number of antibiotics, antidepressants, antihypertensives, antilipid agents, and psychotropic drugs, can produce alterations of the taste system (e.g., severe dysgeusia), alone or in combination with alterations in the smell system (Schiffman, 1983; Schiffman et al., 1998, 1999a,b, 2000). Importantly, recent studies suggest that damage to one of the major taste nerves (e.g., one chorda tympani) may release inhibition on other taste nerves (e.g., the contralateral glossopharyngeal nerve), resulting in hypersensitivity to some tastants and the production of phantom dysgeusias (Lehman et al., 1995; Yanagisawa et al., 1998).

A major advance in the last few years is the discovery that smell loss is among the first, if not the first, signs of such common neurodegenerative diseases as Alzheimer's disease (AD) and idiopathic Parkinson's disease (PD), and that disorders sharing similar motor signs, such as progressive supranuclear palsy (PSP) and MPTP-induced Parkinsonism (MPTP-P), are largely unaccompanied by such loss (see Chapter 18). Such observations imply that olfactory testing can be of value not only in the detection of some neurodegenerative disorders early in their development, but in differential diagnosis. Indeed, odor identification testing accurately differentiates between patients with AD and those with major affective disorder (i.e., depression) (Solomon et al., 1998; McCaffrey et al., 2000). Interestingly, longitudinal studies have now appeared indicating that olfactory dysfunction can be predictive of AD in individuals who are at risk for this disorder, particularly when considered in relation to other risk factors (Bacon et al., 1998; Graves et al., 1999; Devanand et al., 2000). The only neurodegenerative disorder for which a definitive physiological basis has been found to date, however, is multiple sclerosis, where a -0.94 correlation has been observed between odor identification test scores and the number of plaques, as measured by MRI, in the subtemporal and subfrontal regions of the brain (Doty et al., 1997, 1998, 1999).

Among the many diseases or disorders in addition to those noted above that are associated with smell dysfunction include severe alcoholism, amyotrophic lateral sclerosis (ALS), chronic obstructive pulmonary disease,

cystic fibrosis, epilepsy, the Guam ALS/PD complex, head trauma, Huntington's disease, Kallmann's syndrome, Korsakoff's psychosis, myasthenia gravis, pseudohypoparathyroidism, psychopathy, restless leg syndrome, schizophrenia, seasonal affective disorder, and Sjogren's syndrome. Neurological disorders in which olfactory seems to be spared in addition to PSP and MPTP-induced PD are corticobasal degeneration, depression, panic disorder, essential tremor, and multiple chemical hypersensitivity (for review, see Doty, 2012). In addition to traditional medical means for treating or managing diseases responsible for decreased olfactory function, surgical intervention at the level of the olfactory neuroepithelium (e.g., by selectively ablating or stripping away the diseased tissue) or the olfactory bulb (e.g., by removal of one or both olfactory bulbs in an anterior cranial approach) has successfully eliminated or markedly reduced the symptoms of some forms of chronic dysosmia or phantosmia (see Chapter 27). Recent advances in understanding the deleterious influences of oxygen radicals on neural tissue, as well as changes that occur in olfactory tissue at menopause, have led to ongoing studies of the prophylactic potential of antioxidants, hormones, and other agents in mitigating toxin-induced damage to the olfactory (e.g., Dhong et al., 1999).

## 1.6 CONCLUSIONS

In this introduction, a brief description of the significant role that tastes and odors have played throughout the course of human history has been presented. In addition, a number of key studies, events, and trends have been identified which form the backdrop of much of today's chemosensory research enterprise, providing perspective for the chapters that follow. The chapters of this volume provide a detailed contemporary information related to most of these trends and address the important role of chemosensory science in both basic and applied (e.g., clinical) situations. Until recently, the chemical senses have engendered, relative to the other major senses, comparatively little attention on the part of the scientific and medical communities. This has clearly changed, as reflected in the chapters that follow.

## Anatomy of the Nasal Passages in Mammals

TIMOTHY D. SMITH, THOMAS P. EITING, and KUNWAR P. BHATNAGAR

### 2.1 INTRODUCTION

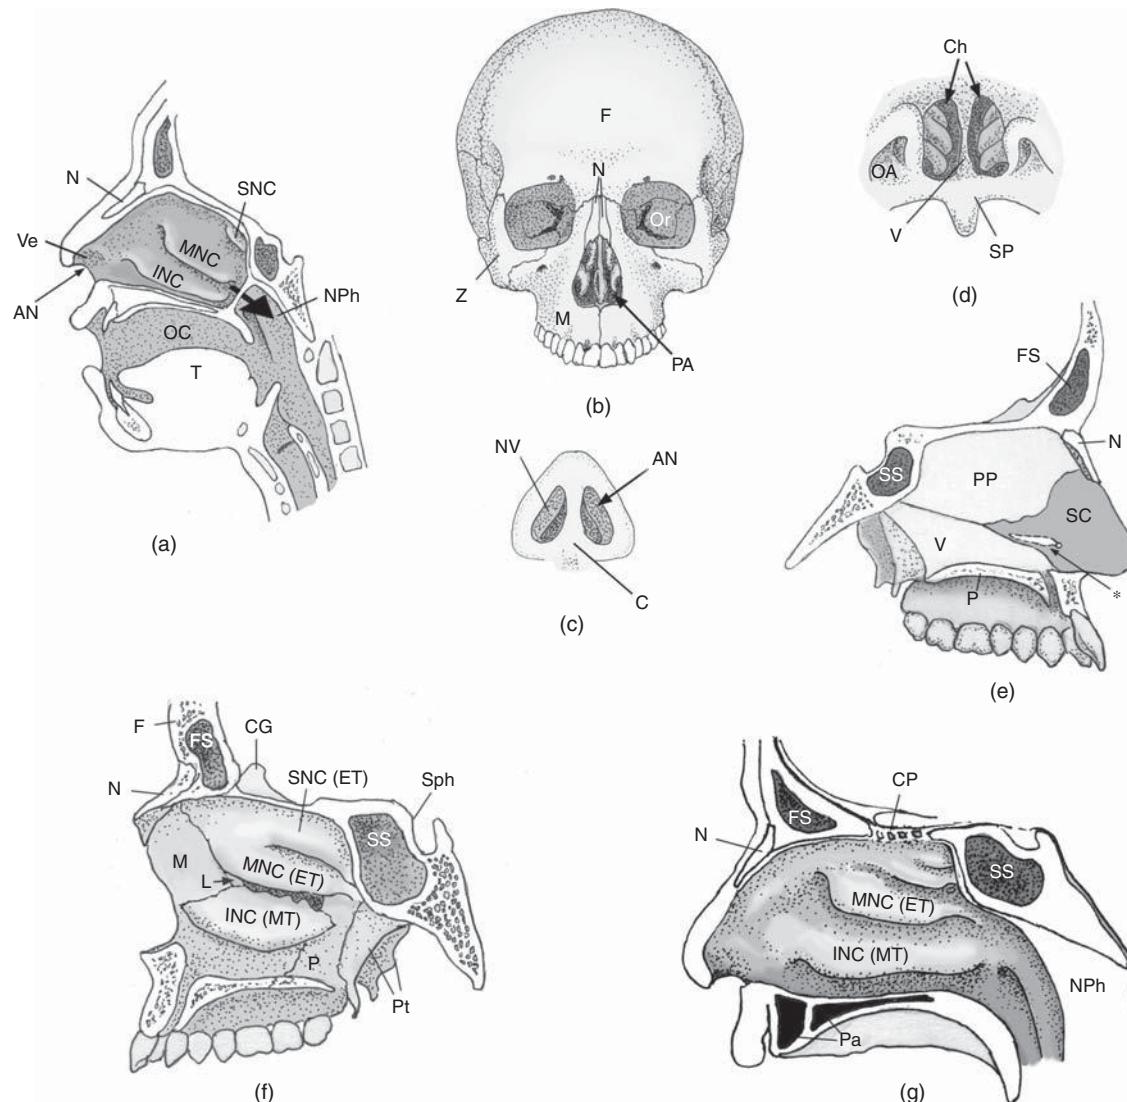

Human nasal anatomy has been well-documented for centuries. The human nasal passages represent the proximal (upper, or facial) part of the respiratory tract, and communicate posteriorly with the pharynx, a shared conduit of the respiratory and digestive tracts (Figure 2.1a). In skeletal anatomy, the piriform aperture is the portal into the nasal cavity (Figure 2.1b). This opening is elaborated by cartilaginous support structures that house the downwardly-oriented, fleshy anterior nares (Figure 2.1c). The anterior nares open to a dilated vestibule on each side. Between the right and left vestibules is the columella, a fleshy structure right under the tip of the nose (Figure 2.1c). The columella is supported internally by the nasal septal cartilage, which extends posteriorly to join the midline portions of the ethmoid and vomer bones. The nasal cavity is thus separated into right and left halves, or nasal fossae, beginning at the anterior nares. The end of the nasal passages is commonly located with reference to paired exit points, the choanae (or posterior nares), that transmit air from the nasal fossae into the nasopharynx (Figures 2.1a,d). The nasal choanae are separated by the posterior end of the nasal septum, which is supported by the vomer bone.

The nasal septum is composed of three elements: the septal cartilage, the perpendicular plate of the ethmoid, and the vomer bone. These three are all related in that the nasal septal cartilage articulates posteriorly with the perpendicular plate of the ethmoid and the vomer bone (Figure 2.1e). In the nasal cavity, this median (septal) component forms the medial boundary for right and left nasal fossae. The lat-

eral wall represents the most complex boundary of the nasal fossa (Figures 2.1f,g). Formed by portions of the maxillary, ethmoid, lacrimal, and palatine bones, this wall has both invaginations that extend into the nasal airway and ostia that communicate to paranasal spaces (Figure 2.1f). The cribiform plate of the anterior cranial base is the roof of each nasal fossa, while the palate forms the floor (Figures 2.1f,g).

Once inspired air is drawn beyond the vestibule, it enters the nasal cavity proper, in which the air passages become more complex. For this reason, the lateral wall of the nasal fossa has received much attention. As reviewed by Wright (1914), the human nasal conchae (turbines, turbinals) that arise from the lateral walls of the ethmoid bone (Figures 2.1f,g) extend into the nasal passages. These were described to some degree by such early anatomists as Galen, Colombo, and Ingrassias. Their function is now understood to be in both air-conditioning and olfaction (see review by Clerico et al., 2003). In addition, they divide the nasal airways into compartments, called meatuses. The inferior nasal concha articulates with the maxillary bone (a basis for its alternate name – maxilloturbinal; Figure 2.1f). The middle and superior nasal conchae are part of the lateral mass of the ethmoid bone.

Interestingly, Galen had recognized the role of turbinals in altering, cleansing, and warming the inspired air, although he apparently did not clearly differentiate between the different turbinals. An exacting description of the turbinals was made by von Haller in his “Icones anatomicae” (1756). The nasal turbinals received their name from Casserius, who had described the turbinals not only of humans, but also of other species, including

**Figure 2.1** Anatomy of human nasal passages. (a) The nasal passages are the upper part of the respiratory tract. On each side, air enters the nasal passage through the anterior nares (AN) and joins the pharynx by passing through the choana (route indicated by arrow). In nasal breathing (as opposed to breathing through the oral cavity – OC), inspired air passes across the complex surfaces of the nasal cavity. First, it is drawn into a small hairy chamber, the vestibule (Ve), in which vibrissa filter relatively large airborne items. Subsequently, the air is drawn across the inferior, middle, and superior nasal concha (INC, MNC, SNC) that extend into the airways with mucosa that functions for air conditioning or olfaction (see text for more details). (b) The piriform aperture is anterior-most osseous opening of the nasal airways, shown here in a frontal view of the skull. (c) In the flesh, nasal cartilages and the integument extend from the piriform aperture to form downwardly-oriented anterior nares, shown here from an inferior perspective. The columella (C) is the fleshy base of the nasal septum, which divides the nasal cavity into right and left sides. (d) The choanae (Ch), seen here in a posterior view, transmit air to the nasopharynx. These channels are separated into right and left sides by the posterior end of the nasal septum, formed by the vomer bone (V). (e) Structural support for the nasal septum is formed by the nasal septal cartilage (SC), vomer bone, and the perpendicular plate of the ethmoid bone (PP). This forms the median boundary for both halves of the nasal cavity. The vestigial vomeronasal organ (\*) is found within the mucosa of the nasal septum. (f) A lateral view reveals the numerous bones that form the lateral wall of the nasal fossa, including the maxilla (M), the inferior nasal concha (INC), the ethmoid (the MNC and SNC are parts of this bone), the palatine (P), and lacrimal (L; most of this bone is hidden by the MNC). These bones comprise the lateral wall (g). The “floor” of the nasal cavity is formed in part by the hard palate (Pa) and the “roof” of the nasal cavity is formed by the cribriform plate of the ethmoid (CP), the nasal bone (N), and the sphenoid bone (Sph), shown surrounding the sphenoid sinus (SS). CG, crista galli; ET, ethmoturbinal (alternate name for MNC, SNC); F, frontal bone; FS, frontal sinus; M, maxillary bone; MT (maxilloturbinal, alternate name of INC); NPh, nasopharynx; NV, “nasal valve”; Pt, pterygoid plates; T, tongue; Z, zygomatic bone.

the cow, horse, sheep, hare, cat, and dog. He stated in his 1610 work, *Pentaesthesia*, that hidden in the depth of the nostrils are

oblong little bones which may be called spongy, and seem like the steps of a ladder, because one is placed above the other. ... Hippocrates not inaptly calls them sleeves. Turbines I would call them from their form and function. They are bones, not cartilages. Turbinated bones (*Turbinata Ossa*) they are rightly called. They are usually three in number, indeed this many at least always.

While knowledge of the engorgement of the erectile tissue covering the turbinals was known by Ruppert as early as 1754, the classic description of the vascular erectile tissue within the nasal mucosa was made in 1853 by Kohlrausch. The so-called nasal cycle – the fluctuating side-to-side variations in nasal engorgement – was quantified by Kayser in 1895. This discovery resulted from his invention of an ingenious device employing calibrated bellows to withdraw a known volume of air through the nose from the oral cavity. By determining the time required to draw the air, he was able to establish an index of nasal resistance for each side of the nose.

The literature on human nasal anatomy, spanning centuries, has thus revealed great complexity. By comparison, a broader understanding of mammalian nasal anatomy has been somewhat hampered because our picture of evolutionary history of nasal anatomy relies mostly on comparisons of living vertebrates, since nasal anatomy fossilizes quite poorly. Moreover, destructive methods and delicate dissection was required to study other vertebrates until quite recently. Modern methods such as computed tomography (CT) have greatly increased our breadth of knowledge (e.g., Rae and Koppe, 2003; Rossie, 2006). In this chapter we provide a comparative overview of vertebrate nasal anatomy, with a primary focus on mammals.

## 2.2 EVOLUTION OF COMPLEXITY IN THE VERTEBRATE NASAL CAVITY

### 2.2.1 Comparative Nasal Anatomy of Terrestrial Vertebrates

The complexity of the nasal cavity of land dwelling vertebrates is intertwined with the evolution of air filtration, breathing, water recovery, and, in some species, the transmission of vocalizations, including echolocation calls of bats.<sup>1</sup> The vertebrate nasal cavity begins as a bilateral invagination of the nasal pits, paired depressions that form

<sup>1</sup>The effects of some of the more specialized functions on the form and functional anatomy of the nasal passages (e.g., sound transmission and echolocation) are interesting and perhaps understudied, but will not be considered further in this chapter.

at the juncture of the maxillary and medial and lateral nasal prominences (Dieulafe, 1906). These pits invaginate into deep nasal sacs, which are bilateral in most extant vertebrates.<sup>2</sup> In postnatal morphology, the respiratory and digestive tracts of air breathing vertebrates often share the same lumina, but this is not the case for more primitive forms. In most species of fish, for example, the nasal sac is entirely separated from the oropharyngeal passageways (Negus, 1958). This changed as vertebrates began to invade terrestrial habitats. While amphibians typically retained relatively simple nasal cavities in the form of nasal sacs, most amniotes – vertebrates fully adapted to terrestrial life – developed complex nasal cavities containing secondary and tertiary turbinals distinct from the ridges found in amphibians (Negus, 1958).

Extant reptiles have a wide range of complexity in internal nasal anatomy. Turtles have a nasal cavity similar to that of amphibians, whereas crocodilians have a somewhat more complex nasal anatomy, possessing three turbinals (Parsons, 1967). Birds and mammals have more complex turbinals than reptiles – complexity that is often related to endothermic regulation of body temperature (Hillenius, 1994; Geist, 2000). In some mammals, the turbinals create a complex labyrinth of recesses, thereby increasing internal surface area and compartmentalizing the internal nose into functional regions. Because the nasal mucosa is specialized for more than one function (Negus, 1958; Moore, 1981; Hillenius, 1992), variations of the mammalian nasal cavity reveal respiratory and special sensory adaptations.

### 2.2.2 Development of the Mammalian Nasal Cavity

The complexity of the nasal cavity in mammals arises from the embryonic and early fetal development of a series of mesenchymal condensations. In some cases, the larger turbinals<sup>3</sup> can be considered primary structures, since they chondrify at or near the same time as the outer walls of the nasal cavity (Vidic, 1971; Moore, 1981). In other cases, the turbinals are clearly secondary, forming from mesenchymal condensations that develop after most of the nasal capsule has chondrified (Smith and Rossie, 2008; Smith et al., 2012). The complexity of individual turbinals in adults appears to arise progressively during development. This developmental progression in mammals that have complex turbinals has been described as

<sup>2</sup>These pits form a single cavity in some chordates, such as the lamprey (Dieulafe, 1906). However, it forms via fusion of the two growing nasal pits, and the lamprey larvae preserve evidence of this fusion in their bilobed nasal sac (Weichert, 1958).

<sup>3</sup>The term “turbinal” is preferred here since it is relatively more commonly used, in recent decades, than “turbinate” in work on evolution and development of the mammalian nasal cavity. However, these terms are entirely synonymous when used with prefixes (endo, fronto, maxillo, etc.).

“splitting” (Parker, 1874), although this may more appropriately be described as a “budding” of accessory lamellae via mesenchymal proliferation.

The largest turbinals within the mammalian nasal cavity project closest to the midline, and are often provided with a collective positional name, the “endoturbinals” (Figure 2.2; Table 2.1). Smaller turbinals, hidden from view deep in the midline row of turbinals are sometimes referred to as “ectoturbinals.” However, due to inconsistent usage and developmental factors (see Smith et al., 2011, and Macrini, 2012 for recent critical evaluations), we use other terms here that relate turbinals to the bones with which they ultimately articulate: maxilloturbinals, nasoturbinals, and ethmoturbinals (Figure 2.2; Table 2.1). Smaller turbinals include those that reside in recesses (e.g., the frontoturbinals) and those that exist between ethmoturbinals (interturbinals) (Maier, 1993a, b). The interturbinals are secondary structures, beginning as mesenchymal condensations after other adjacent regions have started to chondrify (Smith and Rossie, 2008; Smith et al., 2012).

The turbinals develop as inward projections of the nasal capsule cartilage that surrounds and supports the nasal airways during fetal development. The largest space within the nasal airway, bordered by the largest proportion of internal nasal surface area, is termed the “nasal cavity proper.” In humans, this space corresponds to the entire nasal cavity (excluding paranasal spaces and vestibule). Most mammals have a more extensive nasal cavity proper compared to humans, including a posterior dead-ended space, the olfactory recess. The olfactory recess will be discussed functionally below. Developmentally, inwardly-projecting shelves from the inferior margin of the pars posterior form part of the floor of the olfactory recess. On each side, these shelves are formed by cartilaginous elements (*lamina transversalis posterior*) that join choanal (lateral) processes of the vomer, thus sealing off a more superior space (the olfactory recess), from the remainder of the nasal fossa (the nasopharyngeal duct). Once ossified, this horizontal plate is referred to as the transverse lamina (Figures 2.2, 2.3).

A final consideration on the fetal template is the organization of accessory (paranasal) spaces within the nasal cavities. Most paranasal spaces form where embryonic parts of the nasal capsule intersect, due to folding of the middle portion of the nasal capsule (Rossie, 2006). The paranasal spaces are accessory chambers, or recesses (Figure 2.3). Although humans do possess paranasal spaces, which can pneumatize into fairly large paranasal sinuses postnatally, many mammals have more complex paranasal spaces, or recesses, compared to humans and other “higher” primates.<sup>4</sup> The difference in complexity may be related to a

greater amount of encroachment of the nasal cavity by the orbits in primates. In most mammals, the space between the orbits is wide-set enough to make room for portions of the paranasal recesses (especially, the frontal recess). Another consideration pertains to development of the paranasal space after the cartilaginous capsule is mostly ossified or resorbed. If a paranasal recess is enlarged by the process of secondary pneumatization, the term paranasal “sinus” is instead used. In recent literature, the process of secondary pneumatization denotes a critical distinction between paranasal spaces (see Witmer, 1999; Rossie, 2006; Smith et al., 2008, 2010; Macrini, 2012). For example, while the maxillary recess is ubiquitous among extant mammals, it is not clear how commonly the space is pneumatized beyond the limits established by the cartilaginous nasal capsule. Therefore, possession of a maxillary “sinus” cannot presently be considered a primitive feature of mammals.

## 2.3 MAMMALIAN NASAL ANATOMY

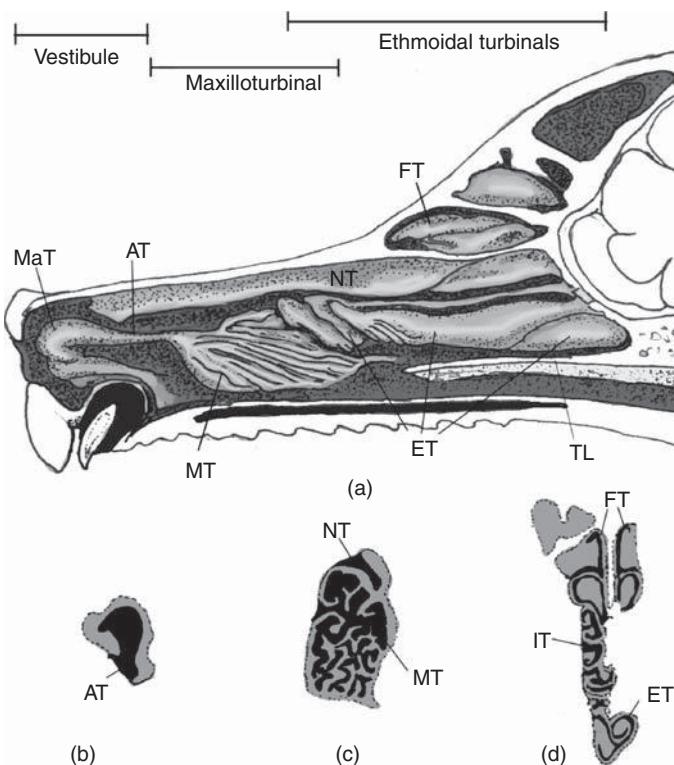

### 2.3.1 General Organization of the Mammalian Nasal Region

Structures within the mammalian nose are bilateral. The exceptions are the columella and the septal core (cartilaginous and/or bony), these being the median and single structures. The nasal septum is a unique structure which has both median as well as bilateral components. While the bony or cartilaginous septum is unpaired, all the mucosal elements, such as the vomeronasal organ (VNO), septal olfactory organ (SOO), paraseptal cartilages, the various nerves, blood vessels, glands and ducts, are bilateral structures within the septum. Other structures, such as the paravomeronasal ganglion that bears connection to vomeronasal nerves, have been observed in the septal lamina propria of some species of bats and primates (Bhatnagar and Kallen, 1974a; Bhatnagar and Smith, 2007; Smith and Bhatnagar, 2009). This structure may merit a more in-depth investigation for its link, if any, to the terminal nerve.

The prototypical mammalian nasal cavity is divided into right and left nasal fossae by the midline nasal septum. As in human anatomy, the nasal fossa may be divided into a small, anterior, vestibule, and the nasal fossa proper (Figure 2.3). The vestibule may be extremely abbreviated or a small “chamber” of its own (as in humans). Its transition to the nasal fossa proper is indicated by a shift in mucosal type, and may be marked by a small ridge (e.g., the limen

<sup>4</sup>“Higher” primates refers to anthropoid primates (monkeys, apes, and humans). However, whenever discussing reduction of nasal anatomy we could equally be referring to Southeast Asian tarsiers – primates that

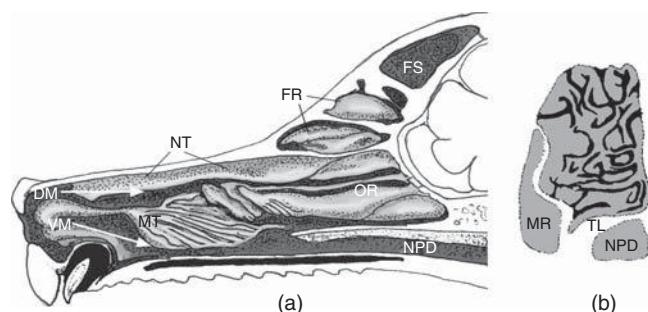

possess some primitive traits. Tarsiers, like anthropoids, have marked reduction of the nasal cavity. This may be especially related to the large eye size in these nocturnal species.

**Figure 2.2** (a) Lateral nasal wall of the dog, showing major cartilaginous and bony structures in mammals. Descriptions of the lateral nasal wall are reflection of its great intricacy. For example, five regions of the nasal spaces are described in canine anatomy: vestibular, maxilloturbinate, nasomaxillary, ethmoid, and frontal sinus regions (Craven et al., 2007). These regions correspond almost neatly to physiological compartments, such as the highly branched canine maxilloturbinal that warms and humidifies inspired air, or the ethmoid that supports most of the olfactory neuroepithelium. The regions of the internal nose, which overlap to a varying degree in mammals, are indicated above. Cross-sections of these regions are shown below, (b) vestibule, showing the atrioturbinal (AT), (c) maxilloturbinal, (d) ethmoturbinals in the olfactory recess, with frontal recesses above. Cross sections are illustrated after (Craven et al., 2007). In B-D, turbinals are emphasized in black and the airway is shown in gray. ET, ethmoturbinal; FT, frontoturbinal; IT, interturbinal; MaT, marginoturbinal; MT, maxilloturbinal; NPD, nasopharyngeal duct; NT, nasoturbinal; TL, transverse lamina.

nasi of humans). The osseous and cartilaginous boundaries of the nasal cavities are essentially the same as described for humans above, except the premaxillary bone is a separate element that forms lateral and inferior boundaries at the anterior limit (this bone is completely merged with the maxilla in humans). The extent to which certain bones (e.g., nasal) border the nasal cavity varies greatly among mammals, and the recesses and turbinals are more elaborate in many mammals compared to humans (Smith et al., 2007a; Stössel et al., 2010). The cribriform plate (essentially a bilateral structure divided by a bony ridge, the crista galli) stands between the posterior nasal fossa and the anterior cranial fossa. The various nerves (olfactory, vomeronasal, trigeminal branches, autonomic, nervus terminalis) pass through the openings in the plate to the olfactory bulb and other central brain regions. Blood vessels also enter or leave through their own foramina (see Bhatnagar and Kallen, 1974b).

Some nasal regions appear to bear physiological significance in a broad range of mammals. For instance, the nasal fossa may be divided into nasal and paranasal component spaces (Figure 2.3b). In addition, the more midline nasal spaces are sometimes divided physiologically into different spaces (meatuses), associated with respiratory or special sensory roles (Figure 2.3). In each of these spatial constructs, the turbinals play an important role in directing airflow to compartments of the nasal airway (see below).

**Figure 2.3** (a) Lateral nasal wall of the dog, showing major internal nasal spaces in mammals. Two major airflow routes are also indicated. The dorsal meatus (DM) is beneath the nasoturbinal (NT); the ventral meatus (VM) is beneath the maxilloturbinal (MT). A cross section just anterior to the transverse lamina (b) shows lateral spaces including the maxillary recess (hidden from view in (a)). Cross section is illustrated after Craven et al. (2007). FR, frontal recess; FS, frontal sinus; FT, frontoturbinal; MT, maxilloturbinal; NPD, nasopharyngeal duct; NT, nasoturbinal; OR, olfactory recess; TL, transverse lamina.

The organization of the canine nasal cavity provides an excellent example of a mammal in which turbinals and spaces can be discussed according to relatively discrete functions (Craven et al., 2007). However, there are departures from this regional specialization in species with proportionally reduced nasal dimensions (Figure 2.1, and

**Table 2.1** Terminology for the bony and cartilaginous structures and recesses of the nasal fossa (based on Smith and Rossie, 2008)

Structure	Homologous Human Structure <sup>1</sup>	Synonyms and Comments
<b>Structures</b>

vomeronasal cartilage		

Spaces	
lateral recess	maxillary recess
anterolateral recess	properly refers to a fetal paranasal space which results in an elongated in fetal human cavity in adults of many mammals (anterolateral and posterolateral recesses); see Rae and Koppe (2003) regarding confusion of this term regarding Old World primates
posterolateral recess	recessus anterior (de Beer, 1937); maxillary sinus (Rowe et al., 2005, see Figure 2.5 therein)
frontal recess	(this is equivalent to both the frontal and maxillary recesses, together - Smith and Rossie, 2008)
maxillary recess	superior maxillary recess (Negus, 1958, p. 313)
olfactory recess	inferior maxillary recess (Negus, 1958, p. 313)
	sphenoethmoidal recess, ethmoturbinal recess (Maier, 1993a, b); cupular recess (Van Gilse, 1927); sphenooidal recess (Loo, 1974)

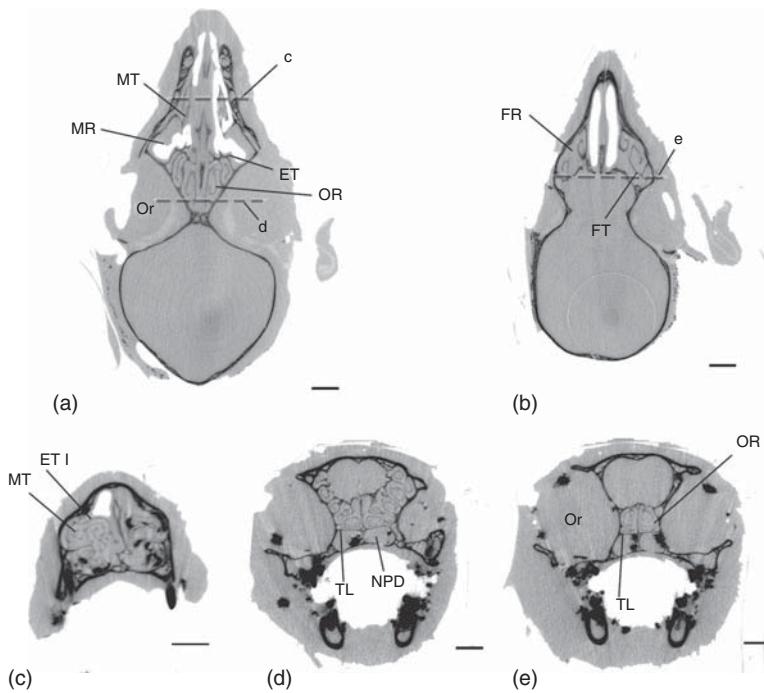

<sup>1</sup>See Moore (1981) and Smith and Rossie (2006, 2008) for further discussion.

<sup>2</sup>NAV (Nomina Anatomica Veterinaria, 2005).

<sup>3</sup>Terms for these evaginations within the nose of terrestrial vertebrates are most commonly termed turbinates or turbinals. But nomenclature is complex and, in some cases, different turbinals have been referred to using the same term (for more detailed accounts, see Moore, 1981; Novacek, 1993; Rowe et al., 2005; Smith and Rossie, 2006, 2008; Smith et al., 2007a; Smith et al., 2011; Macrini, 2012).

<sup>4</sup>Macrini (2012), in a thorough reconsideration of previous studies, notes as many as 18 ethmoturbinals (p. 73, termed “endoturbinals”) have been reported in the monotreme *Tachyglossus*.

<sup>5</sup>The maxillary sinus, technically, results from pneumatic expansion beyond the limits of the fetal maxillary recess in humans.

**Figure 2.4** Micro-CT slices through the nasal region of adult tree shrews (*Tupaia glis*). Horizontal slices are shown in (a) and (b), at more ventral and dorsal levels of the nasal cavity, respectively. (c) a coronal slice through nasal cavity is shown (approximately at the plane indicated in (a)). Here it can be seen that the first ethmoturbinal (ET I) extends far anteriorly, overlapping the maxilloturbinal (MT). (d) a coronal slice showing the nasal cavity at a more posterior level, where the olfactory recess (OR, in (a)) is separated from the nasopharyngeal duct (NPD) by the transverse lamina (TL). (e) a coronal slice showing the olfactory recess at a more anterior level, where the frontal recess and olfactory recess overlap. Scale bars: 2 mm.

see below), and many other mammals have more overlap of these regions than seen in the dog (Figure 2.4).

Major variations in the nasal passages have been documented from the anterior nares to the choanae. For some, adaptive explanations have been proposed. The size and shape of the anterior narial opening correlates with the ecological niche for the species (e.g., slit-like in the camel and in the mouse-tailed bat, *Rhinopoma*, which are denizens of arid environments, and for which respiratory water conservation is crucial). In animals which have a snout or trunk (e.g., elephant, aardvark, ant-eaters, male proboscis monkey, tube-nosed bat), the narial openings are situated at the snout/trunk tip. Posteriorly, the extent to which the vomer divides the posterior nasopharyngeal passages varies. In some mammals there are no choanae; instead a single common nasopharyngeal duct connects the nasal airways to the nasopharynx (Smith et al., 2012). The significance of this anatomy (e.g., to airflow) has yet to be clarified. Structural variation of the lateral nasal wall and paranasal spaces is well-studied, which will be considered further below.

### 2.3.2 Anatomical and Physiological Roles of the Turbinals

The inferolateral margin of the nasal fossa is framed by inwardly scrolled edges of the nasal capsule, the most anterior of which do not ossify. Forming an inferolateral ridge along the anterior naris is the marginoturbinal (Maier, 2000). This turbinal is mobile, owing to insertions of some

muscles of facial expression, and thus can modify airflow. In most mammals, the marginoturbinal forms a continuous ridge with the cartilaginous atrioturbinal in the vestibule. The latter is continuous with the osseous maxilloturbinal in the nasal fossa proper.

Articulating mostly with the maxillary bone, the maxilloturbinal varies from a simple, single scroll (as in the human inferior nasal concha) to a highly branched network of lamellae, with a correspondingly enormous surface area (Negus, 1958; Van Valkenburgh et al., 2004; Figure 2.2c). The maxilloturbinal plays important roles in heat and water conservation and in saturating inspired air before it reaches the lungs. Species with very large maxilloturbinal surface areas (e.g., pinnipeds) often have a great need to conserve both heat and moisture.

Ethmoturbinals are part of the lateral mass of the ethmoid bone. These are rarely branched to the same degree as the maxilloturbinal, but they can be complex nonetheless (e.g., see Macrini, 2012). Ethmoturbinals may vary more in overall number than individual complexity (Cave, 1973; Smith et al., 2007a). The nasoturbinal articulates with the inferior margin of the nasal bone, but also extends posteriorly into the ethmoid complex. In some mammals, the nasoturbinal is a ridge that runs continuously from the anterior nasal fossa to merge posteriorly with ethmoturbinal I. In such cases, the most anterior part may be a glandular swelling, while more posterior parts may ossify from portions of the cartilaginous nasal capsule (see Smith and Rossie, 2008, for more details). To the extent that the nasoturbinal is osseous, the bone itself is part of the ethmoid.

Smaller turbinals are exceedingly variable in number. The frontoturbinals are located within the frontal recess. A thorough reassessment of the number of frontoturbinals is arguably important, because previous work has collectively combined frontoturbinals and other small turbinals according to spatial position away from the midline (i.e., ectoturbinals). Since these are distinguished as elements of the paranasal as opposed to more midline spaces, the frontoturbinals have been argued to receive different air streams, and possibly different odorant types (see below), during inspiration. Interturbinals occur closer to midline spaces. Specifically, one or more interturbinals may be found in the posterior nasal fossa between two adjacent ethmoturbinals (Smith et al., 2011; 2012).

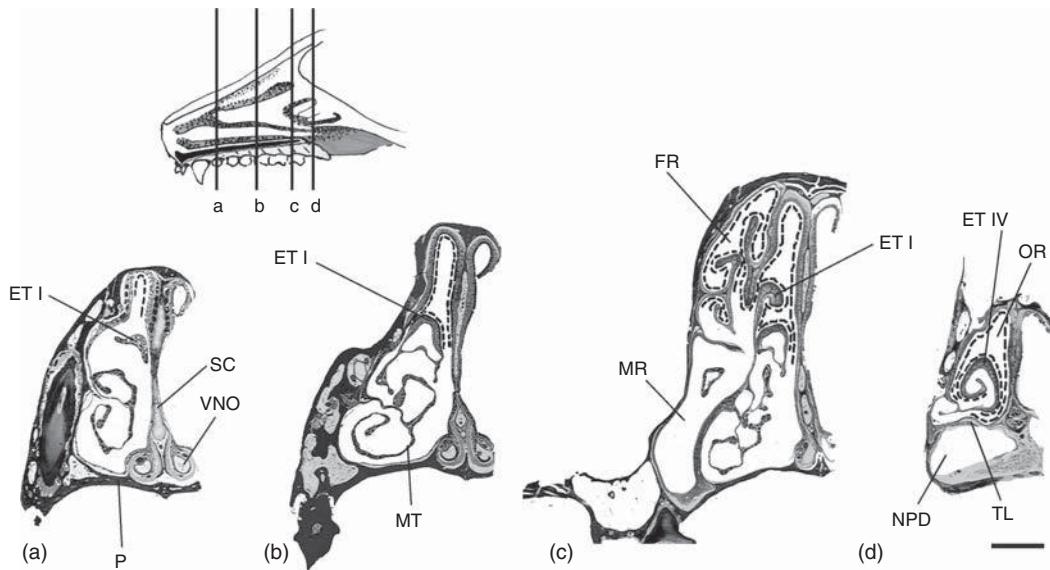

### 2.3.3 Microanatomy

Variations in internal nasal morphology have served as the basis for inferring functional processes, including olfaction and both the warming and humidifying of inspired air. Although the skeletal morphology may be used to infer some physiological specializations (see below), the actual functional anatomy is mostly dictated by the distribution of specific types of nasal epithelia, as well as solitary chemosensory cells that are innervated by the trigeminal nerve (Finger et al., 2003; Ogura et al., 2010). Broadly, the nasal fossa is lined with four types of epithelia: stratified, respiratory, transitional, and olfactory (Harkema et al., 1987; 2006). Stratified epithelium typically lines the vestibule, the floor of the nasal cavity, or the walls of the nasopalatine ducts. Respiratory epithelium is characterized by numerous motile cilia (kinocilia) that propel mucous toward the pharynx. This epithelium also possesses at least four other cell types, such as non-ciliated, goblet (mucous-producing), secretory (small granule), and basal cells (Harkema et al., 1987). Transitional epithelium is a non-stratified type that occurs between stratified squamous and respiratory epithelium, typically as a narrow strip (Harkema et al., 1987; 2006). Additionally, a non-descript, simple epithelium, may be found between the respiratory and olfactory epithelium and in other locations. These epithelia could be termed “junctional epithelia,” as these small patches may only represent transitions, rather than functional types of epithelia. The olfactory epithelium comprises, collectively, the epithelia of the main olfactory system (see Chapter 3), the vomeronasal system (see Chapter 51), and the septal organ of Masera (see Chapter 52). The majority of our discussion concerns the distribution of respiratory and olfactory epithelia, which are the most abundant types that line the nasal cavity proper (Harkema et al., 1987).

Most mammals have an anteriorly situated vestibule just inside the anterior nares. The facial skin (with hair and glands) is reflected within the vestibule. In the nasal

fossa proper, the stratified squamous epithelium lines the floor of the nasal fossa, but respiratory mucosa appears laterally, superiorly, and medially by the level of the maxilloturbinal. Olfactory neuroepithelium may appear first along the roof of the nasal fossa or on the superior margin of ethmoturbinal I (Figure 2.5a). Figure 2.5 shows olfactory and non-olfactory epithelia that are distributed along the boundaries of the nasal fossa at different anteroposterior levels, in the coronal plane. Although all ethmoturbinals bear olfactory neuroepithelium (even the human middle nasal concha may have some – Read, 1908; Leopold et al., 2000; and see discussion in Clerico et al., 2003, regarding variations), the first ethmoturbinal bears a substantial amount of ciliated, non-olfactory neuroepithelium (Smith et al., 2004, 2007b; Rowe et al., 2005; Smith and Rossie, 2008). Thus, to generalize all ethmoturbinals as strictly “olfactory” turbinals (Dieulafe, 1908; Moore, 1981) may be ill advised. Indeed, in some species the first ethmoturbinal and the maxilloturbinal appear to have closely opposed surfaces of respiratory epithelia, implying these structures are collaboratively involved in air conditioning (Figure 2.6). More posterior ethmoturbinals do bear more olfactory surface area, proportionally, compared to ethmoturbinal I (Adams, 1972; Bhatnagar and Kallen, 1975; Smith and Rossie, 2008). In many mammals, one or more of the more posterior ethmoturbinals is sequestered in the olfactory recess, where olfactory neuroepithelium predominates. Below the transverse lamina, the nasopharyngeal ducts are lined with respiratory epithelium.

The septal mucosa matches the lateral wall in terms of superoinferior distribution of mucosa generally (Figure 2.6e). Internally, a specialized chemosensory epithelial organ is found near the base of the nasal septum anteriorly. This structure, the vomeronasal organ (VNO), is present bilaterally and often encapsulated by cartilage or bone (Figure 2.5). In most mammals, the VNO is an epithelial tube lined with two types of epithelia: chemosensory and receptor-free ciliated epithelia (Bhatnagar and Smith, 2007). Teleost fishes do not have a VNO. Their VNO receptors (V1Rs, V2Rs) are expressed in the main olfactory neuroepithelium (Hashiguchi et al., 2008), as may be some of the V2R genes in amphibians (Syed et al., 2013). Amphibians, reptiles and mammals have VNO in numerous stages of development, whereas birds lack it altogether (Halpern and Martínez-Marcos, 2003). The VNO is frequently considered a pheromone-receptor organ, but recent discussion has questioned whether it is truly evolved as such (Baxi et al., 2006) or whether mammals have the equivalent of true pheromonal communication (Doty, 2010). Vomeronasal chemoreception may be multipurpose for sociosexual communication (Powers and Winans, 1975; Wysocki et al., 1991), prey detection (Cooper, 1997), and perhaps even dietary preference (Bhatnagar,

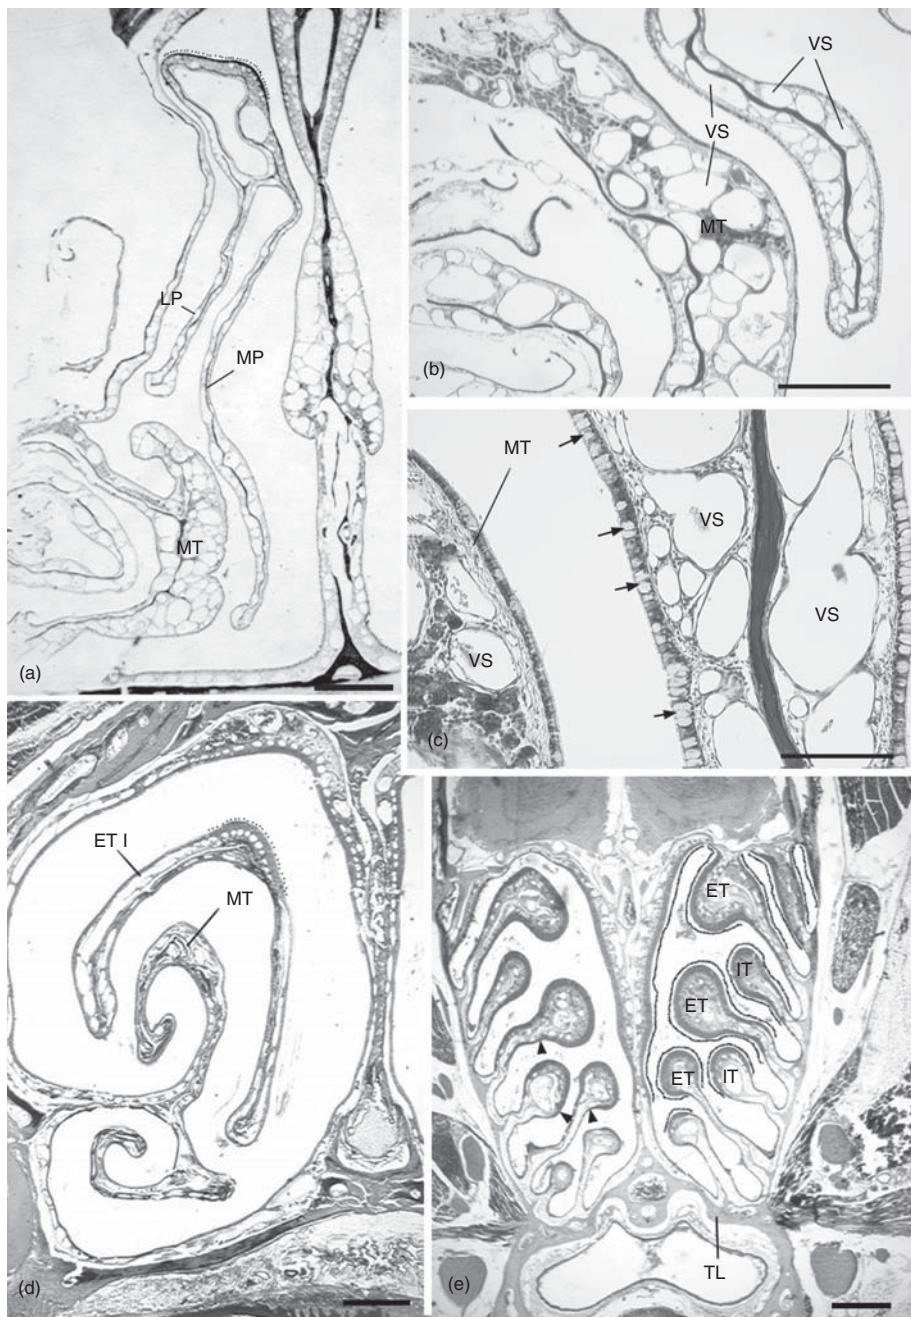

**Figure 2.5** Distribution of respiratory and olfactory epithelia (dashed lines) at four different coronal cross-sectional levels (a through d) in the mouse lemur (*Microcebus murinus*). Modified from Smith et al. (2007a). ET I, ethmoturbinal I; ET IV, ethmoturbinal IV; FR, frontal recess; MR, maxillary recess; MT, maxilloturbinal; NPD, nasopharyngeal duct; OR, olfactory recess; P, osseous palate; SC, septal cartilage; TL, transverse lamina; VNO, vomeronasal organ. Scale bar: 1 mm.

1980; Cooper and Bhatnagar, 1976; Bhatnagar and Kallen, 1974b; Halpern et al., 2005). The VNO receptor epithelium is unlike the olfactory neuroepithelium which presents olfactory cilia, olfactory glands, and other morphological specialties such as a very large number of receptors (which are several thousand times greater in number compared to the VN receptors). The VNO neuroepithelium forms a rather diminutive sensory patch (compared to olfactory neuroepithelium) and has sensory neurons that only project microvilli. Goblet cells may be found in the receptor-free epithelium of the VNO; glands for the VNO are from more distant sources than observed for the olfactory epithelium (the latter having intimately nested Bowman's glands). Vomeronasal nerve bundles (the fila from the vomeronasal (VN) receptors) collect into the VN nerves which reach and ramify in the accessory olfactory bulb. In mammals, ventral septal glands drain into the lumen of the VNO; Smith and Bhatnagar (2009) suggest these glands may not be homologous with "vomeronasal glands" of other vertebrates. The lumen of the VNO itself, in turn, drains into the nasal cavity or the nasopalatine duct through the vomeronasal duct. The VN duct exits anteriorly, quite close to the vestibule in many mammals. In the last several decades, numerous reports have scrutinized a vestige of the human VNO that persists postnatally in humans and perhaps great apes (Johnson et al., 1985; Trotier et al., 2000; Bhatnagar and Smith, 2001; Smith et al., 2002). The most thorough histological studies have categorically demonstrated the absence of a functional VNO neuroepithelium in humans after early

fetal stages (Smith and Bhatnagar, 2000; Trotier et al., 2000; Bhatnagar and Smith, 2001, 2010; Witt et al., 2002).

The SOO has been described as an island of olfactory neuroepithelium in some species (e.g., rodents – Menco and Morrison, 2003; Ma, 2007). This structure has received far less attention than the VNO and MOE, and its distribution throughout mammals is unclear (e.g., it has not been described in primates). This patch of epithelium, spatially anterior to much of the MOE, expresses Olfactory Marker Protein (Weiler and Benali, 2005). In this sense, it possesses olfactory sensory receptor cells, like the VNO and MOE. Overall, Weiler and Benali (2005) consider the SOO more similar to the MOE than VNO in terms of expression of various neuronal markers. This patch of olfactory neurons likely detects chemostimuli that overlap with those perceived by other chemosensory systems (Ma, 2007). More research is needed to establish the extent to which the SOO is distinguished from other olfactory tissues.

Lastly, the nasal mucosa of mammals is traversed by numerous nerves and blood vessels. Nerves include the nervus terminalis, vomeronasal nerve bundles, trigeminal nerve branches, autonomic nerves, and olfactory nerve bundles. Blood vessels to the nasal (and paranasal) mucosae include branches of the sphenopalatine artery (a terminal branch of the maxillary artery), ethmoidal branches of the ophthalmic artery, and the infraorbital artery. Vessels in nasal mucosa also include large venous sinuses. As one of the few examples of erectile tissues in the body, this complex system of arteries and veins

**Figure 2.6** Complementary surfaces of the nasal mucosae on the first ethmoturbinal (ET I) and the maxilloturbinal (MT). (a) The folded ET I of an adult primate (bushbaby) has a descending lateral plate (LP) and medial plate (MP) that closely associate with the MT. Only the dorsal rim ET I has olfactory neuroepithelium (dashed line), while the MP and LP are covered with respiratory epithelium. (b) and (c) Higher magnifications of the MP reveals the MP has a dense array of venous sinuses (VS) in the lamina propria. (d) A similar close association of ET I and MT is seen in a megachiropteran bat (*Megaerops ecaudatus*). (e) The olfactory recess of a bat (*Megaderma lyra*) showing multiple rows of ethmoturbinals (ET) with interturbinals (IT) between them. The transition between olfactory and non-olfactory neuroepithelium is clear even at low magnification (arrow heads, on left). Olfactory neuroepithelium (dashed line) covers the turbinals and septum to approximately the same level ventrally. small arrows, goblet cells; TL, transverse lamina. Scale bars: a, 1 mm; b, 600 µm; c, 150 µm; d, 500 µm; e, 500 µm.

significantly influence the diameter of major sections of the nasal airway (see Chapter 16).

### 2.3.4 Phylogenetic Variations of Internal Nasal Anatomy

Certain specifics about the early form of the nasal fossa in the class Mammalia are difficult to reconstruct, primarily because the delicate anatomy is not pristinely preserved in fossils. It is possible to infer some generalities about the primitive condition by surveying the common nasal

features of extant mammals. Representatives of most extant mammals possess a transverse lamina (Negus, 1958). An extinct mammal from the late Triassic, *Morganucodon*, reportedly possessed a transverse lamina, but earlier mammals likely did not (Kielan-Jaworowska et al., 2004). From this it may be inferred that a likely primitive characteristic of “crown” mammals (the common ancestor of living mammals, and their descendants) is to possess an olfactory recess, in which the posterior-most ethmoturbinals are sequestered.

Among extant species, marsupials have a great complexity of the lateral wall, e.g., with three to seven ethmoturbinals in addition to smaller turbinals (Rowe et al., 2005; Macrini, 2012, 2014). A notable characteristic of the lateral wall in many marsupials is the elaborate folding and branching of the maxilloturbinal and ethmoturbinals, and an obliquely sloping transverse lamina (Macrini, 2012). Extant monotremes have contrasting patterns of olfactory morphology, with the aquatic platypus possessing a relatively reduced complement of turbinals and echidnas possessing a far more complex lateral nasal wall (Ashwell, 2012) and perhaps as many as 18 ethmoturbinals (Paulli, 1900a). Macrini (2012) cautions that as serial homologues, it is difficult to establish equivalency of ethmoturbinals between taxa.

Most placental mammals possess a similar arrangement of turbinals, although the total number of turbinals of the ethmoid bone (including smaller turbinals) may vary greatly (Paulli, 1900a,b,c). Paulli analyzed nasal anatomy in a broad array of mammals and set some of the practices still used in nomenclature, but use of terminology has varied (see discussion by Rowe et al., 2005; Smith and Rossie, 2008; Macrini, 2012, 2014). With recent efforts to clarify (if not standardize) terminology in mind, as well as the incorporation of CT data, a thorough reanalysis of internal nasal anatomy in extant placental mammals is sorely needed. Reviewing the literature, Macrini (2012) notes that placental mammals possess between two and ten ethmoturbinals. Ethmoturbinal I can be tracked developmentally as an important boundary between the nasal cavity proper and paranasal spaces (Maier, 1993a, b; Smith and Rossie, 2008). However, for the remainder of turbinals it is difficult to assess which turbinals are lost in species that have the greatest reduction in turbinals. Conversely, species that possess numerous ethmoturbinals that reach the midline may have a similar or greater number of interturbinals that lie hidden lateral to them (Smith et al., 2012). These interturbinals reflect the multiplicity of the ethmoidal scrolls. The main difference between the interturbinals and the larger ethmoturbinals is the extent of growth. This iterative theme of development in the ethmoid renders species differences much more understandable. The difference between the echidna (18 ethmoturbinals) on the one hand and most other mammals (one to four ethmoturbinals) on the other may be related to the timing and extent of growth of the smaller mesenchymal condensations that form at the lower margins of the nasal capsule (see Macrini, 2014, for a discussion of the implications on turbinal homology).

The extent to which the variation in the number of turbinals relates to olfactory performance is clear in certain comparisons. For example, a comparison of extremes in internal nasal complexity on the one hand (e.g., dogs) and simplicity on the other (e.g., humans) appears to reveal profoundly different special sensory adaptations; this is

largely borne out by other lines of evidence (e.g., olfactory gene repertoire, Quignon et al., 2003). Yet, such stark comparisons do little to reveal how variations in internal nasal form are adaptive. Recent work reveals that even for carnivorans, mammals that rely on turbinals both for being olfactory specialists and for regulating body temperature, variation in turbinal surface area may relate to diet and other ecological variables (Van Valkenburgh et al., 2011, 2014).

Many mammals exhibit some degree of reduction of the turbinals. There are two suggested reasons for such reductions. The first is ecological. Like the platypus, many aquatic forms of placental mammals appear to have reduced olfactory structures relative to terrestrial relatives (Gittleman, 1991; Van Valkenburgh et al., 2011). It is postulated that, for mammals, olfaction is of less utility in aquatic environments (Van Valkenburgh et al., 2011). Certainly the reduction is extreme in cetaceans, mammals that are fully readapted to aquatic life, although some evidence suggests some whales may retain olfactory abilities (Thewissen et al., 2011). Conversely, the maxilloturbinal is relatively enlarged in aquatic mammals (Huntley et al., 1984; Van Valkenburgh et al., 2011). A second idea invokes “competing” functions of nasal structures to explain reductions. The maxilloturbinal, especially important to body temperature regulation in carnivorans (Van Valkenburgh et al., 2004), is enlarged in aquatic environments where body temperature regulation is more challenging. Furthermore, because the nasal surface area is finite within the nasal cavity, selection cannot enlarge one turbinal (e.g., the larger maxilloturbinal in aquatic vertebrates) without taking out potential space for another turbinal (Van Valkenburgh et al., 2011). Van Valkenburgh et al. (2011) present evidence suggesting that the ratios of maxilloturbinals to ethmoturbinals are interdependent, and postulate the existence of an ecological trade-off of turbinal size in aquatic forms.

Two ecological explanations have been put forth to explain olfactory reduction in primate ancestors. One idea, that olfaction is of limited importance in an arboreal habitat (Elliot Smith, 1927; Le Gros Clark, 1959), has been refuted (Cartmill, 1970). A second basis for reduction of nasal structures has also been postulated: an evolutionary trade-off of special senses (see below).

### 2.3.5 Turbins: Their Mucosal Properties and Role in Airflow

Certain generalizations regarding the roles of the turbinals in nasal physiology, derived mainly from rodents and canines, may apply broadly, albeit imprecisely, to mammals as a whole. They provide an example of physiological roles of turbinals that are potentially dichotomous. The maxilloturbinal resides in the ventral air space between

the anterior nares and the nasopharyngeal ducts posteriorly. Most inhaled air passes through the maxilloturbinal (Figure 2.3), which in canines is quite complex and elaborately branched. This air is humidified and warmed before passing to the lower respiratory airways. Mucosal properties in the lower part of the nasal fossa can dictate the extent to which the maxilloturbinal is exposed to airflow. Dilation of blood vessels in the mucosa at the base of the septum (septal swell bodies) blocks air from passing directly through the unobstructed lower part of the inferior meatus, forcing more air to traverse the complicated spaces around the maxilloturbinal (Craven et al., 2007).

During normal respiration, approximately 85–90% of inspired air bypasses the olfactory region and flows ventrally through the nasal cavity of rodents and canids (Kimbell et al. 1997; Craven et al., 2010). However, these animals can increase the percentage of air that reaches the olfactory region by forcefully inhaling air (“sniffing”) (Craven et al. 2010; Kimbell et al., 1997; Yang et al., 2007). Sniffing may allow animals to sample more odorant molecules with each breath, thus aiding olfactory discrimination (Yang et al., 2007). Craven et al. (2010) suggest that this airflow pattern, in which air travels superior to the complex maxilloturbinal, through the dorsal meatus, and to the olfactory recess, may be a characteristic of all macrosmatic species. The arrangement in rodents, canines, and possibly other mammals also leads to prolonged exposure of odorants to the nasal mucosa, for example, during exhalation (Eiting et al., 2014). At least some odorants seem to become entrapped in the olfactory recess and are not washed out during exhalation (Craven et al., 2010; Yang et al., 2007; Youngentob et al., 1987). In contrast, the airflow patterns of humans (and presumably other higher primates) differ significantly from carnivores, ungulates, rodents, and marsupials, all of which possess an olfactory recess.

Another directional influence on inspired air is found in the first ethmoturbinal. Ethmoturbinal I passes diagonally upward from its root, toward the nasal septum. Posteriorly, it typically merges with the nasoturbinal. In doing so, this turbinal divides the nasal fossa into more centralized airflow channels (leading to both the olfactory recess and nasopharyngeal ducts) and lateral (paranasal) spaces (Clancy et al., 1994; Smith et al., 2011). Primitive extant primates, rodents, and many other mammals share this anatomical arrangement. However, airflow in paranasal spaces is poorly understood compared to the main airway, even in well-studied species (Craven et al., 2007). Evidence on the nature of receptivity of the olfactory neuroepithelium indicates these two regions may not detect an identical range of odorant types. In rodents, the olfactory receptor neurons located along more central ethmoturbinals project axons to spatially distinct portions of the main olfactory bulb compared to those along frontoturbinals (Miyamichi et al., 2005). These regions correspond roughly to regions

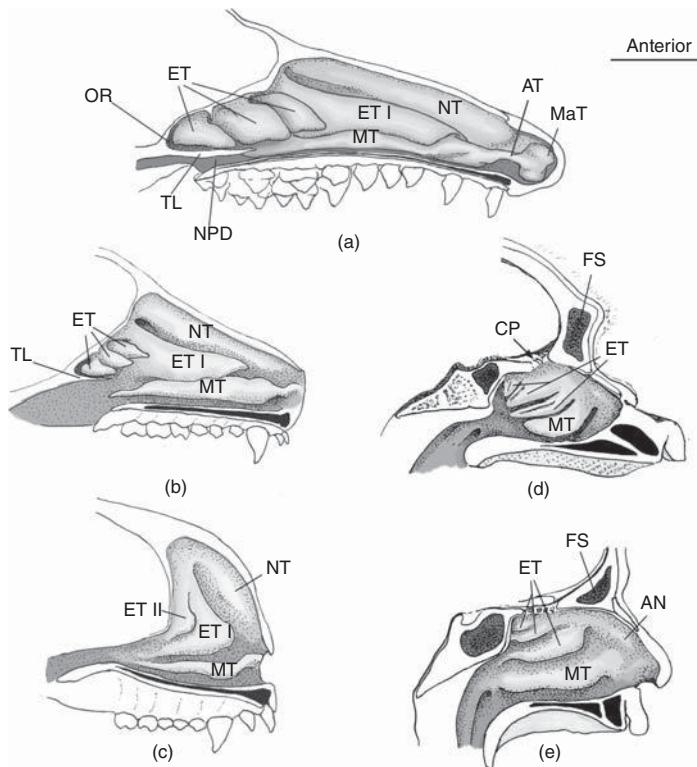

hypothesized to have differences in odorant absorption properties as predicted by computational studies, suggesting a structure-function relationship between airway anatomy and odorant absorption (Schoenfeld and Cleland, 2005; Zhao et al., 2006).

## 2.4 PRIMATE INTERNAL NASAL ANATOMY

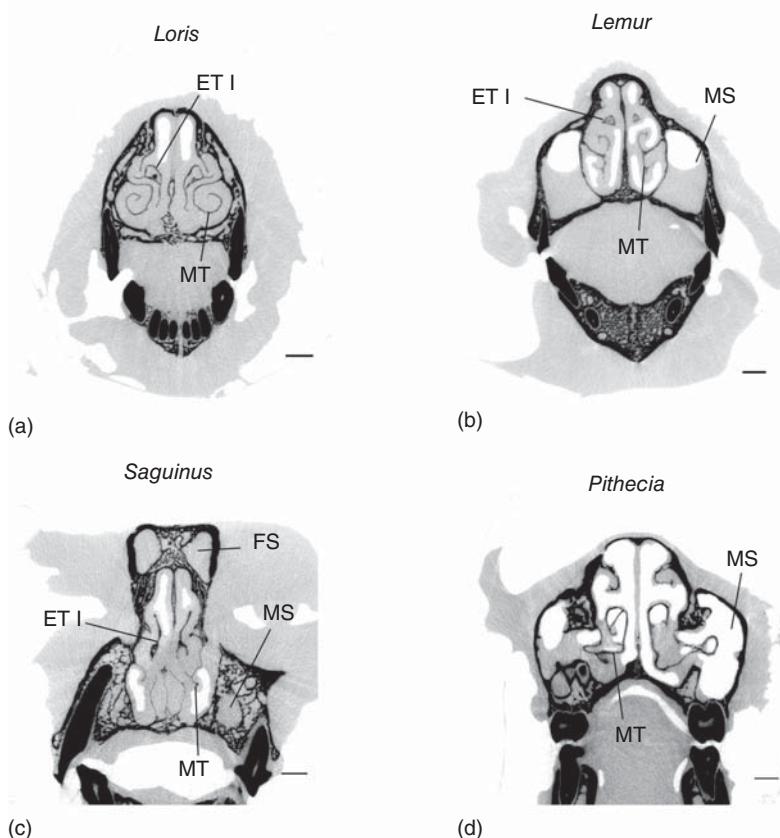

Olfactory anatomy has been described as reduced in the order Primates by some authors (e.g., Elliot Smith, 1927; Cave, 1973). Yet, there is currently no consensus that primates lack a keen sense of smell (Schaal and Porter, 1991; Heymann, 2006; Laska et al., 2000). Behavioral studies, for example, show many “lower” (e.g., lemurs and lorises) and some “higher” primates (e.g., New World monkeys) extensively scent mark (Lewis, 2006; Mertl-Millholen, 2006; Epple et al., 1993). Still, a combination of evidence suggests some primates have a relatively diminished complement of genes as well as morphological structures for olfaction (Liman and Innan, 2003; Gilad et al., 2003; Cave, 1973; Loo, 1974).

The dichotomous arrangement of nasal anatomy in primates is shown in Figures 2.7–2.10. Lemurs and lorises resemble other mammals in possessing an olfactory recess, yet there are also certain distinctions. First, the overlap of ethmoturbinals with other turbinals is quite different in the large lemurids compared to the mouse lemur. Large diurnal or cathemeral lemurids have a somewhat more dog-like arrangement of turbinals compared to nocturnal lemurs and lorises. The ethmoturbinals are more sequestered postero-superiorly, with less spatial overlap of the maxilloturbinal and nasoturbinal.

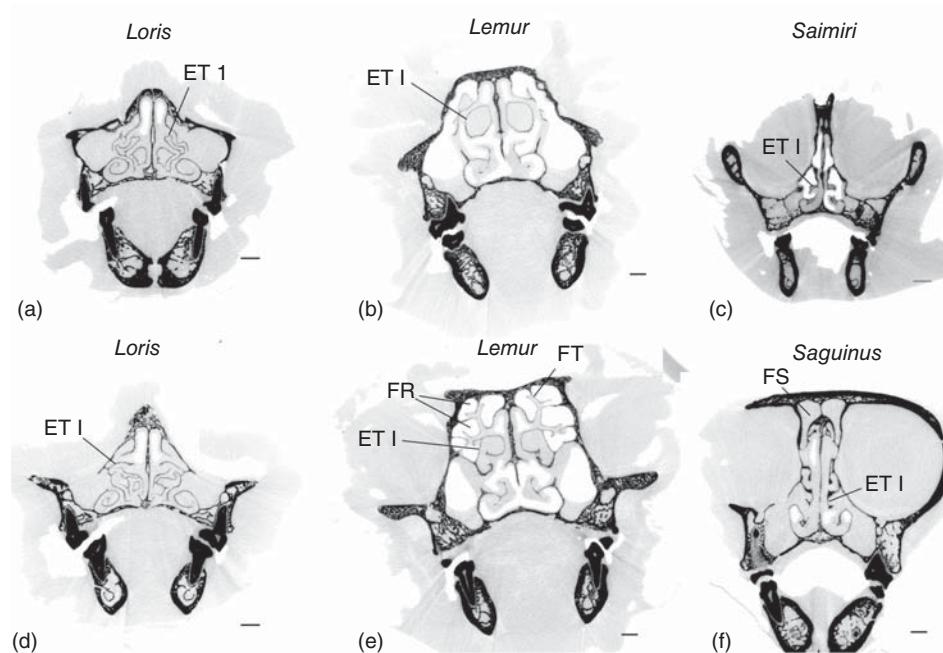

In contrast, the tree shrew and mouse lemur illustrate a somewhat more common arrangement. The first ethmoturbinal is extremely elongated anteriorly, and thus overlaps the maxilloturbinal and nasoturbinal to a great extent (Figures 2.7a,b). The olfactory neuroepithelium projects along the dorsal edge of the first ethmoturbinal, although not to the anterior tip of the turbinal. The portions of the turbinals that descend ventrally are covered, in part, with respiratory epithelium. These laminae overlap the maxilloturbinal, and can be seen to provide complementary surfaces with venous sinuses in the mucosa (Figures 2.6a-c). Based on the available literature, this describes the morphology in all mouse and dwarf lemurs, bushbabies, and lorises (Kollmann and Papin, 1925; Smith et al., 2007b; Figures 2.7b, 2.8a, 2.9a,b). The broad overlap of the ethmoturbinal with the surfaces of other turbinals is therefore common in the most primitive living primates, and could represent a primitive condition. Given that this overlap occurs in tree shrews, at least some megabats (Figures 2.6d,e), and at least some cats (Van Valkenburgh

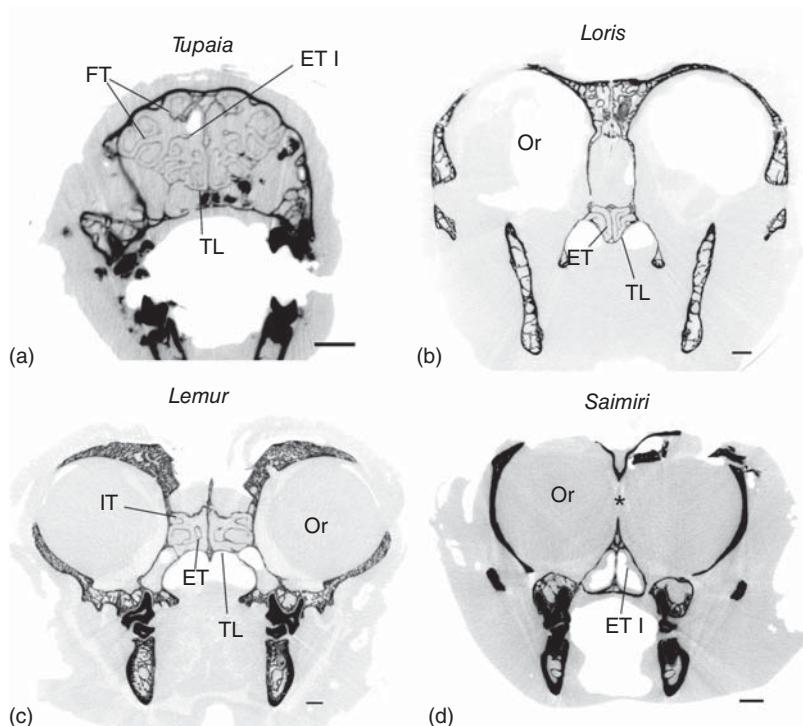

**Figure 2.7** Lateral nasal wall in (a) tree shrew (*Ptilocercus lowii*), (b) mouse lemur (*Microcebus murinus*), (c) monkey (common marmoset, *Callithrix jacchus*), (d) chimpanzee (*Pan troglodytes*), and (e) humans (*Homo sapiens*). A primitive feature retained in lemurs is the presence of a transverse lamina (TL) which separates the olfactory recess (OR) from the nasopharyngeal duct (NPD). However, the transverse lamina of many lemurs (b) does not extend as far anteriorly as in tree shrews (a), which are extant models for many aspects of ancestral primate anatomy. All anthropoids c–e and tarsiers (not shown) lack the transverse lamina and olfactory recess, except as a vestige of the latter. ET, ethmoturbinals; AN, agger nasi; AT, atrioturbinal; ET I, ethmoturbinal I; ET II, ethmoturbinal II; FS, frontal sinus; MaT, marginoturbinal; MT, maxilloturbinal; NT, nasoturbinal. Figure 2.7a is modified after Le Gros Clark (1959) and Wible (2011).

**Figure 2.8** Micro-CT slices of the maxilloturbinal region in primates, showing more primitive nasal form in a loris and lemur (a) and (b) compared to two species of anthropoids (c) and (d). Variation exists in both groups. Nocturnal lemurs and lorises have more elongated first ethmoturbinals (ET I) which extend anterior to the paranasal spaces, and extensively overlap the dorsal surfaces of the maxilloturbinal (MT). Some anthropoids have extremely attenuated midfaces, as in tamarins (e.g., *Saguinus* spp) and many others (including humans). In such cases, the turbinal and paranasal regions are largely coextensive in anteroposterior space. In some other species, especially those with somewhat more pronounced midfaces (or snouts) there is less spatial overlap of maxilloturbinal and ethmoturbinal regions (e.g., *Pithecia*). *Saguinus* has a relatively simple MT with two lamellae. In *Pithecia*, the MT is more extensively folded. Scale bars: a, 4 mm; b; c, 2 mm; d, 3 mm.

**Figure 2.9** Micro-CT slices of the ethmoturbinal region in primates, showing more primitive nasal form in a loris and lemur (a, b, d) and (e) compared to two species of anthropoids (c) and (f). The loris shows continued overlap of first ethmoturbinal (ET I) with the maxilloturbinal (MT). Overall, the central nasal airway is highly packed with turbinals, while the paranasal spaces are markedly reduced compared to the lemur. In the lemur, the interorbital width is greatly expanded and the turbinals are less packed. In addition, the frontal recess (FR) is large, with three frontoturbinals (FT). In some anthropoids the ethmoturbinal region is greatly reduced posteriorly due to enlarged orbits (e.g., *Saimiri*, 8c). Reduction is far less pronounced in the smaller-eyed *Saguinus* (8F). FS, frontal sinus. Scale bars: a, d, 4 mm; b, e, 2 mm; c, f, 3 mm.

**Figure 2.10** Micro-CT slices of the posterior ethmoturbinal region, showing more primitive nasal form in (a) tree shrew, (b) loris and (c) lemur compared to (d) a monkey. In the first three species, the CT slice is at the anterior end of the olfactory recess. The olfactory recess extends farther anteriorly in the tree shrew, enclosing even the posterior end of the first ethmoturbinal (ET I), and overlapping the frontal recess (FT, frontoturbinals). In the loris and lemur only the most posterior ethmoturbinal (ET) is enclosed in the olfactory recess. The ethmoturbinal region may be complicated by the presence of smaller interturbinals (IT) between the larger turbinals. The orbit (Or) of *Saimiri* is so enlarged and convergent (facing forward) that the interorbital region is devoid of bone. A membrane-covered interorbital fenestra (\*) is found between the orbits. Not even a vestige of the olfactory recess is seen. TL, transverse lamina. Scale bars: a, c, d, 4 mm; b, 4 mm.

et al., 2014) the possibility exists that in many mammals the turbinals function collaboratively (see discussion above in Section 2.3.3). This arrangement blurs the roles of ethmoturbinals to a greater degree than is commonly known for so-called “macrosmatic” mammals (e.g., rodents and canines).

The anthropoid pattern, which also applies to the large-eyed Southeast Asian tarsiers, involves a loss of posterosuperior nasal structures. Instead, a more vertically arranged set of turbinals is observed. In all anthropoids, the maxilloturbinal is found most inferiorly, and is the most anteroposteriorly extensive of the turbinals in primates (Figure 2.7). One or two ethmoturbinals are found superiorly and somewhat posteriorly to the maxilloturbinal. The frontoturbinal and the posterior part of the nasoturbinal are absent in many higher primates (some species may possess a nasoturbinal – e.g., *Pithecia*, Figure 2.8). These characteristics describe human nasal anatomy as well (Figure 2.7e). The lateral nasal wall of humans has a very simple, single fold. At least some anthropoids have folded turbinals, or even double scrolls (Figures 2.8c,d).

Overall, the nasal anatomical characteristics of primates appear, at least in gross anatomical terms, to support the notion that there are some taxa that are “microsmatic” and others that are “macrosmatic” (relatively reduced and relatively heightened olfactory abilities, respectively). However, recent literature includes great debate on the topic (see Schaal and Porter, 1991; Laska et al., 2000; Smith and Bhatnagar, 2004; Heymann, 2006). In light of continued disagreement on the importance of olfaction in primates, it is worth discussing existing anatomical evidence that bears on two particular questions regarding extant primates.

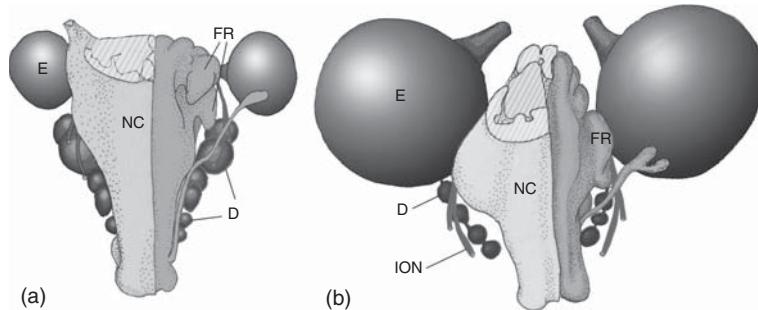

#### **2.4.1 Is Olfactory Reduction a Characteristic of All Primates?**

Epple and Moulton (1978) contrasted olfactory anatomy of various primates to the tree shrew (*Tupaia glis*), a living model that may bear some resemblance to the most distant ancestors of all primates. Their description reflects one common view: that all primates have a reduced nasal (especially olfactory) anatomy; some more than others. They describe the tree shrew as being distinct from primates in having olfactory neuroepithelium covering all of the ethmoturbinals as well as the olfactory recess. Primates are then described to display reductions, with lorises having some reduction of ethmoturbinals (compared to *Tupaia*) and macaques and apes having still more reduction as well as absence of an olfactory recess. Such statements imply a “gradistic” reduction across the order Primates. At the same time, these are generalizations that rely perhaps too strongly on isolated observations of a few taxa; as a result some details may be inaccurate as generalizations whilst others may remain overlooked.

Some evidence supports the claim that even the most primitive living primates (lemurs and lorises) have some degree of nasal reduction. While it has been long known that lemurs and lorises retain more ethmoturbinals than higher primates (Kollmann and Papin, 1925), they are also acknowledged to have some degree of crowding of the interorbital space. This is because in all extant primates, the orbits converge further toward the midline than in other living mammals (Figures 2.10, 2.11). Thus, progressive encroachment of the potential space for nasal structures is postulated as a basis for olfactory reduction (Cartmill, 1970, 1972). Looking very broadly, this is true in a graded fashion: More primitive extant primates have a lesser degree of orbital convergence compared to more specialized anthropoids and tarsiers (Ross, 1995). This explains in great part (though not entirely) why nasal cavities are more capacious in the former.

Quantitative data known for extant mammals do not clearly indicate that lemurs have a lesser percentage of olfactory surface area (SA) compared to other mammals. The lesser mouse lemur (*Microcebus murinus*) has a similar or greater percentage of olfactory mucosa compared to some bats of similar or smaller body size, and to the domestic cat (see review in Smith et al., 2012, 2014). Insectivores, rodents, and the opossum have a considerably greater percentage of olfactory SA, while humans have considerably less (Negus, 1958; Smith et al., 2012). Still, reduction of olfactory anatomy may be subtle. Two regions that are known to be relatively small in some lemurs are the frontal and olfactory recesses (Smith and Rossie, 2008; Smith et al., 2011). For example, the olfactory recess SA comprises only 7% of the total internal nasal SA in *Microcebus*, compared to 31% in a bat of nearly the same body mass (*Megaderma lyra*, Smith et al., 2011, 2012). However, total ethmoturbinal SA is similar in these species, indicating a possible relationship with airflow dynamics but not necessarily the amount of olfactory SA. The frontal recess is 6.5% of the total nasal surface area in the mouse lemur (Smith et al., 2012). Although the frontal recess contributes significantly to total olfactory surface area (20% in the mouse lemur), it appears relatively small compared to some insectivores. Smith and Rossie (2008) attribute this to its closer adjacency to the orbits in mouse lemurs compared to insectivores (Figure 2.11). An analysis of all primates to determine the relative size of the frontal recess would therefore be of great interest. Even among “lower” primates (lemurs, lorises), the relationship between orbital convergence and frontal recess size is likely to be complex, because eye position relative to the snout varies among taxa (Cartmill, 1972).

Thus, existing evidence supports the hypothesis that living primates exhibit some reduction of nasal anatomy. However, the extent to which mucosal surfaces have been reduced as opposed to reorganized is not entirely clear.

**Figure 2.11** Three dimensional reconstruction of the soft tissue structures of the face in a fetal non-primate (a), *Tenrec ecaudatus* and a mouse lemur (b), *Microcebus murinus*, anterior and slightly dorsal view. By stripping away bone, the association of the eyes (E) with interorbital structures is clearer. On the left side of each image, the as-yet unossified nasal capsule (NC) is shown. On the right side, the nasal capsule is stripped away to reveal nasal mucosa. Note the eyes of the lemur are relatively large and somewhat more forward facing (convergent) compared to the non-primate. This has an effect to reorganize the nasal capsule and cavity, shifting the frontal recess (FR) anteriorly. The extent to which primate nasal capsules are reorganized or possibly reduced might now be investigated using micro-CT methods. D, deciduous teeth; ION, infraorbital nerve.

Moreover, Epple and Moulton's (1978) specific suggestion that primates bear less olfactory neuroepithelium in the olfactory recess than tree shrews has not been well tested. Indeed, the contrast in internal architecture is more profound when contrasting the frontal recess anatomy of tree shrews to lorises and lemurs (Figures 2.9–2.10) – which suggests a link between either eye size or convergence and paranasal reduction. Moreover, detailed “maps” and quantitative information of the internal microanatomy, including olfactory surface area, olfactory sensory neuron density, olfactory cilia length, and other parameters are known only for very few primate species (Smith and Bhatnagar, 2004, 2014). Therefore, our ability to know whether some primate species, let alone entire suborders, are microsmatic is limited at this time.

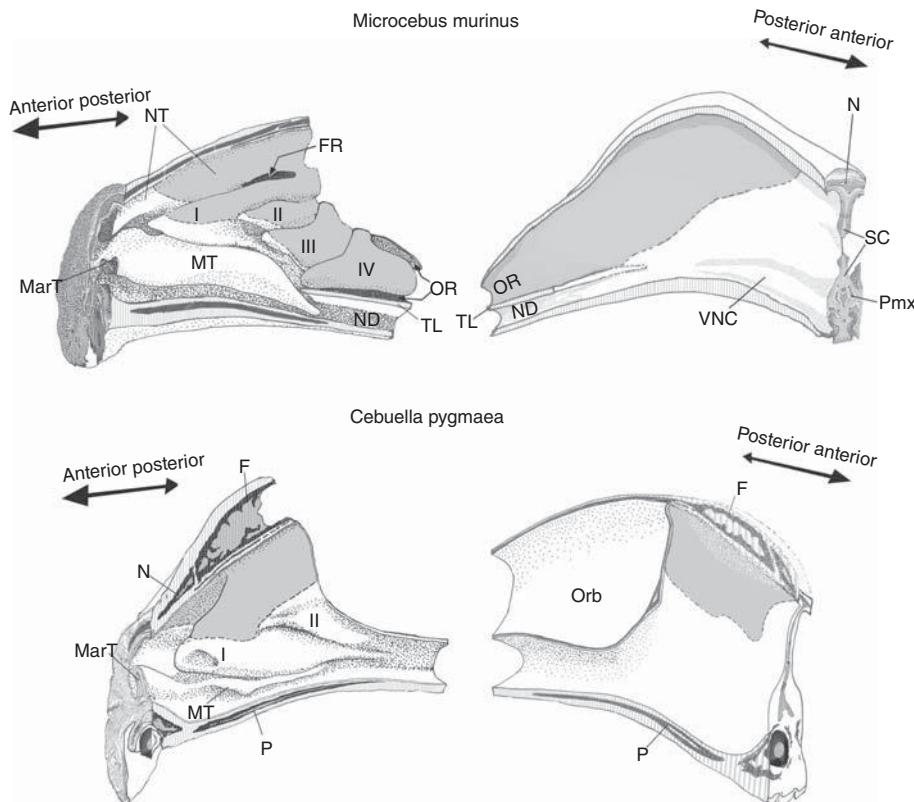

#### 2.4.2 Is Olfactory Reduction a Characteristic of Higher Primates?

In part, the categorization of some mammals as macrosomatic, or “keen-scented” (Negus, 1958; Turner, 1891), has been made as a contrast to our own species – a manner of better understanding our own sensory specializations. We also recognize some similar morphological traits of humans and our closest relatives. “Higher” primates (i.e., anthropoids) are often discussed as being microsmatic, or having reduced olfactory abilities (Elliot Smith, 1927; Cave, 1973; Baron et al., 1983; Martin, 1990; Wako et al., 1999; Gilad et al., 2003). This is based on morphological, physiological, and/or genetic contrasts to relatively “macrosomatic” species (lemurs and lorises). The validity of this view need not be debated again here, as a rather large base of literature from recent years can provide the reader with differing opinions (e.g., Schaal and Porter, 1991; Laska et al., 2000; Gilad et al., 2003; Smith and Bhatnagar, 2004; Heymann, 2006; Smith et al., 2007a; Hepper et al.,

2008). However, recent work clearly establishes that some morphological concepts related to olfactory anatomy are in error. Specifically, the persistently greater “snout” length, on average, in more primitive living primates (lemurs and lorises) compared to higher primates is not by itself an indicator of olfactory reduction. Much of the snout region is lined with respiratory mucosa (Smith et al., 2004; 2007a,b; 2011). Accordingly, a recent text on primate anatomy draws no direct parallel between snout length and olfactory abilities (Ankel-Simons, 2007). Here, we revisit the extent to which a true dichotomy exists between lemurs and lorises compared to higher primates as it pertains to olfactory and frontal recesses.

All anthropoids and tarsiers have extreme reduction of the posterosuperior nasal fossa, the location of the olfactory recess in other mammals. In some anthropoids the interorbital region is so highly approximated that there is only a single midline bony plate, the interorbital septum, or even a partial opening (interorbital fenestra) in which only a membrane separates the orbits (Maier, 1983). Such extreme orbital approximation also occurs in some large-eyed lemurs and lorises, but the resulting interorbital septum is found above the olfactory recess (Cartmill, 1972). In lieu of an olfactory recess, anthropoids may have a small vestige, the *recessus cupularis*, which is devoid of turbinals (Rossie, 2006), but in all cases the result of this extreme approximation is a reduction in ethmoturbinal number. Anthropoids also lack frontoturbinals (Maier and Ruf, 2014).

Few studies have quantitatively studied the nasal mucosa of primates, so it is still unclear to what extent the distribution of olfactory mucosa is reduced (or perhaps redistributed) as a result of this nasal cavity reduction. Qualitatively, several studies suggest that the distribution of olfactory mucosa covers a portion of each of the ethmoturbinals in anthropoids (Wako et al., 1999; Harkema et al., 1987, 2006), including the middle and superior nasal

**Figure 2.12** Three dimensional reconstruction of the nasal mucosa in the smallest lemur (*Microcebus murinus*) and smallest monkey (*Cebuella pygmaea*). Olfactory (shaded) versus non-olfactory (unshaded) surface areas of the lateral nasal wall (left) and nasal septum (right) are shown (*Microcebus* modified from Smith and Rossie, 2008; *Cebuella* from Smith et al., 2014). Note that the absence of the more posterior ethmoturbinals in the monkey corresponds to the close approximation of the orbits. The orbital surface of the ethmoid bone (Orb) is included to emphasize this. I-IV, ethmoturbinals I through IV; F, frontal bone; FR, frontal recess; MarT, marginoturbinal; MT, maxilloturbinal; N, nasal bone; ND, nasopharyngeal duct; NT, nasoturbinal; OR, olfactory recess; SC, septal cartilage; TL, transverse lamina; VNC, bulge of vomeronasal cartilage.

concha of humans (Read, 1908). Only recently have detailed “maps” of mucosa distribution been produced in a lemur. Figure 2.12 shows the distribution of olfactory mucosa in the world’s smallest lemur and monkey. The absence of an olfactory recess in the monkey is readily related to the approximation of the eyes toward the midline. The orbit wall appears posterosuperiorly along the septum, and on the contralateral side it may be inferred that the orbit obliterates the space occupied by the olfactory recess in the mouse lemur. Although the morphological differences are extreme and loss of more posterior ethmoturbinals in the monkey is clear, there are two respects in which these differences reflect reorganization (rather than loss) of mucosal SA. First, while the lemur has a dedicated respiratory passageway beneath the olfactory recess (the nasopharyngeal ducts), in the monkey the ethmoturbinals simply end in the nasopharyngeal meatus (albeit with non-olfactory SA). Second, olfactory SA appears to be distributed somewhat more anteriorly in the monkey compared to the mouse lemur (see also Smith et al., 2004, 2014).

In summary, it is beyond dispute that the humans and other anthropoids have reduced or eliminated certain olfactory regions of the nasal airway (olfactory recess, frontal recess), probably in connection with encroachment by the orbits (Maier and Ruf, 2014). The functional consequences of this reduction are unclear. Indeed, since our understanding of how morphology relates directly to airflow is based

on very few species of mammals (e.g., see Schoenfeld and Cleland, 2005; Zhao and Dalton, 2007), the significance of regional reduction or reorganization are presently hard to assess.

## 2.5 CONCLUSIONS

The internal nasal airway of mammals is a morphologically complex space that reflects the developmental constraints and functional necessities of the mid-facial region. This chapter has reviewed mammalian nasal anatomy to provide a context for understanding our own, rather unusual nasal form. In brief, our major differences in nasal anatomy compared to other mammals may be related, in part, to 1) some degree of olfactory reduction in our own Infraorder (Anthropoidea) compared to most other mammals and some other primates; 2) different nasal adaptations to climate, perhaps due to an alternative means of body temperature regulation (e.g., skin cooling).

A broad comparative understanding of internal nasal anatomy has remained elusive, in part due to the difficulty in exposing and gathering data on the delicate internal nasal region. In addition, our understanding of quantitative aspects of the nasal mucosae in different mammals has progressed slowly over the past five decades, which have for a long time been limited to a comparison of humans

to several domestic animals (Negus, 1958; Moulton and Beidler, 1967). Still, recent work shows that modern methods such as computed tomography (CT) hold immense promise as tools to uncover adaptive morphological patterns in internal nasal structure (Van Valkenburgh et al., 2004, 2011). The combination of CT with knowledge of microanatomical variations (e.g., epithelial surface areas) across mammals may prove an especially powerful research method (Rowe et al., 2005, Smith et al., 2011). One pattern is already clear: not all “macrosmatic” mammals are alike (Stöbel et al., 2010). If that term is used too broadly, we may lose sight of variations among mammals that may pertain to ecology, either directly (e.g., dietary correlates of turbinal surface area) or indirectly (e.g., airflow patterns) (Van Valkenburgh et al., 2011; Gross et al., 1982).

Some authors use the term macrosmatic in a very narrow sense, to refer to carnivores, ungulates, and rodents (Craven et al., 2007); a very restrictive use of this term is wise. These and perhaps a few other mammals may be the original basis for some morphological generalizations (e.g., “olfactory” and “respiratory” turbinals), which are not equally applicable to all mammals. This knowledge offers insight into our own species’ nasal evolutionary history. None of our closest extant relatives bear a very close similarity to noted olfactory specialists, such as the canids. Many nocturnal lemurs and lorises have vastly overlapping surfaces of ethmoturbinals, nasoturbinal, and maxilloturbinal. This condition is common in other mammals, including many bats (Smith, unpublished observations) and the tree shrew (Wible, 2011; note that Scandentia (tree shrews) and Primates are two of the three extant orders comprising the clade Euarchonta). As such, this is quite possibly the ancestral appearance from which anthropoids (such as ourselves) and their allies evolved. Much more work is needed to understand how turbinals may work collaboratively, via overlapping complementary mucosal types. In tandem with the need for a more detailed appreciation of comparative microanatomy of the mammalian nasal boundaries, a broader understanding of airflow patterns in mammals with differently organized nasal airways is essential. In this broad context, we may more fully understand our own nasal airflow dynamics (see Chapter 16), olfactory anatomy, and olfactory abilities.

## A2.1 SOME TECHNIQUES FOR STUDYING THE NASAL PASSAGEWAYS

A full appreciation of this topic can be reached by consulting bibliographies of scholarly writings of Charles Evans, Richard L. Doty, Charles Wysocki, Mimi Halpern and

others. See also Simon and Nicolelis (2001) *Methods in Chemosensory Research*. CRC Press, Boca Raton, 328 pp.

- 1. GROSS EXAMINATION:** The entire head of the specimen is partially decalcified; the anterior nasal segment (posterior to the cribriform plate) is then bisected a bit lateral to the nasal septum, thus separating the right and left nasal fossae. Using a dissecting microscope, the minute internal anatomy of the structures therein (such as various turbinals) is examined. We have found formic acid decalcifier (see Bhatnagar and Kallen, 1974a for details) to be very safe for the delicate nasal parts.
- 2. ENDOCASTS:** Some delicate nasal and related cranial anatomy has been successfully studied by creating endocasts using elastic molding material. The cribriform plate was studied in this way by Pihlström et al. (2005), although computerized reconstructions are a more recent option (Bird et al., 2014).
- 3. IN VITRO STAINING** of the bones and cartilages using Alizarin Red S, toluidine blue, and other procedures.
- 4. PREPARATION OF THE ENTIRE NASAL SEPTUM** to study the Vomeronasal organ, VN nerves, Nervus terminalis, ganglionic structures, and glands (see, Bojsen-Møller, 1975).
- 5. EMBRYONIC (DEVELOPMENTAL) studies in staged embryos** (Müller and O’Rahilly, 2004).
- 6. HISTO-MORPHOLOGY:** The entire head, specifically the anterior nasal segment, is prepared for 10 µm thick serial sections. Depending on the size, the head is generally first decalcified, then divided into three parts: anterior, middle, and posterior cranium. This is to allow maximum paraffin infiltration. Further decalcification, processing through paraffin (Cellosolve or other media) under vacuum leading to complete serial section series. Ten-micron thick serial sections are recommended to allow morphometric studies of the neuronal nuclei. Generally every fifth serial section is arranged on glass slides; the remaining sections are saved. A trichrome stain (e.g., Gomori one-step) works brilliantly in well-preserved (embalmed) specimens (see Bhatnagar and Kallen, 1974a; Bhatnagar and Smith, 2007). Results from a study from such carefully prepared serial series cannot be overemphasized.
- 7. IMAGE-ADVANCED, MICRO-CT studies, computer reconstruction techniques.** Comparative anatomy of the internal nasal region has been notoriously difficult to study, except through destructive means (e.g., Allen, 1882; Paulli, 1900a,b,c; Cave, 1973). The availability of non-destructive imaging methods, such as micro-computed tomography (CT),

has made nasal anatomy far more accessible (e.g., Van Valkenburgh et al., 2004, 2011; Rowe et al., 2005; Rossie, 2006; Macrini, 2012). Various software programs are used in conjunction with micro-CT to reconstruct and quantify delicate nasal structures (e.g., see Rossie, 2006; Van Valkenburgh et al., 2014). Histology and micro-CT can be co-registered to enhance imaging of bone with soft tissue information (Rehorek and Smith, 2007; DeLeon and Smith, 2014).

- 8. SCANNING, TRANSMISSION, AND CONFOCAL MICROSCOPIC STUDY** of tissues obtained by dissection (after intracardiac perfusion with EM fixatives).
- 9. ELECTRO-OLFACTOGRAMS, VOMERONASOGRAMS, AND ELECTRODE IMPLANTING STUDIES.** See review by Scott and Scott-Johnson, 2002).
- 10. ETHOLOGICAL STUDIES OF FLEHMEN** (see Estes, 1972).
- 11. PARASITOLOGICAL EXAMINATION OF THE NASAL EPITHELIA** (see, Lichtenfels et al., 1981).
- 12. MOLECULAR GENE RECEPTOR STUDIES, UPTAKE OF RECEPTORS** (Bannister and Dodson, 1992, and autoradiographic studies).
- 13. EXPERIMENTAL PROTOCOLS:** An understanding of the “division of labor” among olfactory systems was achieved in great part through nerve ablation studies (e.g., Powers and Winans, 1975).
- 14. IMMUNOREACTIVE STUDIES:** Our understanding of functional capacity of the human vomeronasal organ was achieved, in part, through immunohistochemical studies that showed only few cells that express neuronal markers (e.g., Witt et al., 2002), in contrast to other primate (Dennis et al., 2004). More broadly, all olfactory epithelia express a Olfactory Marker Protein (Weiler and Benali, 2005).
- 15. ARTIFICIAL (ELECTRONIC) NOSES:** The first artificial-nose system was reported by Persaud and Dodd (1982). Since then sensory designs have been progressively updated and refined. The e-noses generally have three main components: a vapor-delivery system, a sensory array, and a pattern-recognition algorithm (also see Walt et al., 2012).
- 16. AIRFLOW MEASUREMENTS THROUGH THE NASAL PASSAGES.** The olfactory and respiratory epithelium directly and intimately react with the passing air currents serving olfaction, warming of the internal *milieu* and other functions (see discussion in Craven et al., 2007, 2010; Hillenius, 1992). Note: the VNO is not directly involved with the incoming or outgoing air currents (see Brunner, 1914; Hillenius and Rehorek, 2005).

## Olfactory Mucosa: Composition, Enzymatic Localization, and Metabolism

XINXIN DING and FANG XIE

### 3.1 INTRODUCTION

The olfactory mucosa, as well as the nasal respiratory mucosa, has a very high metabolic capacity for endogenous and exogenous, or xenobiotic, substrates. Olfactory tissue also has a high degree of inflammatory and immune responsiveness stimulated by contact with foreign substances, exfoliates in response to toxic insults, and regenerates to varying degrees following this exfoliation. The olfactory epithelium (OE) is distinctive in containing the only recognized mammalian neurons that regenerate from precursor basal cells. In addition, these neurons are unique in contacting the external environment with their dendritic processes while the axonal processes of the same cells synapse within the central nervous system (CNS) in the olfactory bulbs. The olfactory mucosa, therefore, represents a tissue where interactions are continually occurring between external stimuli and various physiological processes, including biotransformation, mucus secretion, immune responses, neural signaling, and cell differentiation, development, and death. This chapter examines the basic structure and cell types of the olfactory mucosa and then focuses primarily on the enzymatic capacity of this tissue. The anatomic characteristics generally common to all species are outlined and followed by a brief discussion of interspecies variability in the magnitude, localization, or occurrence of these characteristics. The identity and localization of nasal enzymes and their metabolic capacities are compared across several species. Finally, the potential for these enzymes to modulate the toxicity of xenobiotics and to

influence tissue function, including homeostasis and odor signal detection, is discussed.

This chapter is not a review of all enzymes detected in nasal tissues. A number of review articles on various biotransformation enzymes detected in nasal tissues, their localization, regulation, and substrates, or the specific toxic effects that they are thought to mediate, have been published, including Dahl and Hadley (1991), Ding and Coon (1993), Thornton-Manning and Dahl (1997), Ding and Kaminsky (2003), Jeffrey et al. (2006), Harkema et al. (2006); and, Watelet et al. (2009). This chapter describes the complexity in the composition and regulation of the major known biotransformation enzymes in the olfactory mucosa. Additionally, it discusses various physiological and pathological processes in which nasal metabolic activity is thought to play a role, providing the reader with a framework in which to incorporate enzyme-specific information and relevant sources for a more detailed examination of specific questions. In many cases, data on nasal metabolism have been obtained from whole tissue homogenates, making it impossible to determine the relative contributions of epithelial or subepithelial enzymes, or olfactory versus respiratory mucosa. Because the olfactory mucosa occupies the most caudal region of the nose, metabolism in other nasal regions or in nasal glands can affect olfactory function as well. Therefore, data from nasal homogenates are also discussed and noted as such.

### 3.2 ANATOMY OF THE NASAL CAVITY

To understand the contribution of metabolism in the olfactory mucosa, it is necessary to understand its relationship to other nasal tissues. Before reaching the olfactory mucosa, inhaled air comes in contact with three other epithelial types in the nasal cavity: squamous, transitional, and respiratory. These epithelial regions differ in their metabolic capacities, but metabolism in these tissues can alter the chemical composition of inhaled toxicants before they reach the olfactory mucosa.

The anterior vestibule of the nasal cavity is lined with a stratified squamous epithelium. Although enzymes primarily involved in metabolism of endogenous substrates such as alkaline phosphatase and gamma glutamyl peptidase have been localized to squamous epithelium (Randall et al., 1987), this epithelium has not been reported to have significant xenobiotic-metabolizing capacity. The squamous epithelium has neither secretory capacity nor cilia. The squamous epithelium gives way, in some species, to a narrow region of transitional epithelium, which is a cuboidal, nonciliated epithelium that has a high metabolic capacity for substrates of specific cytochrome P450 (P450 or CYP) enzymes (Bond et al., 1988). This transitional epithelium often displays metaplastic changes in response to toxicants. For example, chronic exposure to ozone results in a metaplastic change of the transitional epithelium to secretory, respiratory epithelium, and cigarette smoke exposure produces squamous metaplasia in this region (Harkema, 1990).

Continuing in a caudal direction, the nasal cavity is lined by a respiratory mucosa consisting of an epithelium made up of ciliated cells and mucous-secreting goblet cells. Underlying this epithelium are subepithelial glands that produce the majority of serous secretions in the nose. The respiratory mucosa plays the major role in both production of nasal secretions and clearance of inhaled materials. This epithelium contains ciliated cells that are responsible for movement of the mucous layer through the nasal cavity as well as secretory goblet cells that produce and secrete mucus. The respiratory epithelium is underlaid by subepithelial glands, which also secrete mucus to the mucous layer. High metabolic capacity is found in the respiratory mucosa as well.

The most dorsal and caudal region of the nasal cavity is lined by the olfactory mucosa. The surface area of this mucosa is greatly enhanced by a convoluted turbinate structure, which varies greatly across species (Harkema et al., 2006). The olfactory mucosa is composed of the OE lining the nasal cavity and separated from the underlying lamina propria by the basal lamina (Figure 3.1).

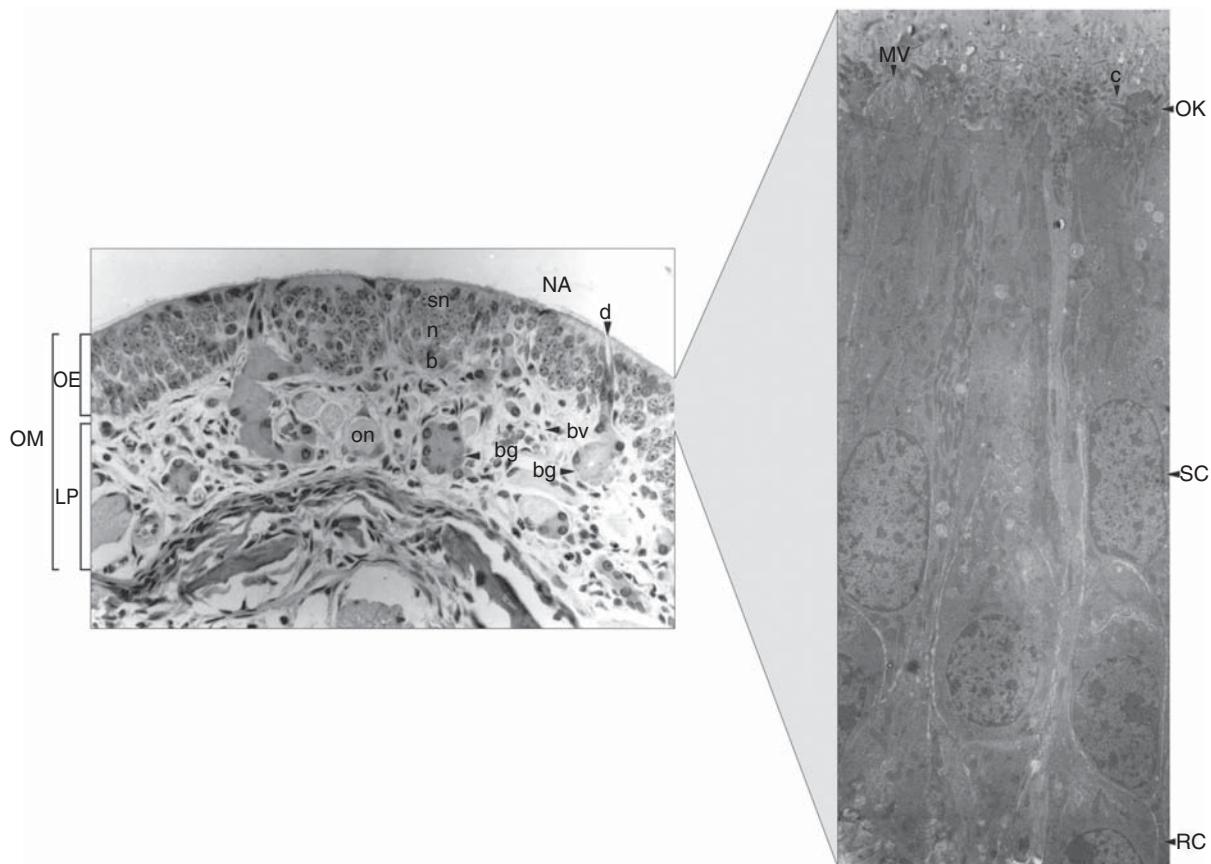

### 3.3 COMPOSITION OF THE OLFACTORY MUCOSA

The following is a brief, general description of the olfactory mucosa discussing primarily those elements common to most species. For more details, the reader is referred to the following reviews: for general nasal and olfactory tissue anatomy—Sorokin (1988) and Uraih and Maronpot (1990); for comparative anatomy – Reznik (1990); and for *human* olfactory anatomy – Chapters 2 and 4 in this volume, as well as a recent immunohistochemical characterization of human olfactory mucosa using a comprehensive series of marker antibodies (Holbrook et al., 2011).

#### 3.3.1 Epithelial Cell Types

The OE is made up of four primary cell types: the olfactory receptor cells; the sustentacular or supporting cells; the basal cells; and the duct cells of Bowman's glands (Figure 3.1). Cilia containing the olfactory receptors project from the receptor cells into the mucous layer lining the nasal cavity. These cells are unique in two respects: (1) they project directly into the brain before their first synapse, which makes them the only cells directly contacting both the CNS and the external environment; and (2) in contrast to almost all other neuronal cells, olfactory receptor cells regenerate from basal cells after damage (Graziadei and Monti-Graziadei, 1983; Huard et al., 1998; Jang et al., 2003; Leung et al., 2007; Iwai et al., 2008). The cilia on the receptor cells are nonmotile. The ciliary membrane has unique properties; the contents of cardiolipin and phosphatidylethanolamine in an enriched porcine cilia preparation are lower than in lipid extracted from the whole olfactory mucosa, and sulfoglycosphingolipids are detected only in the ciliary membrane but not in the whole olfactory mucosa lipid extract (Lobasso et al., 2010). It remains to be determined whether these unique membrane properties are required for optimal functioning of the odorant receptors.

The olfactory receptor neurons (ORNs) generally have very little xenobiotic-metabolizing capacity. The majority of xenobiotic-metabolizing enzymes in the OE have been localized to the sustentacular cells, the duct cells of Bowman's glands, and the progenitor basal cells. Sustentacular cells have secretory functions in some species (Getchell et al., 1988; Zielinski et al., 1988), but generally are not the primary source of the seromucous secretions covering the olfactory epithelium. The microvilli of sustentacular cells contain a transporter protein named low density lipoprotein receptor (also named megalin), which seems to provide a local mechanism for rapid clearance of hydrophobic odorants, by mediating internalization of complexes of odorant-binding proteins (OBP) and odorants/xenobiotics into lysosomes within sustentacular cells (Strotmann and Breer, 2011).

**Figure 3.1** Cellular anatomy of the olfactory mucosa. The left panel shows a transverse section in the region of the ethmoturbinates of an adult rat. Tissues on the luminal side of the basal lamina compose the olfactory epithelium (OE), and tissue inferior to the basal lamina forms the lamina propria (LP). The two layers are included in the olfactory mucosa (OM). Structures identified include sustentacular cell nuclei (*sn*), olfactory neuronal cells (*n*), basal cells (*b*), olfactory nerve bundles (*on*), Bowman's glands (*bg*), Bowman's gland ducts (*d*), blood vessels (*bv*), and nasal airway (NA). [5 µm paraffin embedded sections stained with hematoxylin and eosin; approximately x 250 (Modified from Gu et al., 1997)]. The right panel shows a transmission electron micrograph of the olfactory epithelial surface of an adult rat (Approximately x 3500). The structures identified are olfactory receptor cells (RC); olfactory dendritic knobs (OK); cilia of receptor neurons (C); sustentacular (or supporting) cells (SC), and microvilli (MV) at the luminal surface of supporting cells.

### 3.3.2 Subepithelial Structure

The lamina propria consists of the acinar cells of Bowman's glands, olfactory nerves and their associated Schwann cells, blood vessels, lymphatic vessels, and connective tissue. Because this tissue is so often exposed to inhaled foreign substances, cells associated with inflammation and immunity – including neutrophils, plasma cells, monocytes, and macrophages – often are present within the submucosa and epithelium.

**3.3.2.1 Bowman's Glands.** These subepithelial glands are the primary source of mucous and serous secretions in the olfactory mucosa. The acinar and duct cells of Bowman's glands contain many xenobiotic-metabolizing enzymes, although this localization is species dependent. In some cases, there is evidence that these enzymes are

secreted, again depending on the species (Bogdanffy et al., 1987; Chen et al., 1992; Lewis et al., 1992a). However, whether the secretion is from Bowman's glands or from sustentacular cells has not been determined. Secretory glands from the more anterior part of the nasal cavity may also contribute to the mucus content in the olfactory region; the complex structure and cellular compositions of these glands in the lamina propria of the human anterior middle nasal turbinate have been described (Tandler et al., 2000).

**3.3.2.2 Blood Vessels and Lymphatic Vessels.** The highly vascularized lamina propria in the olfactory mucosa is supplied by the ethmoidal artery, a source distinct from the sphenopalatine supply of the respiratory mucosa. In mice, the blood flow through the total nasal mucosa has been estimated at 0.87% of cardiac output

(Stott et al., 1983); and in rats, 0.32 ml/min (Morris and Cavanagh, 1986), or 0.53% of cardiac output (Stott et al., 1983). The high perfusion rates in nasal tissues allow for rapid absorption and systemic distribution of substances that penetrate the olfactory epithelium. Conversely, this high perfusion can also allow toxicants in the bloodstream to come in contact with xenobiotic-metabolizing enzymes in the olfactory mucosa. Therefore, because of the high metabolic capacity for xenobiotics, the olfactory mucosa can show significant tissue damage following even systemic administration of toxicants that require metabolic activation. Examples of this are discussed in Section 3.5.

The nasal mucosa also contains a network of lymphatic vessels, which, in addition to their normal functions in transporting fluids, lymphocytes, and antibodies, may also contribute to the transport of xenobiotics to or from the nasal cavity. In normal human nasal mucosa and sinus mucosa, the lymphatic vessels are located in the superficial layer of the submucosa, arranged in a network consisting of antler-like branches and blind ends, but not lymphangion chains (Kim et al., 2007).

### 3.3.3 Secretions of the Olfactory Mucosa

Acinar cells of Bowman's glands and, in some species, sustentacular cells secrete acidic, sulfated, or neutral mucopolysaccharides, the percentage of each depending on the species and specific physiological, neuronal, and environmental conditions. The distribution of different carbohydrate residues in the mucociliary complex is not homogeneous (Getchell et al., 1993b; Berger et al., 2005). Human nasal secretions contain immune factors including IgA, IgM, and IgG (Kaliner, 1991). Secretory component and J chain have been localized to acinar and duct cells of Bowman's glands, as well as the mucociliary apparatus in the human olfactory mucosa (Mellert et al., 1992). Other components of mucus thought to play a defensive role include the antimicrobial proteins lysozyme and lactoferrin (Mellert et al., 1992; Mullol et al., 1992), enzymatic constituents, including aminopeptidases, endopeptidases, carboxypeptidases, angiotensin-converting enzyme, peroxidase, and kallikrein (Kaliner, 1991; Ohkubo et al., 1998), and a number of antioxidants (Cross et al., 1994), such as reduced glutathione (GSH), mucin, and an abundant, thiol-specific antioxidant protein belonging to the mono-cysteine subfamily of peroxiredoxins (Novoselov et al., 1999). Nasal mucus also contains regulatory proteins and peptides, including secretory leukoprotease inhibitor (Lee et al., 1993), substance P, vasoactive intestinal peptide (Chaen et al., 1993), adrenomedullin (Fujikura and Okubo, 2011), antimicrobial peptides such as psoriasin (Laudien et al., 2011), and insulin-like growth factor-I and its binding proteins (Federico et al., 1999), as well as transport

proteins such as OBP (Pelosi, 1996; Badonnel et al., 2009), salivary androgen binding protein (sABP) (Zhou et al., 2011), and vomeromodulin (Krishna et al., 1995b).

The concentrations of ions and proteins in the nasal mucus are influenced by rates of water loss to evaporation and rates of replenishment; the latter are partly controlled by aquaporins, which are water channel proteins, expressed in the supporting cells and basal cells in the OE and in secretory acinar cells and duct cells in the Bowman's glands (Ablimit et al., 2006; Solbu and Holen, 2012). Nasal secretion may be controlled by nerve stimulation (Revington et al., 1997) and by corticosteroids (Fong et al., 1999). The latter, via mineralocorticoid receptors in supporting cells and Bowman's glands (Robinson et al., 1999), may modulate olfactory  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase and active ion transport, which results in hyperosmolarity of mucus with respect to serum, as well as secretion of water. In mouse anterior nasal glands and lateral nasal glands (LNG), mucus secretion is mainly mediated by receptors for inositol 1,4,5-trisphosphate (IP<sub>3</sub>R2 and IP<sub>3</sub>R3); genetic ablation of these receptors leads to large decreases in secretion of fluid and protein from LNG acinar cells, nasal inflammation, and increases in detection threshold for odorants (Fukuda et al., 2008). Nasal secretion can also be regulated by nutritional cues. The secretion of OBPs, which function as scavengers of reactive oxidants (Grolli et al., 2006), as well as odorant transporters and possibly facilitator for odorant binding to their olfactory receptors (Hajjar et al., 2006), can be upregulated in the olfactory mucosa by food deprivation or by exposure to leptin, a satiety hormone (Badonnel et al., 2009).

The composition as well as quantity of nasal secretions can change dramatically with inflammation, disease, or toxicant exposure (Harkema et al., 1988; Corps et al., 2010). For example, cigarette smoke, antigens, and diethyl ether cause leakage of macromolecules and small ions into the mucous layer (Morgan et al., 1986). The levels of growth factors and neuropeptides in the mucus also change in pathological conditions (Chaen et al., 1993; Federico et al., 1999). The concentration of adrenomedullin, a vasodilatory and anti-inflammatory peptide produced by mast cells in the nasal mucosa, is lower in the nasal discharge of patients with allergic rhinitis than in the nasal discharge of non-allergic patients (Fujikura and Okubo, 2011); whereas the levels of lipids with antimicrobial properties were higher in maxillary sinus secretions from patients with chronic rhinosinusitis when compared with those without the disease (Lee et al., 2010). Finally, the levels of signaling cyclic nucleotides, cAMP and cGMP, are decreased in nasal mucus from patients with impaired taste and smell functions (Henkin and Velicu, 2008).

The cilia on respiratory epithelial cells move mucus over the surface of the epithelium to produce mucociliary clearance of environmental airway contaminants. However,

the OE does not contain beating cilia and therefore must rely on the movement and flow created by the cilia in the respiratory epithelium for clearance. As is the case with mucous composition, the efficacy of ciliary beating can be altered by toxicant exposure or disease (e.g., Morgan et al., 1986; Min et al., 1999; Iravani and Melville, 1974). In humans, clearance rates have been described as characteristic of a given individual, which may vary from 1 to 20 mm/min (Proctor et al., 1978), and nasal ciliary beat frequency appears to be age independent (Jorissen et al., 1998).

The presence in nasal secretions of macromolecules suggests that the protective function of secretions is not simply related to clearance, but includes reactions such as bacterial destruction by lysozyme, proinflammatory peptide degradation by peptidases, viral inactivation by IgA interaction, and possibly metabolism of toxicants prior to tissue contact or absorption into systemic circulation. For example, carbonic anhydrase VI is secreted to nasal mucus, where it may play a role in CO<sub>2</sub> sensation and acid-base balance (Kimoto et al., 2004). Plunc, a member of the secretory gland protein family, is found in nasal respiratory epithelium and nasal mucus, where it may offer protection against bacterial infection (Sung et al., 2002). The precise activity and in vivo function of these macromolecules in mucous secretions have not been well studied to date. However, it is clear that transport, binding, and clearance of xenobiotics occurring in the mucociliary apparatus will influence deposition of these substrates in nasal tissues. Therefore, alterations in mucous constituents and ciliary function may alter metabolism as well.

### 3.3.4 Comparative Aspects of Mucosal Composition

The primary interspecies anatomical differences in olfactory mucosa result from differences in turbinate structure and related proportion of the nasal cavity lined with olfactory mucosa. In general, the surface area to nasal cavity volume ratio reflects the reliance on olfaction of a given species. For example, the rat has a surface area to luminal volume ratio of 3350 mm<sup>2</sup>/cm<sup>3</sup>; macaque monkey, 775 mm<sup>2</sup>/cm<sup>3</sup>; and human, 820 mm<sup>2</sup>/cm<sup>3</sup> with comparative luminal volumes of 0.4 cm<sup>3</sup> for rat and 25 cm<sup>3</sup> for human (Harkema, 1991). Increased surface area results from an increase in the complexity of turbinates in the nasal cavity; generally the greatest difference occurs in the number of olfactory turbinates. For example, in the rat, the percentage of the nasal surface area covered by OE is nearly 50%, a much greater percentage than in the human (Harkema, 1991). Increased infolding in the turbinates also results in alteration in airflow patterns, and therefore in intranasal deposition patterns. However, studies on airflow indicate that the percentage of inspired air reaching

the olfactory mucosa is roughly 15% in rat, monkey, and human (Kimbell et al., 1993; Jaillardon et al., 1992; Hahn et al., 1993). Because of the differences in relative proportion of olfactory tissue, however, the percentage of inhaled dose deposited in olfactory tissue may still be quite different across these species. These differences are therefore important considerations in extrapolating data derived from laboratory animal research to the human population.

Although the cytoarchitecture of the OE is remarkably similar across mammalian species, there are species-related differences in the topographical organization of immature and mature ORNs. In human OE, immature and mature ORNs are dispersed, in striking difference from the highly compact, laminar organization found in rodents (Hahn et al., 2005). In addition, there are species differences in basal cell morphology. In rodent OE, the horizontal basal cells and globose basal cells are morphologically distinct; whereas, in human OE, almost all basal cells appear similar to the globose basal cells found in rodents (Hahn et al., 2005). The capacity and localization of xenobiotic metabolism can also be markedly different among different species (Dahl and Lewis, 1993; Hadley and Dahl, 1983; Gervasi et al., 1989; Morris, 1997; Sheng et al., 2000).

Because biopsy samples of human olfactory mucosa are difficult to obtain, most human nasal enzyme activity to date has been studied in respiratory mucosa. Notably, human fetal olfactory mucosa is readily available, and has been shown to contain efficient metabolic activity toward a xenobiotic compound (Wong et al., 2005).

The cells containing xenobiotic metabolic activity in the olfactory mucosa are relatively consistent across species. The primary localization for xenobiotic metabolizing enzymes is within the sustentacular, basal, and duct cells of the epithelium and within the acinar and duct cells of Bowman's glands in the lamina propria. Much like squamous epithelial cells, olfactory receptor cells contain enzymes having primarily a homeostatic function, such as alkaline phosphatase (Bourne, 1948) and carbonic anhydrase (Brown et al., 1984); however, xenobiotic-metabolizing enzymes have generally not been localized to these cells.

Although the cell types identified in the previous paragraph are consistent sites of enzyme localization across species, the specific distribution of a given enzyme, such as the cyanide-metabolizing enzyme rhodanese (Lewis et al., 1991), within these cell types can vary across species; whereas other enzymes, such as carboxylesterase (Lewis et al., 1994b) and the P450 CYP2A isoforms (Su and Ding, 2004), show remarkable similarity in distribution across species. These features can be important determinants of toxicant-induced damage in different species, and must be kept in mind when generalizing from one species to another.

### 3.4 IDENTITY, TISSUE- AND CELL-SELECTIVE EXPRESSION, AND DEVELOPMENTAL REGULATION OF NASAL BIOTRANSFORMATION ENZYMES

The dramatic capacity of mammalian nasal mucosa to metabolize inhaled substances is now well recognized. Since the first reports that P450 activity in rat nasal mucosa sometimes exceeded activity in liver when normalized to tissue protein content (Hadley and Dahl, 1982), numerous laboratories have reported activity in the nasal mucosa for families of xenobiotic-metabolizing enzymes, including flavin-containing monooxygenases, aldehyde dehydrogenases, alcohol dehydrogenase, carboxylesterases, epoxide hydrolases, UDP glucuronosyltransferase (UGT), glutathione transferase (GST), and rhodanese (Dahl and Hadley, 1991). In addition, xenobiotic-metabolizing capacity has been demonstrated in olfactory and other nasal tissues from a broad range of species, including *Drosophila melanogaster* (Wang et al., 1999), lobsters (Trapido-Rosenthal et al., 1990), rainbow trout (Starcevic and Zielinski, 1995), rabbits (Ding and Coon, 1988, 1990a; Shehin-Johnson et al., 1995), rodents (Hadley and Dahl, 1982; Genter et al., 1995b), dogs (Dahl et al., 1982), pigs (Marini et al., 1998), sheep (Larsson et al., 1994), cows (Longo et al., 1997), and humans (Lewis et al., 1991, 1994b; Gervasi et al., 1989; Getchell et al., 1993a; Gu et al., 2000; Wong et al., 2005).

Steadfast progress has been made in the identification and characterization of nasal biotransformation enzymes. While studies on P450 enzymes have moved forward to the determination of in vivo functions, the nasal expression of many other phase-I biotransformation enzymes as well as phase II conjugation enzymes and transporters has been reported. The biological model systems ranged from insects to fish and to humans. Although most of the xenobiotic-metabolizing enzymes localized in the nose are also found in other tissues, some are uniquely or preferentially expressed in the olfactory mucosa in a number of species.

#### 3.4.1 Cytochrome P450

The P450 gene superfamily encodes a large number of structurally similar monooxygenases (Nelson et al., 1996). All P450s contain a heme prosthetic group ligated to a highly conserved cysteine residue in the carboxyl terminal portion of the proteins. In a single species, for example, the humans, the total number of P450 genes can be more than 50, and individual genes are expressed more or less in tissue- and cell-selective fashions. Within a cell, the majority of P450s are located in the endoplasmic reticulum

(microsomal fraction) while some are specifically located in the mitochondria.

The substrates for microsomal P450s include physiologically important substances such as steroid hormones, eicosanoids, and retinoids, and xenobiotics such as drugs, procarcinogens, antibiotics, organic solvents, anesthetics, pesticides, and odorants. P450-catalyzed biotransformations lead to the formation of more polar compounds that are more readily excreted directly or after conjugation with water-soluble agents such as glucuronic acid and GSH (Porter and Coon, 1991).

P450 and NADPH-cytochrome P450 reductase (CPR), a flavoprotein required for microsomal P450-catalyzed monooxygenase reactions, have been found in relatively high concentration in the olfactory mucosa of rodents, rabbits, cows, dogs, pigs, monkeys (Dahl and Hadley, 1991; Ding and Coon, 1993; Hua et al., 1997; Longo et al., 1997; Marini et al., 1998), and humans (Getchell et al., 1993a; Su et al., 1996). Both P450 and CPR have also been identified in the olfactory organ of *Drosophila melanogaster* (Hovemann et al., 1997; Wang et al., 1999). On a per mg microsomal protein basis, the level of total microsomal P450 in olfactory mucosa is second only to liver among all tissues examined in rodents and rabbits; the level of CPR in olfactory mucosa microsomes is even higher than in liver (Ding et al., 1986; Reed et al., 1986). The evolutionarily conserved presence of the P450 enzymes supports their functional importance in olfaction.

Many different P450s have been identified in mammalian olfactory mucosa, including members of the CYP1A, 2A, 2B, 2C, 2D, 2E, 2G, 2F, 2J, 2S, 3A, 4A, and 4B subfamilies (Dahl and Hadley, 1991; Deshpande et al., 1999; Ding and Coon, 1993; Gu et al., 1998; Zhang et al., 1997; Minn et al., 2005; Zhang et al., 2005; Saarikoski et al., 2005; Tyden et al., 2008; Li et al., 2011). Of these, CYP1A2, CYP2A, and CYP2G1 are the major forms in rabbits and mice (Ding and Coon, 1990a; Genter et al., 1998; Gu et al., 1998). Multiple genes are present in the CYP2A subfamily, which were named sequentially according to the time of discovery. The functional CYP2A genes expressed in the olfactory mucosa include CYP2A3 in rats, CYP2A5 in mice, CYP2A6 and CYP2A13 in humans, and CYP2A10 and CYP2A11 in rabbits (Koskela et al., 1999; Peng et al., 1993; Su et al., 1996, 2000). There is only a single CYP2G gene in rats, mice, and rabbits, all named CYP2G1 (Nef et al., 1990; Ding et al., 1991; Hua et al., 1997). In humans, there may be two copies of the CYP2G gene, but both contain loss-of-function mutations in the majority of individuals, and a functional cDNA has not been identified (Sheng et al., 2000). Monkeys also have two copies of CYP2G genes; the second copy, CYP2G2, is expressed in the nasal mucosa in cynomolgus monkey, and is active toward coumarin, an odorant (Uno et al., 2011).

The human CYP2A13 gene is preferentially expressed in the respiratory tract, with highest levels found in the nasal mucosa, and it is the most efficient P450 enzyme in the *in vitro* metabolic activation of 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK), a tobacco-specific nitrosamine and potent nasal and lung carcinogen (Su et al., 2000; Jalas et al., 2005). CYP2A13 is also active toward many other toxicants and carcinogens, including aflatoxin B<sub>1</sub> (He et al., 2006), 4-aminobiphenyl (Nakajima et al., 2006), naphthalene, styrene, and toluene (Fukami et al., 2008), and 3-methylindole (3-MI) (D'Agostino et al., 2009), as well as odorants, such as nicotine (Bao et al., 2005). CYP2F1 is another human P450 that is primarily expressed in the nasal mucosa and the lung (Zhang and Ding 2008; Carlson, 2008; Weems et al., 2010), with little expression in other tissues (Carr et al., 2003). CYP2F1 appears to be active toward several pulmonary toxicants, including naphthalene, styrene, 3-MI, and benzene (Lanza et al., 1999; Nakajima et al., 1994; Powley and Carlson, 2000; Cruzan et al., 2002); however, as a result of difficulties encountered in attempts to heterologously express CYP2F1, the substrate specificity and biochemical properties of this enzyme are still unclear (e.g., Baldwin et al., 2005). A CYP2A13/2F1-transgenic mouse has been produced (Wei et al., 2012), in which both CYP2A13 and CYP2F1 proteins are abundantly expressed in the olfactory mucosa. Several P450 knockout mouse strains targeting CYPs preferentially expressed in the nasal mucosa have also been generated, including *Cyp2a5*-null (Zhou et al., 2010), *Cyp2f2*-null (Li et al., 2011), *Cyp2g1*-null (Zhao et al., 2004; Zhou et al., 2010), and *Cyp2s1*-null (Wei et al., 2013), as well as a *Cyp2a(4/5)bgs*-null mouse model, in which nine *Cyp* genes on mouse chromosome 7 (including, sequentially, *Cyp2a5*, *2g1*, *2b19*, *2b23*, *2a4*, *2b9*, *2b13*, *2b10*, and *2s1*) are deleted (Wei et al., 2013). Additionally, a mouse model (named Cpr-low) that targets CPR, thus affecting all microsomal P450 enzymes in all cells, has been described (Wu et al., 2005; Wei et al., 2010). These mouse models are being utilized for *in vivo* functional studies of the various P450 enzymes in the olfactory mucosa.

In addition to the P450 forms in gene families 1–4, which are often referred to as the xenobiotic-metabolizing P450s, there are also several microsomal P450 gene families specifically involved in steroid biosynthetic pathways in the endocrine and reproductive organs or bile acid metabolism in liver, such as *CYP7*, 17, 19, 21, and 51 (Nelson et al., 1996). Of these, *CYP19*, also known as the aromatase, which is responsible for estrogen biosynthesis, is expressed in olfactory mucosa in mice (Zhou et al., 2009).

Several olfactory mucosal P450s are specifically or preferentially expressed in this tissue. For example, *CYP2G1* is only expressed in the olfactory mucosa (Ding and Coon, 1990a; Hua et al., 1997; Nef et al., 1989) and, at much lower levels, in the vomeronasal organ (VNO) (Gu

et al., 1999). Several *CYP2As* are expressed in olfactory mucosa at levels much higher than in other tissues (Ding and Coon, 1990a; Su et al., 1996). Preferential expression of a P450 in the olfactory organ was also found in *Drosophila* (Wang et al., 1999). Although the specific biological roles of these tissue-selective P450s have not been identified, their unique or preferential presence in the olfactory mucosa strongly suggests functional importance in the chemosensory organ. In mice, *CYP2A5* has been found to play a role in the maintenance of androgen homeostasis in the LNG (Zhou et al., 2011).

Immunohistochemical studies of several olfactory mucosa microsomal P450s, including *CYP1A*, 2A, 2B, 2G, and 4B, indicated that they are expressed in non-neuronal cells, particularly in the sustentacular cells in the epithelium and in the Bowman's glands in the submucosa (Adams et al., 1991; Chen et al., 1992; Getchell et al., 1993a; Thornton-Manning et al., 1997; Voigt et al., 1985; 1993; Zupko et al., 1991; Chen et al., 2003; Piras et al., 2003; Genter et al., 2006). Distribution of CPR was found to resemble that of the P450s (Adams et al., 1991; Baron et al., 1986; Voigt et al., 1985); however, CPR expression in ORNs has also been reported (Voigt et al., 1985; Verma et al., 1993). The lack of known microsomal P450 expression in the neuronal cells is also supported by toxicological studies implicating the Bowman's glands and the supporting cells as the initial targets following chemical treatment (Brittebo, 1997). The localization of P450s to the mucus-producing cells in the Bowman's glands and the detection of P450 immunoreactivity in the mucociliary complex at the epithelial surface led to suggestions that they may be secreted to the mucus layer where they may directly act on inhaled chemicals (Adams et al., 1991; Chen et al., 1992; Genter et al., 2006).

Little is known about the molecular mechanisms that regulate the tissue- and cell-selective expression of P450s and other transformation enzymes in the olfactory mucosa. Early studies identified nuclear factor I (NFI)-like cis-acting elements in the proximal promoter region of rat *CYP2A3* and *CYP1A2* genes (Zhang and Ding, 1998; Zhang et al., 2000). These highly conserved DNA sequences, which are critical for transcriptional activity of the cognate P450 promoters *in vitro*, appear to interact with olfactory mucosa-restricted nuclear proteins. A similar regulatory element is not identified in the promoter of mouse *Cyp2g1* gene, but a 3.6-kilobase *Cyp2g1* 5'-flanking sequence was sufficient to direct olfactory mucosa-specific and proper developmental expression of a beta-galactosidase reporter gene in transgenic mice (Zhao et al., 2001). However, the transgene expression pattern in the olfactory mucosa did not exactly match that of the *Cyp2g1* gene, which suggested that additional regulatory sequences are required for correct cell type-selectivity.

In vitro studies showed that the transcriptional regulation of human *CYP2A13* gene involves C/EBP transcription factors, instead of NFI. In vivo studies using chromatin immunoprecipitation assays indicated that C/EBP is associated with *CYP2A13* promoter in the olfactory mucosa of *CYP2A13*-transgenic mice (Ling et al., 2007). It also appears that the tissue specific expression of CYP2A3 and CYP2A13 may involve epigenetic repression of the genes' expression in non-permissive tissues (Ling et al., 2004; 2007). Notably, genetic polymorphisms in CYP2A13 that are associated with decreased CYP2A13 expression in lung and, presumably, also nasal mucosa have been identified (D'Agostino et al., 2008; Wu et al., 2009; Zhang et al., 2004; 2007); more in-depth studies of the relationships between these genetic variations with expression of CYP2A13 in the nasal tissues may not only reveal the underlining regulatory mechanisms, but also provide opportunities to study relationships between variations in CYP2A13 expression and olfactory function or disease susceptibility. A *CYP2A13*-null allele has also been identified (Zhang et al., 2003).

The developmental expression of P450s and CPR in olfactory mucosa has also been examined. In rabbits, CYP2G1 was detected at 2 days before birth (Ding et al., 1992). In rats, CYP2G1 expression was detected at E20, which was suggested to coincide with the appearance of Bowman's glands (Margalit and Lancet, 1993). Prenatal expression of several P450s and CPR has also been found in humans (Gu et al., 2000). The earlier onset of P450 expression in olfactory mucosa than in other tissues may indicate a functional significance in the perinatal period when olfactory ability is important for the survival of the newborn. In humans, a number of biotransformation genes are expressed in the fetal nasal mucosa at gestational ages of ~3 months, including aldehyde dehydrogenase 6 (ALDH6), ALDH7, CYP1B1, CY2E1, CYP2F1, CYP4B1, UGT2A1, flavin-containing monooxygenase 1, and GSTP1 (Zhang et al., 2005).

### 3.4.2 Other Enzymes

GSTs catalyze the conjugation of GSH with numerous electrophilic substrates, including reactive intermediates formed in P450-catalyzed reactions, which decrease their reactivity with proteins and other cellular macromolecules (Armstrong, 1997; Eaton and Bammler, 1999), as well as unaltered odorants (Ben-Arie et al., 1993). Most GSTs are located in the cytosol, although some have also been found in microsomes and mitochondria (Eaton and Bammler, 1999). At least five cytosolic GST gene families are known in humans. Multiple GSTs have been detected in the olfactory mucosa in a number of species (Aceto et al., 1993; Ben-Arie et al., 1993, Banger et al., 1993, Krishna et al., 1995a, Starcevic and Zielinski, 1995, Rogers et al., 1999).

A tissue-specific GST has not been found in mammals, although one has been found in the sphinx moth *Manduca sexta* (Rogers et al., 1999). In rats, GSTA and GSTM immunoreactivity was detected in sustentacular cells and Bowman's glands in the olfactory mucosa. In humans, GSTA immunoreactivity was detected mainly in the acinar cells of the Bowman's glands, as well as in the supranuclear region of supporting cells, but GSTP immunoreactivity was detected only in the supporting cells in the olfactory mucosa (Krishna et al., 1994; 1995a). In mice, GSTA and GSTM, but not GSTP, show a preferential expression in the main olfactory tissue, in comparison to the VNO (Green et al., 2005), and GSTM expression as well as GST activity displays a zonal distribution pattern in the olfactory mucosa, favoring the lateral olfactory turbinates over the dorsal or septal regions (Whitby-Logan et al., 2004).

UDP glucuronosyltransferases (UDPGT or UGTs), also named UDP glycosyltransferases, catalyze the conjugation of UDP glucuronic acid with a variety of substrates (Mackenzie et al., 1997). In mammals, the UGTs are found in microsomal fractions and belong to two different gene families, each having multiple genes (Mackenzie et al., 1997). An olfactory mucosa-specific UGT has been identified in rats, cows, and humans, which are all named UGT2A1, and are active toward numerous compounds, including many odorants (Lazard et al., 1990, 1991; Mackenzie et al., 1997; Jedlitschky et al., 1999). A tissue-specific UGT (DmeUgt35a) has also been identified in the olfactory organ of *Drosophila melanogaster* (Wang et al., 1999). Multiple UGTs are believed to be expressed in mammalian olfactory mucosa (Marini et al., 1998). In rats, UGT2A1 mRNA is found in sustentacular cells and Bowman's gland, as well as in the olfactory sensory neuron and olfactory bulb (Heydel et al., 2001). UGT2A1 is also preferentially expressed in the nasal mucosa than in liver of human fetus (Zhang et al., 2005). A second member of the human UGT2A subfamily, UGT2A2, has been studied. It is also preferentially expressed in the nasal mucosa and, as UGT2A1, it has broad glucuronidation activities toward different endobiotic and xenobiotic substrates, including odorants (Sneitz et al., 2009). A comprehensive survey of the expression profile of 19 human UGT1A, 2A and 2B genes showed that, in both adult and fetal olfactory mucosa, the composite UGT mRNA expression level is also high, ~20% of the adult hepatic level, and that there is a large developmental shift from high UGT2A1 and UGT2A2 expression in the fetus to predominantly UGT1A6 expression in the adult (Court et al., 2012).

Sulfotransferases (ST), which include phenol ST (PST), hydroxysteroid ST (HSST), and, in plants, flavonol ST (FST) gene families, catalyze the transfer of a sulfonate group from 3'-phosphoadenosine 5'-phosphosulfate to both endogenous and xenobiotic compounds (Weinshilboum et al., 1997). Mouse nasal cytosol had high activity for a

number of phenolic aromatic odorants (Miyawaki et al., 1996; Tamura et al., 1997). Mouse PSTG immunoreactivity, which is detectable prenatally, is localized mainly in the sustentacular cells in the most dorsal and medial zone of mouse olfactory mucosa (Miyawaki et al., 1996).

Microsomal epoxide hydrolase often plays a protective role against xenobiotic toxicity by detoxifying reactive epoxides formed by monooxygenase reactions. Microsomal epoxide hydrolase is abundantly expressed in the olfactory mucosa (Genter et al., 1995a; Faller et al., 2001); however, it is intriguingly absent in the epithelium lining the dorsal medial meatus in rats, making that region vulnerable to toxicity induced by epoxide-forming compounds such as 2,6-dichlorobenzonitrile (DCBN) (Genter et al., 1995a). The NADPH:quinone oxidoreductase also displays a zone-specific expression in olfactory epithelium, which may underlie zone-specific toxicity of certain quinoidal drugs and nasal toxicants (Gussing and Bohm, 2004).

Carboxylesterases are abundantly expressed in the olfactory mucosa in a number of mammalian species; human nasal mucosal carboxylesterases actively participate in the metabolism of drugs and other xenobiotics, such as methyl methacrylate, dexamethasone cipeptide and ciclesonide (Mainwaring et al., 2001; Sato et al., 2007a,b,c; Sasagawa et al., 2011). A molybdo-flavoenzyme named aldehyde oxidase homologue 3 is expressed in Bowman's glands of mouse olfactory mucosa and has aldehyde oxidase activity toward exogenous substrates (Kurosaki et al., 2004). Other nasal biotransformation enzymes include acetyltransferases, which show strikingly higher activity in olfactory mucosa than in liver (Genter, 2004), as well as aminopeptidase and dipeptidyldipeptidase, which may influence stability of nasally applied peptide drugs (Agu et al., 2009).

The nasal expression and function of a number of transporters have been studied. These include peptide transporters (Agu et al., 2011; Quarcoo et al., 2009), drug/xenobiotic transporters, such as the multidrug-resistance related protein 1 (MRP1) (Kudo et al., 2010), and metal transporters, such as the divalent metal transporters (DMTs) (Thompson et al., 2007). MRP1, which is expressed in supporting cells in olfactory mucosa, but not in cells of the respiratory mucosa, has been suggested to participate in olfactory signal termination (Kudo et al., 2010). The metal transporters DMT1, which is found on both the apical microvilli and the end feet of sustentacular cells, is believed to mediate absorption of inhaled manganese into the CNS (Thompson et al., 2007).

The expression of enzymes and transporters mainly involved in the metabolism or transport of endogenous signaling compounds has also been studied in the olfactory mucosa. For example, monoamine oxidase (MAO), active in dopamine inactivation, and dopamine transporter, responsible for dopamine uptake, are both

expressed and functional in the olfactory mucosa, where they may influence bioavailability of intranasally administered dopamine in replacement therapy (Chemuturi et al., 2006; Chemuturi and Donovan, 2006). Enzymes important for arachidonic acid metabolism, including cyclooxygenases, lipoxygenases, and phospholipase A2, are abundant in nasal glands, sinonasal mucosa and respiratory mucosa, and may play important roles in nasal inflammatory responses associated with rhinitis and cystic fibrosis (Gosepath et al., 2004; Owens et al., 2008; Ishige et al., 2008). On the other hand, leukotriene A4 hydrolase, a key enzyme in leukotriene B-4 biosynthesis, is widely distributed in neurons of the OE and VNO, and proposed to play a neuromodulatory function (Chiba et al., 2006).

The expression of many genes that are crucial for various cellular "house-keeping" functions has been detected in the olfactory mucosa. For example, heparanase, which degrades proteoglycans associated with cell surface and extracellular matrix, is possibly involved in neural differentiation (Moretti et al., 2006). Peptidylglycine alpha-amidating monooxygenase, responsible for amidation of neuropeptides, such as the pituitary adenyl cyclase-activating polypeptide, may play important roles in proliferation of the OE (Hansel et al., 2001). Glucose transporters and monocarboxylate transporters, some of which show a polarized pattern of expression in different cell types, are believed to regulate energy supply throughout olfactory mucosa (Nunez-Parra et al., 2011); whereas the vacuolar proton-pumping ATPase is thought to regulate the pH in the mucous layer (Paunescu et al., 2008). Both vacuolar proton-pumping ATPase and carbonic anhydrases, which catalyze the reversible hydration of CO<sub>2</sub>, may contribute to interindividual differences in the nasal ability to detect CO<sub>2</sub> (Tarun et al., 2003; Paunescu et al., 2008). Finally, several anti-oxidative enzymes, including superoxide dismutase, catalase, glutathione peroxidase, and DT-diaphorase, are present in both nasal respiratory and olfactory mucosa (Reed et al., 2003), and likely play important roles in maintaining cellular redox balance.

A number of studies have examined global gene or protein expression profiles in nasal tissues from various sources, including olfactory, transitional, and respiratory mucosa, or olfactory sensory cilia, or olfactory cleft mucus, of rats, mice, or humans (Barbour et al., 2008; Debat et al., 2007; DeStefano-Shields et al., 2010; Hester et al., 2002; 2003; Mayer et al., 2008, 2009; Poon et al., 2005; Roberts et al., 2007; Simoes et al., 2011). Results of these and other similar studies provide a rich resource for further identification of additional biotransformation genes that are expressed in the nasal tissues, and/or regulated by pathophysiological events, such as aging and xenobiotic exposure.

### 3.5 FUNCTIONS OF NASAL BIOTRANSFORMATION ENZYMES

Nasal xenobiotic metabolism likely serves multiple functions. Four possibilities, discussed in more detail below, are: (1) detoxication of inhaled and systemically-derived xenobiotics; (2) protection of other tissues, such as the lung and CNS, from inhaled toxicants; (3) modification of inhaled odorants, including the special case of steroids as reproductive stimuli; and (4) modulation of endogenous signaling molecules. In addition, the roles of nasal biotransformation enzymes in the metabolic activation and toxicity of inhaled or systemically-derived xenobiotics are also considered.

#### 3.5.1 Detoxication of Inhaled Toxicants

The nose is the portal of entry for inhaled chemicals and, as such, is continually exposed to toxic insults. Therefore, one function of xenobiotic metabolism could be detoxication of inhaled toxicants. Because of the small mass of nasal mucosa, the protective function of nasal metabolism is probably more a form of local tissue protection than protection of downstream tissues such as lung. It can be said for the vast majority of lipophilic compounds that would normally build up in the nasal tissue that combined P450 and phase II metabolism, or metabolism by other routes, decreases toxicity either by increasing solubility and subsequent clearance or by other chemical modification to less toxic forms. The presence of relatively high amounts of anti-oxidative enzymes may also serve to protect the nasal tissues against damage.

In some instances, nasal metabolic systems may work in tandem to provide local protection (Dahl and Hadley, 1983; Morgan and Monticello, 1990; Bogdanffy, 1990). Therefore, the regional distribution of damage will be influenced by the relationships among airflow, deposition, and chemical solubility and reactivity, as well as localization of enzymes involved in the sequential metabolic steps. For example, the enzyme rhodanese, which metabolizes cyanide to the less toxic metabolite thiocyanate (Lewis et al., 1991), may also metabolize cyanide produced from the P450 metabolism of inhaled organonitrile compounds such as acetonitrile (Dahl and Waruszewski, 1990).

With respect to the secondary detoxication of toxic metabolites, the cellular localization of specific enzymes may be important when generalizing across species. The organonitrile  $\beta,\beta'$ -iminodipropionitrile (IDPN) is toxic to the acinar cells of Bowman's glands following systemic administration in rats (Genter et al., 1992). P450 metabolism of IDPN would yield cyanide. The cells of Bowman's glands in the rat contain several isoforms of P450 (Dahl and Hadley, 1991); however, they do not

contain rhodanese (Lewis et al., 1992b). It is therefore likely that the toxicity of IDPN in these cells is caused by a buildup of the metabolite, cyanide. Because the cellular distribution of rhodanese differs across species, the target cells for IDPN toxicity may also differ.

It should be remembered that nasal xenobiotic enzymes act not only on inhaled substrates, but on substrates in the systemic circulation as well, as evidenced by metabolite-induced toxicity to the olfactory mucosa seen following intravenous administration of toxicants such as NNK (Belinsky et al., 1990), 3-MI (Turk et al., 1986), and acetaminophen (Jeffery and Haschek, 1988). Teleologically, this metabolism of systemic compounds could serve to reduce stimulation of olfactory receptors by circulating odorants, thereby eliminating possible interference with or masking of inhaled odorants. In addition, such metabolism could serve to protect this important sensory tissue from damage induced by circulating toxicants. Notably, as will be discussed later, the toxic metabolites formed are usually removed by phase II enzymes or other further biotransformation mechanisms, thus avoiding tissue damage.

#### 3.5.2 Protection of Other Tissues from Inhaled Toxicants

##### 3.5.2.1 Lung.

Based on activity, most nasal enzymes probably have little effect on reducing concentrations of toxicants entering systemic circulation unless inhaled concentrations are very low. Two exceptions to this might be toxic substrates of carboxylesterases and cyanogenic compounds detoxified by the cyanide-metabolizing enzyme rhodanese (Dahl, 1988; Lewis et al., 1991). Across several species, the capacity of nasal carboxylesterases is sufficient to detoxify inhaled concentrations of esters such as ethyleneglycol monomethyl ether acetate in the 1000 to 3000-ppm range (Dahl, 1988), a concentration in excess of occupational exposure limits. However, in many cases, such as with dibasic esters, the metabolites of esters are themselves toxic to olfactory tissues (Bogdanffy, 1990). Likewise, nasal rhodanese activity is sufficient to detoxify inhaled concentrations of hydrogen cyanide as high as 2800 ppm in the rat (Lewis et al., 1991).

This capacity to significantly alter systemic toxicant exposure through nasal metabolism does not hold for all enzyme families. The capacity for nasal metabolism of some P450 substrates is considerably lower: 0.1-5 ppm for *p*-nitroanisole and 0.1-3 ppm for aniline. At these levels of activity, significant systemic protection from inhaled toxic substrates would probably not result from nasal metabolism.

##### 3.5.2.2 Central Nervous System.

Xenobiotic metabolism in the OE as well as in the olfactory bulbs may

be a component of a “nose-brain barrier.” The OE has a unique anatomy wherein a single receptor cell contacts the external environment in the nasal lumen and projects directly to its synapse within the CNS in the glomeruli of the olfactory bulbs. These cells, then, provide direct access for inhalants to the CNS. Several studies have demonstrated that a variety of materials instilled or surgically implanted into the nasal cavity can be transported to the olfactory bulbs (Shipley, 1985; Schultz and Gebhardt, 1934; Tomlinson and Esiri, 1983; McLean et al., 1989; Henriksson and Tjälve, 2000; Larsson and Tjälve, 2000). Generally, these studies have used concentrations of material far in excess of those encountered environmentally. Therefore, the importance of this phenomenon for *inhalation* of environmentally relevant concentrations of toxicants is not yet clear. The factors involved in a nose-brain barrier that might protect the brain from toxicant exposure have not yet been elucidated. However, they most likely include xenobiotic metabolism and transport in the olfactory mucosa, as well as in the olfactory bulb, where biotransformation enzymes such as UGT2A1 (Heydel et al., 2001) and xenobiotic efflux transporters such as the multidrug resistance P-glycoprotein are also expressed (Thiebaud et al., 2011). In addition, mucociliary clearance, immune responses in the olfactory or other nasal mucosa, tight junctions between epithelial cells, and the rapid death of epithelial cells following toxicant exposure are also likely to play a role (Lewis et al., 1994a).

### 3.5.3 Modification of Olfactory Stimuli

**3.5.3.1 Odorants.** A third possible function for nasal metabolism is either activation of inhaled nonodorants to odorants or, conversely, clearance of odorants from the olfactory receptor cells to allow reactivation of receptors (Dahl, 1988; Getchell and Getchell, 1977; Lazard et al., 1991). Although most biotransformation enzymes are located in the non-neuronal cells, the lipophilic substrates can quickly diffuse to all cells in the olfactory mucosa. This phenomenon of receptor reactivation has also been demonstrated in lobsters (Trapido-Rosenthal et al., 1990) and in silk moths (Vogt and Riddiford, 1981).

Odorant metabolites may contribute to potency and odor quality. Many odorant metabolites are more water soluble than the parent odorants, and they may reach very high concentrations in the mucus bathing ORNs (Dahl, 1988; Price, 1984). If olfactory stimulation includes summation of signals from parent odorant and its metabolites (Kashiwayanagi et al., 1987; Price, 1984), such metabolites could be important to the sensitivity, intensity, and quality perception of an odor. Thus, it was hypothesized that odor quality and intensity may reflect effects of the odorant and its metabolites on ORNs (Dahl, 1988; Price, 1984, 1986).

In a recent study in mice, it was convincingly demonstrated that pharmacological inhibition of enzymatic conversion of odorants that are aldehydes or esters to corresponding acids and alcohols in the nasal mucus is associated with changes in odorant-induced glomerular activation patterns in the olfactory bulb, as well as failure of the animals to identify the tested odorants, which they normally can discriminate, in olfactory discrimination tests (Nagashima and Touhara, 2010). These results, which suggested that biotransformation of odorants in the nasal mucus is rapid enough to affect odorant detection and identification, support the previously proposed role of nasal biotransformation enzymes in odorant signal modification.

Lipophilic odorants can partition favorably into the membranous structure of the neuroepithelium. Their accumulation may adversely affect many aspects of cellular function. They may saturate the odorant clearance mechanism, disturb mitochondrial energy production, and suppress or sensitize local immune systems. They may also change the electrophysiological properties of the plasma membrane and thus the functional capacity of ion channels and other signal transduction components. Thus, in addition to the role in odorant signal modification, biotransformation reactions which convert these lipophilic compounds into more water-soluble metabolites may also be indispensable for maintaining the homeostasis of the chemosensory tissue.

**3.5.3.2 Steroids.** Steroids are likely to represent a special case of metabolic modulation of olfactory stimuli. Inhaled steroids can serve as primary olfactory cues in the regulation of reproductive function in a number of species, as well as modulators of olfactory function. Androstenone is a steroid found in the urine and saliva of pigs and humans, and also in human sweat. In pigs, androstenone excreted by boars has been shown to initiate mating behavior in estrus sows with intact olfactory function (Beauchamp et al., 1976). Sensitivity to the odor of androstenone varies widely in humans (Dorries et al., 1989). Interaction of exogenous steroids with the olfactory system has also been demonstrated through modification of serum testosterone, testicular size, and spermatogenesis in rhesus monkeys by intranasal administration of estradiol and progesterone (Anand-Kumar et al., 1980). Estradiol present in the urine of male mice can cause failure of blastocyst implantation in females (Guzzo et al., 2012).

It is likely that the ability of the olfactory mucosa to metabolize steroids will influence responses to exogenous steroids. Mammalian olfactory mucosa has very high activities in the metabolism of all three major sex steroids (Brittebo and Rafter, 1984; Brittebo, 1985; Ding and Coon, 1990a, 1994; Hua et al., 1997; Longo et al., 1997; Marini et al., 1998). The VNO is also capable of metabolizing sex

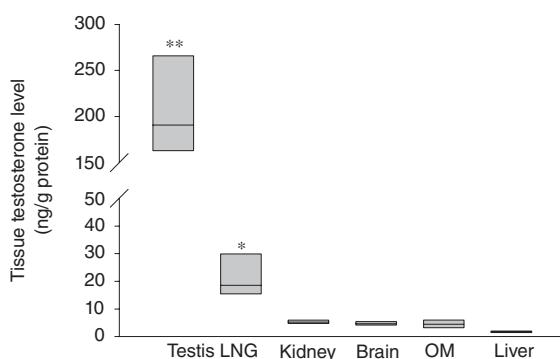

steroids (Gu et al., 1999). Accumulation of sex steroids and other endogenous or exogenous compounds that are normally removed by P450 metabolism could affect signal transduction by competing for receptors. To that end, Rosenblum et al. (1991) reported that receptor binding of  $17\alpha,20\beta$ -dihydroxy-4-pregnen-3-one to goldfish olfactory mucosa is competitively inhibited by progesterone and other sex steroids. Androstenone is metabolized by the nasal mucosa in pigs (Gennings et al., 1974) and is a competitive inhibitor of steroid metabolism by CYP2G1 (Ding and Coon, 1994), which suggests that it may be metabolized by this or other P450 enzymes.

The LNG, which is a non-steroidogenic organ, may play an important role as a storage organ for androgens (Zhou et al., 2009). In adult male mice, testosterone levels in the LNG are substantially higher than those in the olfactory mucosa and other non-reproductive or non-endocrine tissues examined (Figure 3.2). The high levels in the LNG are accompanied by high levels of sABP, low microsomal testosterone-hydroxylase activities, and absence of steroid  $5\alpha$ -reductases and the aromatase, enzymes that can convert testosterone to other forms of steroid hormones. The levels of testosterone in olfactory mucosa and LNG are influenced by circulating androgen levels, by rates of steroid metabolism in the tissue, and by the presence of steroid binding proteins, such as sABP, which may impede testosterone metabolism, and sequester steroids inside cells. Thus, the unusually high testosterone level in the LNG can be explained by the very high sABP levels and very low testosterone metabolism activities in this tissue. The role of P450-mediated testosterone hydroxylation in maintaining LNG testosterone levels are demonstrated by the

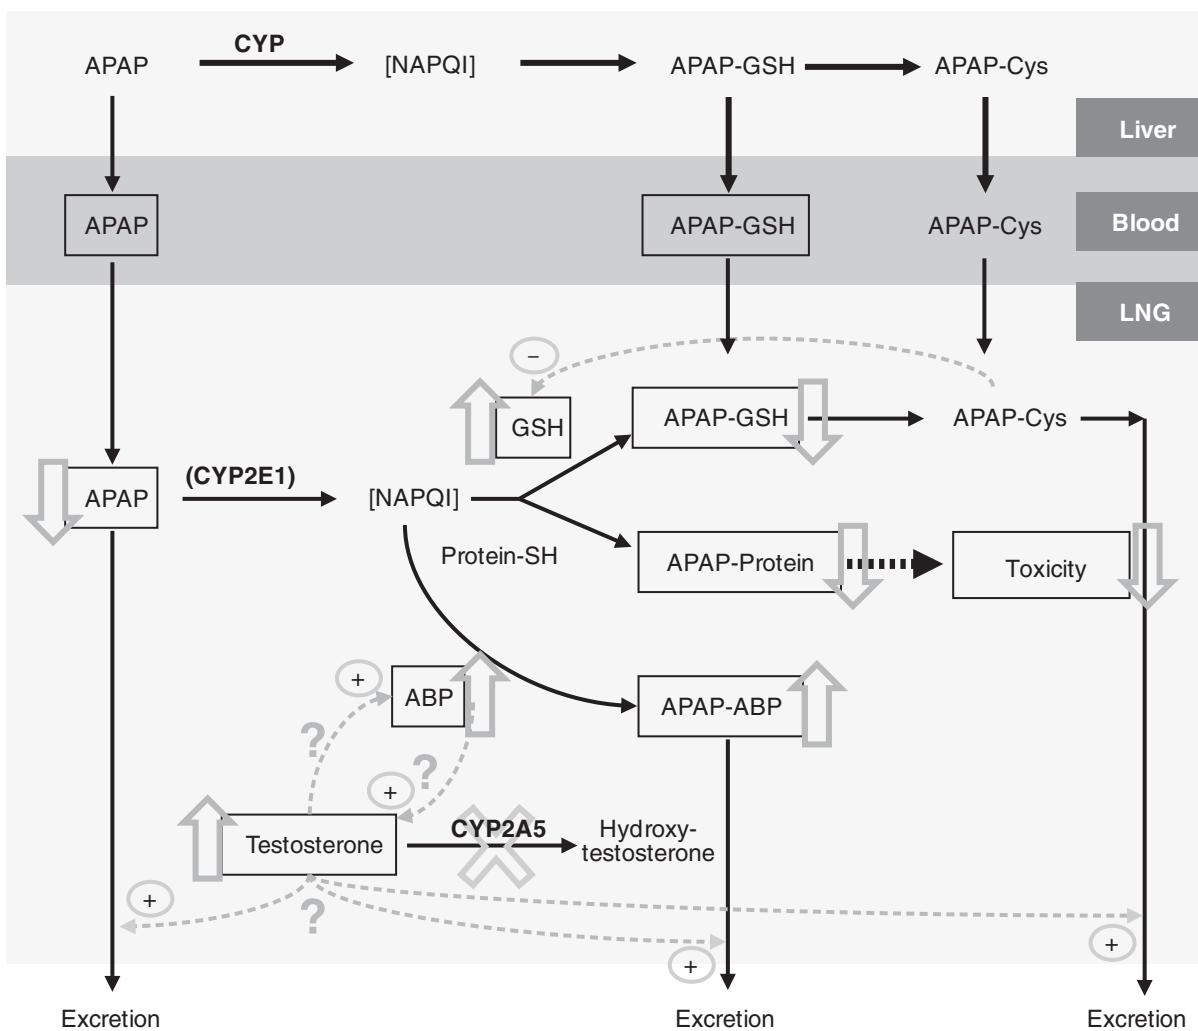

finding that LNG testosterone levels are further increased in *Cyp2a5*-null mice (Zhou et al., 2011); CYP2A5 encodes an avid testosterone hydroxylase.

The functional significance of the unusually high testosterone level in the LNG, a gland known for its secretion of OBPs (Snyder et al., 1988) and IgA (Adams et al., 1981) to the nasal cavity, is intriguing. It has been proposed that the stored androgen can be secreted, together with sABP, from LNG to nasal mucus, thus potentially functioning in a paracrine fashion in other parts of the male olfactory system, including the olfactory mucosa and VNO. Testosterone in the nasal mucus may activate membrane androgen receptors; interact with odorant/pheromone receptors (either as an agonist or an antagonist); or inhibit putative pheromone-metabolizing enzymes in the mucus (Zhou et al., 2009).

The sABPs are members of the secretoglobin family (Laukaitis and Karn, 2005). They are expressed in a number of organs in the head and neck region, including the VNO, olfactory bulb, salivary glands, lacrimal gland, and Harderian gland (Laukaitis et al., 2005). They can bind testosterone, progesterone, but not estradiol or cholesterol, with high affinity (Karn, 1998). Their biological functions have not been determined, though, in addition to the proposed roles in concentrating testosterone in the LNG and delivery of testosterone to the nasal mucus, they are also believed to function as pheromones, in modulation of odorant detection, or in reproductive behavior (Emes et al., 2004; Laukaitis et al., 1997; Talley et al., 2001). Interestingly, CYP2A5, testosterone and sABP are integral parts of a defensive mechanism against xenobiotic toxicity in the LNG and possibly other nasal tissues (Zhou et al., 2011). The *Cyp2a5* gene knockout not only led to increases in testosterone levels, but also induction of sABP, the latter can protect glutathione and cellular proteins by quenching reactive metabolites of acetaminophen, a drug and model nasal toxicant, and presumably other xenobiotic compounds. This mechanism (Figure 3.3) explains the finding that *Cyp2a5*-null mice are resistant to the toxicity of acetaminophen in the LNG even though CYP2A5 is not responsible for the bioactivation of acetaminophen in LNG (Zhuo et al., 2004; Zhou et al., 2011). Earlier studies on the liver-Cpr-null mice also showed that, while the toxicity of acetaminophen in the olfactory mucosa was not dependent on bioactivation by hepatic P450 enzymes, its toxicity in the LNG was at least partly dependent on hepatic bioactivation, thus supporting the idea that liver produced acetaminophen metabolites can be transported to the LNG to cause toxicity (Gu et al., 2005).

**Figure 3.2** Serum and tissue testosterone level in male mice (From Zhou et al., 2009, with permission). Testosterone levels were determined for 8-week old male mice ( $n = 8$ ). The values shown are medians, together with the 25% (lower bar) and 75% (upper bar) percentile marks. \*\*, levels in testis were significantly higher than those in other tissues ( $P < 0.05$ ). \*, levels in the LNG were significantly higher than levels in all other tissues examined, except for testis ( $P < 0.05$ ).

**Figure 3.3** A proposed novel defensive mechanism against acetaminophen (APAP) toxicity in the male mouse LNG (From Zhou et al., 2011, with permission). Boxed items represent entities measured in APAP-treated mice. Boxed arrows indicate direction of changes observed in *Cyp2a5*-null mice. *In situ* metabolic activation of APAP in the LNG (presumably mediated by CYP2E1) leads to the formation of the reactive N-acetyl-p-benzoquinone imine (NAPQI), which forms conjugates with GSH or protein (including ABP), and eventually leads to cytotoxicity. APAP-GSH and APAP-CYS, either locally formed, or absorbed from systemic circulation, cause further depletion of GSH (through the  $\gamma$ -glutamyl cycle), and thus increase vulnerability of cellular proteins to attack by N-acetyl-p-benzoquinone imine. Testosterone is speculated as a positive regulator of ABP expression and possibly mucus secretion. LNG testosterone level is regulated negatively by CYP2A5 and positively by ABP. Genetic ablation (or xenobiotic inhibition) of CYP2A5 leads to suppression of testosterone disposition in the LNG, consequent increases in tissue testosterone levels, up-regulation of ABP, and enhanced protection against APAP toxicity, through increased formation of APAP-ABP adducts, reduced depletion of cellular GSH, reduced formation of APAP conjugates with other cellular proteins, and (presumably) increased excretion of APAP and APAP-GSH/APAP-CYS to nasal mucus.

### 3.5.4 Modulation of Endogenous Signaling Molecules

The P450 isoforms identified in the olfactory mucosa are all active in the metabolism of endogenous compounds, although they are also involved in metabolizing foreign chemicals. For example, CYP1B, 2A, 2B, 2G, and 3A are active in the hydroxylation of sex steroids (Ding and

Coon, 1994; Hayes et al., 1996; Liu et al., 1996; Waxman et al., 1991), CYP1A, 2B, 2C, 2E, 2J, and 4A are active in the hydroxylation or epoxidation of arachidonic acid (Laethem et al., 1992; Luo et al., 1998; Scarborough et al., 1999), CYP1A2 and CYP2J4 are active in converting retinols to retinoic acids (RAs), and CYP1A and 2B are active in the hydroxylation of RA (Roberts et al., 1992; Zhang et al., 1998). The consequences of microsomal

P450 catalyzed metabolism of endogenous compounds are usually inactivation of the bioactive substance, as with hydroxylation of testosterone and RAs. However, the epoxygenated or hydroxylated products of arachidonic acid have been implicated in many biological processes, such as regulation of vascular tone, ion transport, calcium release from endoplasmic reticulum, and modification of biophysical properties of plasma membrane (Capdevila et al., 1992; Makita et al., 1996). It is believed (Nebert, 1990, 1991) that the xenobiotic-metabolizing P450s regulate steady state levels of endogenous compounds important for growth, homeostasis, differentiation, and neuroendocrine functions.

P450-catalyzed formation of arachidonic acid epoxide and hydroxides can regulate vascular tone and thus rate of blood flow (Capdevila et al., 1992; Makita et al., 1996). Decreased ability to produce these regulatory molecules may lead to congestion and restrictions in airflow in the nasal cavity, which could affect threshold sensitivity in odor detection. On the other hand, accumulation of arachidonic acid may lead to increased production of leukotrienes and other mediators through the lipoxygenase pathway and potentially induce airway hypersensitivity (Pinto et al., 1997).

ORNs are one of the few vertebrate neuronal populations that undergo continuous turnover and replacement throughout the life of an animal and following injury (Graziadei and Monti-Graziadei, 1983; Goldstein et al., 1998). Such remarkable regenerative capacity may be at least partly related to the presence of the highly active biotransformation enzymes, which control the availability and level of various endogenous bioactive substances capable of regulating growth and differentiation in the target tissue. The relatively high efficiency and broad substrate specificity of the P450 enzymes toward steroid hormones (Ding and Coon, 1994) and retinoids (Roberts et al., 1992) suggest that these compounds may accumulate in olfactory mucosa or other nasal tissues when the P450s are inhibited or down-regulated, as has been demonstrated for testosterone in the LNG (Zhou et al., 2011).

RA plays essential regulatory roles in the differentiation and regeneration of the olfactory system (for a review see Rawson and LaMantia, 2006). RAs are degraded in target tissues by microsomal P450s (Duester, 1996). RA inactivation catalyzed by an embryonic P450 isoform (P450RA) results in RA hyposensitivity in cultured cells (Fujii et al., 1997). RA biosynthetic activity and retinoid receptors are expressed in the olfactory mucosa of adult mice (Zhang, 1999). Metabolism of RA by CYP26B1 in the olfactory neurons impacts neuronal survival and formation of neural circuit map (Hagglund et al., 2006).

Olfactory mucosa is a known target tissue for steroid hormone action (Balboni, 1967; Balboni and Vannelli,

1982; Fong et al., 1999; Vannelli and Balboni, 1982). In male rats, olfactory mucosa morphology is altered by castration, and testosterone replacement counteracts these alterations (Balboni, 1967). Castration during development also leads to decreases in the volume of neurosensory epithelium in the VNO (Segovia and Guillamon, 1982), and circulating sex steroids can also modulate expression of VNO pheromone receptors (Alekseyenko et al., 2006). In addition, corticosteroids may regulate olfactory secretion by modulating Na<sup>+</sup>,K<sup>+</sup>-ATPase (Fong et al., 1999). Thus, prolonged accumulation of these endogenous compounds may lead to changes in olfactory mucosa structure, cell biology, and functional capacity.

### 3.5.5 Metabolic Activation and Xenobiotic Toxicity in the Nasal Mucosa

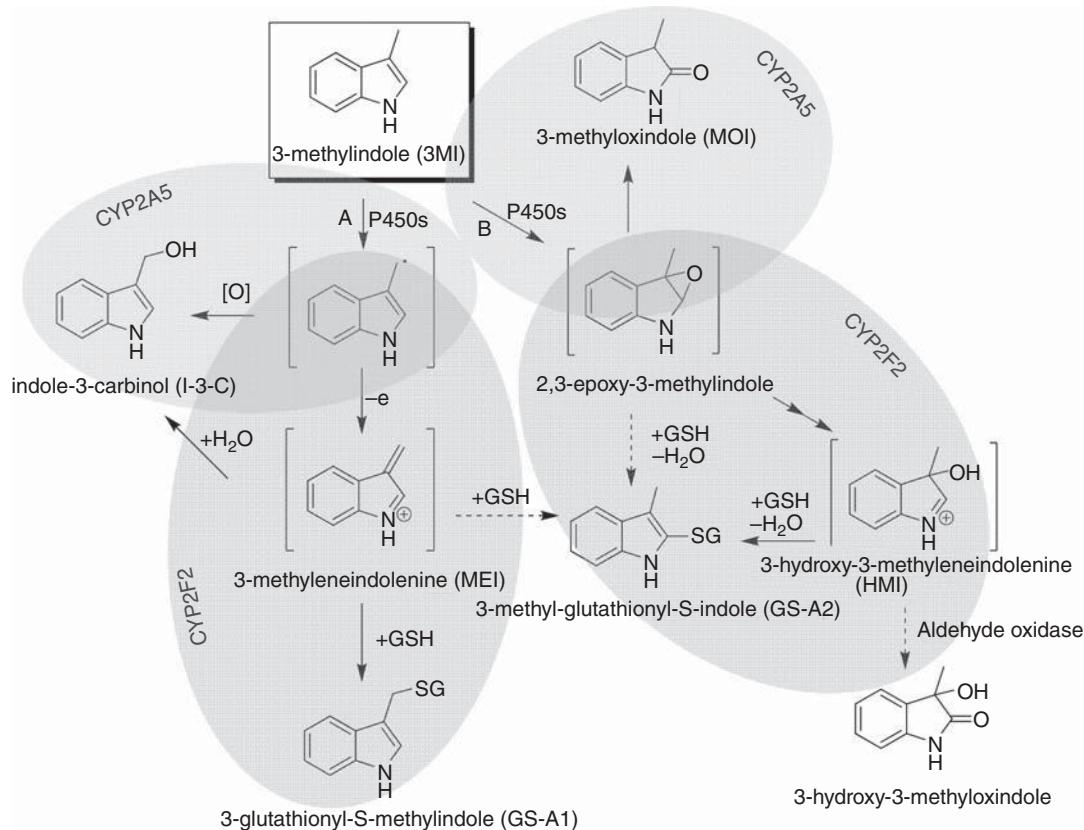

The powerful biotransformation enzymes, particularly the P450 enzymes, generate reactive intermediates from inhaled or systemically-derived xenobiotic substrates, which could lead to toxicity. The activated metabolites, such as the proposed epoxide intermediates from DCBN or coumarin (Ding et al., 1996; Zhuo et al., 1999), can usually be efficiently removed by phase II enzymes such as GST. However, when the dose is high or when the phase II enzymes are compromised due to chemical inhibition or genetic deficiency, the reactive metabolites would accumulate and cause cytotoxicity in the olfactory mucosa. In cases where a reactive intermediate with relatively long half-life is generated, such as the benzo(a)pyrene epoxides (Dahl et al., 1985), it may be transported to nearby organs, such as the pharynx, the esophagus, the anterior nasal cavity, and the olfactory bulb, where local biotransformation activities are much lower compared to the olfactory mucosa, and potentially cause toxicity (Dahl et al., 1985; Ghantous et al., 1990; Persson et al., 2002).

Numerous compounds, such as ferrocene (Sun et al., 1991), 3-trifluoromethylpyridine (Gaskell, 1990), acetaminophen (Jeffery and Haschek, 1988, Genter et al., 1998), NNK (Belinsky et al., 1990), DCBN (Brittebo, 1997), styrene (Green et al., 2001), methimazole (Bergstrom et al., 2003), 2,6-dichlorophenyl methylsulfone (Franzen et al., 2006), naphthalene (Lee et al., 2005), and coumarin (Gu et al., 1997) are metabolized to toxicants that produce necrosis of the OE. This toxicity can occur following not only inhalation, but systemic administration as well. Recent studies with P450 and Cpr knockout (global or tissue-specific) mouse models indicate that, for DCBN and methimazole, bioactivation in the target tissue plays an essential role, and that CYP2A5 is the major enzyme responsible for the bioactivation (Xie et al., 2010; Xie et al., 2011).

For some compounds, which induce toxicities both in nasal mucosa and elsewhere, the specific enzymes responsible for the nasal toxicity may differ from those responsible in other tissues. For instance, 3-MI is toxic to both olfactory mucosa and lung. However, 3-MI bioactivation is mediated mainly by CYP2F2 in the lungs, but by both CYP2A5 and CYP2F2 in the olfactory mucosa (Zhou et al., 2012). Furthermore, the reactive metabolites produced by the two enzymes through common dehydrogenation and epoxidation pathways have different fates, with CYP2A5 supporting direct conversion to stable metabolites and CYP2F2 supporting further formation of reactive iminium ions (Zhou et al., 2012) (Figure 3.4). Similarly, whereas CYP2F2 is essential for naphthalene induced lung toxicity, it only had a minor role in naphthalene-induced olfactory mucosal toxicity (Li et al., 2011). Therefore, knowledge of the specific enzymes involved in the biotransformation of a given toxicant in olfactory mucosa is important for understanding mechanisms of toxicity.

Often, the relative toxicity of a compound in different species or in tissues within a given species is affected

by levels of activating or detoxicating enzymes. However, when compounds are administered systemically, the capacity for other organs to clear the compound must be considered, as it may reduce the amounts reaching the nose. An example is the finding that although rat and mouse olfactory P450s are equally active in metabolic activation of coumarin, rats are much more sensitive to the nasal toxicity of coumarin than mice are, because of a lower hepatic clearance of the parent compound (Zhuo et al., 1999). The observation that nasal toxicity of DCBN is augmented in a mouse model with ablated hepatic DCBN metabolic clearance (the liver-specific Cpr-null mouse) further supports the idea that hepatic clearance can impact nasal exposure to a parent toxicant (Xie et al., 2010). Additionally, when a toxicant is inhaled, differences in nasal airflow patterns, mucociliary clearance, or epithelial status may also affect the toxicity. For example, with inhaled naphthalene, cellular injury is confined to the medial meatus, regions characterized as having relatively slow airflow but high P450 activity, whereas with systemically administered naphthalene, injury occurs throughout the olfactory mucosa (Lee et al., 2005).

**Figure 3.4** Scheme for the metabolic activation of 3MI by mouse olfactory mucosa and lung microsomal P450s (From Zhou et al., 2012, with permission). Pathway A represents dehydrogenation and pathway B represents epoxidation. Shaded areas show metabolites preferentially formed by CYP2A5 or CYP2F2.

Nasal cancers are relatively uncommon in humans, although in certain populations, notably Chinese males, the rate of occurrence is quite high (Tricker and Preussman, 1991). The occurrence of nasal tumors in laboratory animals exposed by inhalation to toxic materials, on the other hand, is a common finding. Often, the toxic materials are procarcinogens requiring metabolic activation, suggesting that differences in nasal xenobiotic metabolism between humans and laboratory animals may underlie the observed differences in nasal tumor formation.

The ability of rodent nasal mucosa to bioactivate procarcinogens is well documented, for example, for the herbicide acetochlor (Green et al., 2000) and the tobacco-specific carcinogene N'-nitrosornicotine (Murphy et al., 2000). Few studies have been able to demonstrate bioactivation activities for nasal procarcinogens in human nasal mucosa (e.g., Green et al., 2001). However, the human nasal tissues studied are rarely of olfactory origin. A study with human fetal olfactory mucosa demonstrated relatively high efficiency for bioactivation of NNK, another tobacco-specific procarcinogen, although the rates were low, as a result of the very low levels of P450 expression in the human tissue, compared to rodents (Wong et al., 2005). More studies on the capability of human nasal tissues to bioactivate procarcinogens are needed.

Among laboratory animal species, differences in rates of carcinogen bioactivation are often predictive of species sensitivity and tissue specificity in nasal tumorigenesis. For example, alachlor induces nasal tumors in rats in regions with high CYP2A3 expression (Genter et al., 2000). Rat nasal mucosa preferentially activates N-nitrosopiperidine, a potent rat nasal carcinogen, over N-nitrosopyrrolidine, a weak nasal carcinogen (Wong et al., 2003). However, although such relationships are compelling as explanations of toxicity, as in the case of noncarcinogenic responses, relative metabolic capacity is not always sufficient to explain differences in toxicity. In the case of alachlor-induced olfactory carcinogenesis, differential rates of hepatic alachlor elimination in mice and rats may explain the resistance in mice (Genter et al., 2004), and differences in other factors, such as induction of olfactory mucosal matrix metalloproteinase, may also be relevant (Genter et al., 2005). The nasal carcinogens NNK and N'-nitrosornicotine produce DNA adducts in nasal tissue via the reactive  $\alpha$ -hydroxylated *N*-nitrosamine metabolites. Although metabolic capacity of the tissues might lead to the prediction that the olfactory mucosa would produce comparatively more adducts than the respiratory mucosa, more adducts were actually found in the respiratory mucosa (Belinsky et al., 1990; Zhang et al., 2009a; Zhang et al., 2009b). Again, other factors, perhaps in this case route of exposure and DNA repair rates, must be taken into account to explain or predict toxicity.

### 3.6 MODIFICATION OF OLFACTORY XENOBIOTIC METABOLISM

As is the case of other xenobiotic-metabolizing enzymes, nasal enzymes are susceptible to modification in their levels of activity. Specific chemical inhibitors, and in some cases inducers, can alter nasal metabolic capacity. In at least some instances, such an alteration has been demonstrated to subsequently alter toxicity as well. Induction of P450 activity by administration of  $\beta$ -naphthoflavone decreased the severity of 3-MI-induced olfactory lesions (Turk et al., 1986), possibly as a result of lower blood levels due to enhanced liver metabolism. Conversely, treatment with dexamethasone potentiates the 3-MI olfactory toxicity, which could be partly due to the inducing action of dexamethasone on the P450 responsible for metabolic bioactivation of 3-MI in the olfactory mucosa (Kratskin et al., 1999). In addition, changes in endogenous steroid hormones may modify the biotransformation capacity of the olfactory mucosa, as demonstrated by the effects of castration on nasal metabolism of testosterone. Castrated male rats have a reduced ability to metabolize testosterone, while testosterone replacement restores metabolic capacity for the steroid (Lupo et al., 1986). However, little else is known about this potentially very interesting subject.

As the following section will detail, many common environmental exposure scenarios can result in alterations of nasal enzymatic activity, thereby enhancing individual variations in responses to toxicant exposures. These alterations can result from either direct inhalation or systemic exposure to chemicals that induce or inhibit nasal enzymes, or from toxicant insults that alter the histology of the tissue. For example, many toxicants cause exfoliation of the OE and a concomitant loss of metabolic capacity from those lost cells. Enzymatic expression also appears sensitive to hyperplastic or metaplastic alterations in the epithelium that can result from toxicant exposures, infections, or inflammatory processes. Consideration of a patients' exposure history may therefore be helpful in diagnosing what appears to be an atypical response to a subsequent toxicant exposure.

#### 3.6.1 Enzyme Induction

Early reports, primarily from studies on rat nasal tissue, indicated that nasal P450s were relatively refractory to induction by a wide range of inducers effective for hepatic enzymes. Either no induction or mild induction of rat nasal P450 activity was observed following treatment with the classic inducers: phenobarbital, benzo(a)pyrene, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin, or 3-methylcholanthrene (Hadley and Dahl, 1982; Bond, 1983; Baron et al., 1988; Longo et al., 1988). Although one study reported the induction of mouse nasal P450

activity by phenobarbital (Brittebo, 1982), the apparently increased activity may have resulted from induction of phase II enzymes occurring downstream from the P450 breakdown step, as only increased  $^{14}\text{CO}_2$  production was reported (Dahl and Hadley, 1991). Induction of phase II enzymes would be consistent with reports of induction of these enzymes in rat nasal tissue by phenobarbital (Guengerich et al., 1982; Longo et al., 1988). The phase II enzyme UGT is also induced by both Arochlor 1254 and 3-methylcholanthrene (Bond, 1983; Longo et al., 1988). Nevertheless, not all phase II enzymes are readily inducible in the olfactory mucosa. Olfactory GSTs were not induced in rats by trans-stilbene oxide, which caused a 2-fold induction in the liver (Banger et al., 1996); only a marginal induction (1.3-fold) by phenobarbital was achieved in the olfactory mucosa while a 2.8-fold induction was found in liver (Banger et al., 1996).

Rabbit nasal CYP2E1 (involved in the metabolism of ethanol and other alcohols, acetone, acetaminophen, nitrosamines, and diethyl ether) can be increased 2-fold by treatment with ethanol and 6-fold following acetone treatment (Ding and Coon, 1990b). These data represent the first evidence of an increase in nasal xenobiotic-metabolizing capacity of a magnitude that can be considered important physiologically. Induction of CYP2E1 in the olfactory mucosa has been confirmed in other species (Longo and Ingelman-Sundberg, 1993; Genter et al., 1994; Gu et al., 1998; Wang et al., 2002; Nannelli et al., 2005). Nasal CYP2E1 and CYP1A2 can also be induced in rats by fasting (Longo et al., 2000). Interestingly, induction of rat CYP2E1 by dioxane occurred only at the protein level in the liver, but was at both protein and mRNA levels in the nasal mucosa (Nannelli et al., 2005). CYP1A1, which is active in the metabolic activation of polycyclic aromatic hydrocarbons, was not induced in the olfactory mucosa by 3-methylcholanthrene, but was significantly induced in Bowman's glands and in the olfactory and respiratory epithelia following a single intraperitoneal injection of Arochlor 1254 in rats (Voigt et al., 1993). CYP1A1 protein is also induced in olfactory mucosa of mainstream cigarette smoke-exposed rats, but a corresponding increase in CYP1A1 activity was not observed (Wardlaw et al., 1998). Induction of nasal P450 enzymes by tobacco smoke has been proposed as a possible mechanism for developing resistance to the environmental toxins implicated in Parkinsonism and other neurologic diseases (Gresham et al., 1993).

CYP2As represent major P450 isoforms in the olfactory mucosa of a number of species. A study by Beréziat et al. (1995) suggested that a CYP2A-like P450 may be induced in rats by treatment with coumarin in drinking water. However, the same results were not obtained in another study with a different strain of rats (Gu et al., 1997), and no induction of CYP2A was found following

treatment of mice with several chemicals known to induce the same enzyme in the liver (Su et al., 1998). Expression of CYP2A3 mRNA in rat nasal mucosa was not induced by 3-methylcholanthrene, pyrazole, or beta-ionone (Robottom-Ferreira et al., 2003). Interestingly, one of the known CYP2E1 and CYP2A5 inducers, pyrazole, was found to induce CYP2J4 in rat olfactory mucosa as well as in other tissues (Zhang et al., 1999). Pyrazole also induces CYP2J proteins in mouse olfactory mucosa (Xie et al., 2000). Expression of CYP2B and 2C, as well as CYP1A and microsomal epoxide hydrolase, is induced in rat olfactory mucosa by the environmental contaminant 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (Genter et al., 2002). A recent study in rats showed that mRNAs for P450 2A3, CYP3A9, UGT2A1, multidrug resistance-related protein type 1, and sulfotransferase 1C1 was increased by dexamethasone in the olfactory mucosa (Thiebaud et al., 2010).

The tissue-differential inducibility of some, but not all, P450 enzymes may be related to the unique (yet still unknown) function of each P450 enzyme and the need for the olfactory mucosa to maintain certain enzymes at a relatively constant level. Alternatively, it is possible that nasal biotransformation enzymes may respond preferentially to inhaled odorants. For example, carboxylesterase is induced in the olfactory mucosa following inhalation exposure to the common solvent pyridine (Nikula et al., 1995), which is not a substrate for this enzyme.

### 3.6.2 Inhibition of Nasal Xenobiotic Metabolism

Unlike the case for nasal enzyme induction, inhibition of nasal xenobiotic metabolism occurs in a wide range of enzyme families. Several P450 isoforms have been inhibited in homogenates of nasal mucosa by hepatic P450 inhibitors such as metyrapone,  $\alpha$ -naphthoflavone, piperonyl butoxide, and a number of odorants, including 5- $\alpha$ -androstenedione. Because these inhibitors are common ingredients in many products in everyday usage such as perfumes, cosmetics, and household insecticides, exposure to these compounds may alter nasal metabolic capacity from that observed in controlled laboratory situations (Dahl and Brezinski, 1985; Dahl, 1982; Laethem et al., 1992; Ding and Coon, 1994; Marini et al., 2001).

Cigarette smoke is another common environmental pollutant that is known to modify olfaction (Frye et al., 1989) and to alter the capacity for nasal xenobiotic metabolism (Wardlaw et al., 1998). Alterations in nasal metabolism may be the direct result of exposure to the myriad of components of cigarette smoke known to be metabolized in the nasal epithelium including benzo(a)pyrene, *N*-nitrosonornicotine, and cyanide. Rhodanese, the primary enzyme of cyanide metabolism, shows nearly a 50% reduction in activity in respiratory mucosa

from human smokers compared to nonsmokers (Lewis et al., 1991).

Inhibitors of biotransformation enzymes have been used *in vivo* to demonstrate the role of local metabolism in xenobiotic toxicity. For example, treatment with metyrapone reduced or abolished cytotoxicity caused by a number of toxic chemicals, such as methimazole (Bergman and Brittebo, 1999), 2,6-dichlorothiobenzamide (Eriksson and Brittebo, 1995), DCBN (Walters et al., 1993), and IDPN (Genter et al., 1994). Metyrapone has also been used to demonstrate that inspired styrene is metabolized in nasal tissues in the rat and mouse (Morris, 2000). Other P450 inhibitors used for *in vivo* studies include diethyldithiocarbamate (Eriksson and Brittebo, 1995; Deamer and Genter, 1995), carbon tetrachloride (Genter et al., 1994), disulfiram (Deamer and Genter, 1995), 3-aminobenzamide (Eriksson et al., 1996), and cobalt protoporphyrin IX (Chamberlain et al., 1998); the latter depletes P450 by interfering with heme synthesis. Some inhibitors cause inactivation of a subset of P450s, such as xylene and xylene metabolites (Blanchard and Morris, 1994; Vaidyanathan et al., 2003; Foy and Schatz, 2004) and chlormethiazole (Longo et al., 2000). Inhibition of nasal GST-dependent conjugation activity has been achieved by depleting GSH with phorone (Larsson and Tjälve, 1995) or phorone plus L-buthionine sulphoximine (Chamberlain et al., 1998). But, GST expression and activity in mouse olfactory mucosa are unchanged at 24 hr after treatment with polyinosinic:polycytidylc acid to induce acute phase response, while the expression of CYP2E1 was decreased (Weech et al., 2003). In addition, the role of aldehyde dehydrogenase on nasal uptake of inspired acetaldehyde has been examined using cyanamide as an inhibitor. While these inhibitors have been useful for the initial identification of biotransformation enzymes or pathways involved in the metabolism and toxicity of a compound, they are generally not specific for any single enzyme or even a single family of enzymes (e.g., Eriksson et al., 1996; Von Weymarn et al., 2005; D'Agostino et al., 2009). Furthermore, these inhibitors are most likely also toxicants. Therefore, caution should be exercised in interpreting the results obtained using chemical inhibitors as tools. Alternatively, mouse models with targeted gene deletion of specific P450 and other biotransformation enzymes are more preferable.

### 3.6.3 Effects of Mucosal Damage on Nasal Metabolism

Expression of olfactory mucosa P450s and CPR is suppressed when ORNs undergo degeneration either as a consequence of chemical toxicity, unilateral naris closure, or olfactory bulbectomy (Gu et al., 1997; Schwob et al., 1995; Walters et al., 1992, 1993; Sammeta and McClintock,

2010). In the cases of tissue damage caused by exposure to DCBN and methimazole in mice, CYP2A5 expression disappeared in damaged Bowman's glands, but persisted in damaged OE (Piras et al., 2003). In rats treated with methyl bromide, another olfactory toxicant, P450 expression returns to normal following successful regeneration of ORNs, but not when degenerated olfactory mucosa was replaced by respiratory type of epithelium (Schwob et al., 1995). In alachlor-induced tumors in rat olfactory mucosa, neither olfactory marker protein nor CYP2A3 was detected (Genter et al., 2000). The suppressed expression of P450 following olfactory bulbectomy is particularly intriguing since the P450-expressing cells were apparently intact after the operation (Walters et al., 1992). The latter result contrasts with report that the expression of PSTg protein is not affected in the olfactory mucosa following olfactory bulbectomy (Miyawaki et al., 1996). Decreases in GSH and GST levels have also been found in the peripheral olfactory organ of rainbow trout during retrograde olfactory nerve degeneration, which are followed by widespread recovery as the ORNs begin to repopulate the olfactory mucosa (Starcevic and Zielinski, 1997).

Tissue damage resulting from chemically-induced nasal toxicity may underlie some of the *in vivo* inhibitory effects of enzyme inhibitors described in the previous section, as well as the apparent resistance of nasal biotransformation enzymes to xenobiotic induction (Su et al., 1996). Furthermore, although it may appear logical to assume parallel alterations in histopathology and metabolic activity in nasal tissue, interpretation of data from these correlative studies can be complicated by the multifaceted nature of the toxic response. For example, tissue damage may lead to increased influx of immune cells, which may contribute to local metabolic activity.

Another complexity in interpretation of data indicating altered metabolism following exposure to specific toxicants lies in the parallel pathological alterations to the nasal epithelium. Biochemical data are often normalized per mg protein, per mg tissue, per mg mitochondrial or microsomal protein, and so forth. If cellularity has decreased in the tissue (as is often the case in the OE), the normalized data may show no alteration in metabolism, but the total capacity of the tissue to metabolize inhalants may be severely reduced. Conversely, hyperplastic responses may greatly increase the metabolic capacity without altering the normalized biochemical data. Although this problem exists in other tissues as well, the structure of the nasal epithelium and the close association with cartilage and bone make it difficult to control the problem by normalizing to total tissue weight, as can readily be done in most other organs. In addition, toxicant exposure and age are both known to produce metaplastic alteration in the OE. Because these alterations in cell type can also affect metabolic capacity,

close evaluation of both biochemical and histopathological alterations in the interpretation of data from nasal epithelium is necessary for valid extrapolations. Finally, because inhalants can contact and be metabolized in the respiratory or transitional mucosa before reaching the olfactory mucosa, metabolic processes occurring in these nasal mucosa will also affect olfactory processes.

### 3.7 CONCLUSIONS

The olfactory system has several unique properties, which make it interesting as well as important to study. These include its continuous exposures to inhaled environmental toxicants, its vulnerability to cell loss resulting from toxicant insult, and its capacity to regenerate neuronal cells following this loss. In addition, its histological structure, with neuronal cells contacting the external environment at the nasal lumen and projecting directly to the olfactory bulb, makes it a viable portal of entry for inhaled environmental toxicants, as well as a potential route of entry for therapeutic drugs, into the CNS. Although olfaction has traditionally been thought of as a sensory system of minor importance in humans, evidence is accumulating that olfaction plays an important role in learning and memory, hedonic responses, and reproductive function in humans as well as in other species.

Current knowledge on nasal biotransformation enzymes indicate that they are very likely to play important roles in many cellular processes in the olfactory mucosa, as supported by their high metabolic capacity, their diverse substrates of both endogenous and exogenous origins, and their tissue and cell-type specific expression. The precise nature of these roles, which will likely be enzyme specific, is not yet fully understood; however, as reviewed in this chapter, with the increasing availability of knockout mouse and other genetically modified animal models, there are already exciting results.

Nasal biotransformation enzymes can alter inhaled toxicants either by converting them to less toxic metabolites or by activating them to reactive chemicals that result in local damage and in some cases damage to other tissues as well. As such, the role of nasal biotransformation enzymes has historically received most attention in the field of toxicology. The biotransformation capacity in the olfactory mucosa is vulnerable to modification by a variety of toxicant exposures, histological changes, and disease or inflammatory processes. Further, the nasal xenobiotic-metabolism activities will be influenced by genetic polymorphisms of the participating biotransformation enzymes. Thus, the capacity to detoxify or activate inhaled toxicants is likely to be a fluid system best understood with respect to an individual case history and genetic makeup. Future studies on the interactions

of various components of the olfactory system, the activities of individual biotransformation enzymes and their genetic polymorphisms, the link between genetic polymorphisms in biotransformation enzymes and various diseases that involve the nasal tissues, and the impact of nasal xenobiotic-metabolism on other systems such as the CNS will make it possible to identify situations, periods, or individuals of increased vulnerability to inhaled xenobiotics, and to reduce the risk of toxicity through targeted prevention.

### ACKNOWLEDGMENTS

The authors acknowledge Drs. Bert Menco and Virginia Carr for the transmission electron micrograph in Figure 3.1. Research in the authors' laboratory was supported in part by NIH Grants ES07462 and ES020867 from the National Institute of Environmental Health Sciences and CA092596 from the National Cancer Institute.

## Development, Morphology, and Functional Anatomy of the Olfactory Epithelium

JOHN C. DENNIS, SHELLY AONO, VITALY J. VODYANOY, and EDWARD E. MORRISON

### 4.1 INTRODUCTION

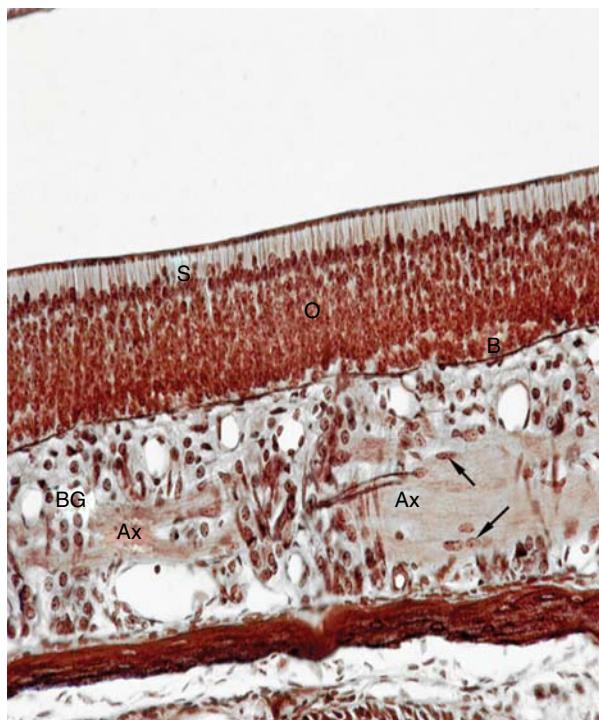

The main olfactory epithelium (MOE) has provided an excellent model for studying several aspects of neural development for more than a century (Bedford, 1904; Ramon y Cajal, 1909). Examination of, and experimentation on, the MOE has produced important insights into adult neurogenesis, remodeling of central synaptic circuits and neuroendocrine functions, to mention a few. Key advances in understanding the MOE were made employing classical histological techniques that described the structural MOE components and a neuroblast population that uniquely separates the MOE from other sensory epithelia (Breipohl et al., 1974; Cuschieri and Bannister, 1975; Graziadei and Monti-Graziadei, 1978; Morrison and Costanzo, 1989). Powerful modern techniques like gene identification and manipulation have allowed further definition of the MOE (Buiakova et al., 1996; Youngentob and Margolis, 1999; Lee et al., 2011).

The MOE has been extensively examined in a number of vertebrates including humans (Costanzo and Morrison, 1989; Engstrom and Bloom, 1953; Graziadei, 1973a; Menco, 1977; Moran et al., 1982; Morrison and Costanzo, 1990) and, in all tetrapod species, the sensory epithelium consists primarily of three cell types: columnar, nonsensory supporting cells, bipolar olfactory receptor neurons (ORNs), and a neuroblast-containing population of basal cells. The underlying lamina propria contains

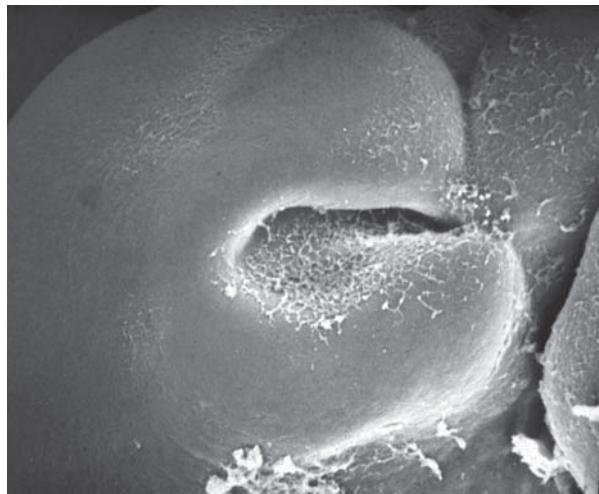

vascular structures, olfactory axon fascicles, and secretory Bowman's glands that are present in all terrestrial vertebrates (Figure 4.1). This chapter reviews the development and cytoarchitecture of the MOE, a recently discovered defense mechanism that protects the olfactory sensory apparatus and the nasal cavity in general, and a novel functional property of ORN signal transduction.

#### 4.1.1 Development of the Olfactory Epithelium

The olfactory placodes develop in the rostral-lateral regions of the embryonic head (Cuschieri and Bannister, 1975; Klein and Graziadei, 1983). The placodal epithelium and adjacent mesenchyme will give rise to the nasal cavity. These ectodermal regions proliferate, thicken, and then form the olfactory pits, which are invaginations that extend into the underlying mesenchyme (Figure 4.2). The nasal pit epithelial organization shows a remarkable similarity to the developing neural tube, namely a proliferating ependymal/ventricular layer and a cellular mantle layer (Figures 4.3 and 4.4). The subsequent development of the nasal cavity involves a concert of molecular signals involving, among others, retinoic acid (RA), fibroblast growth factor, and bone morphogenetic factors from the developing MOE and surrounding mesenchyme (see Beites et al., 2005 for review). Studies have shown that RA signaling

**Figure 4.1** Silver stain of rodent olfactory epithelium illustrates cells of epithelium and underlying structures of the lamina propria. Supporting cell (S); Olfactory receptor neurons (O); Basal cells (B); Olfactory axon fascicles (Ax); Bowman glands (BG); Olfactory ensheathing cells (arrows). (See plate section for color version.)

**Figure 4.2** Scanning electron micrograph of the head region rodent embryo. The olfactory pit forms a groove bounded by lateral and medial nasal processes.

between placode ectoderm and mesenchyme is critical to driving molecular and cellular diversity within the MOE (LaMantia et al., 2000; Rawson and LaManita, 2006). The general process of molecular signaling between

**Figure 4.3** Horizontal section through telencephalon (TEL) and olfactory pit (OP) region of pig embryo. Olfactory pits form a groove as it extends into underlying mesenchyme.

**Figure 4.4** Higher magnification of olfactory pit groove bounded by lateral and medial nasal processes. The epithelium of the developing telencephalon and nasal epithelium are similar in structure with a proliferative region and a cellular mantle (arrows).

mesenchyme and epithelia is not specific to the MOE but is common in the development of complex systems such as limb bud, heart; brachial arches and lower motor neuron development (see Balmer and LaManita, 2005 for review).

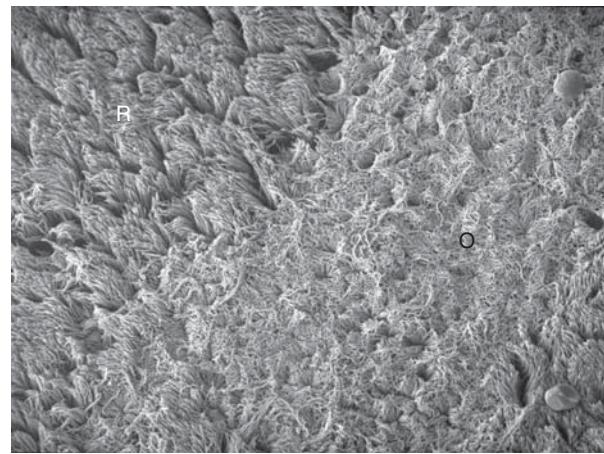

MOE development gives rise to a pseudostratified neuroepithelium composed of several cell types. Mature and immature ORN cell bodies typically occupy the lower two thirds of the neuroepithelium, whereas cell bodies of the non-neuronal supporting cells are located in the upper third. There are two basal cell populations: horizontal basal cells (HBC) that reside along the basal lamina and globose basal cells (GBC) that are located just above the HBC layer.

### 4.1.2 Olfactory Receptor Neuron

The ORN is a true bipolar neuron. A single dendritic process extends from the 5–7  $\mu\text{m}$  cell bodies to the epithelial surface. The dendrite in most vertebrate species terminates in a knob-like swelling with 5–30 sensory cilia, which originate from basal bodies within the dendritic knob. In some fish, reptile, and bird species the dendrite is covered with microvilli similar to those of vomeronasal neurons. Proximally, olfactory cilia resemble typical motile non-sensory cilia in that microtubules are present in a 9 + 2 arrangement. As they extend to form a dense blanket on the epithelial surface, the cilia taper and may contain only a few microtubules (Figure 4.5) (Graziadei, 1973b; Menco, 1977; Morrison and Costanzo, 1990). Although motile respiratory cilia and olfactory sensory cilia have a similar morphology, olfactory cilia typically extend relatively long distances from their dendrites, forming a dense network that greatly increases their sensory surface area (Figure 4.6). Individual transmembrane odorant receptors (OR) are located on the olfactory cilia. The classic work of Buck and Axel (1991) led to the understanding that each olfactory receptor neuron expresses only one of ~1000 olfactory receptors on the ciliary processes (Mombaerts, 2004). The OR is a seven transmembrane G-protein coupled receptor that, following the binding of an odorant, activates the signal cascade that results in olfactory receptor neuron depolarization (see below).

### 4.1.3 Microvillar Cells

Microvillar cells have neuron-like morphology and are observed in the apical neuroepithelium. These cells have a thin unmyelinated axon arising from the basal cell body which courses through the basal lamina (Figure 4.7). These cells have been observed in humans,

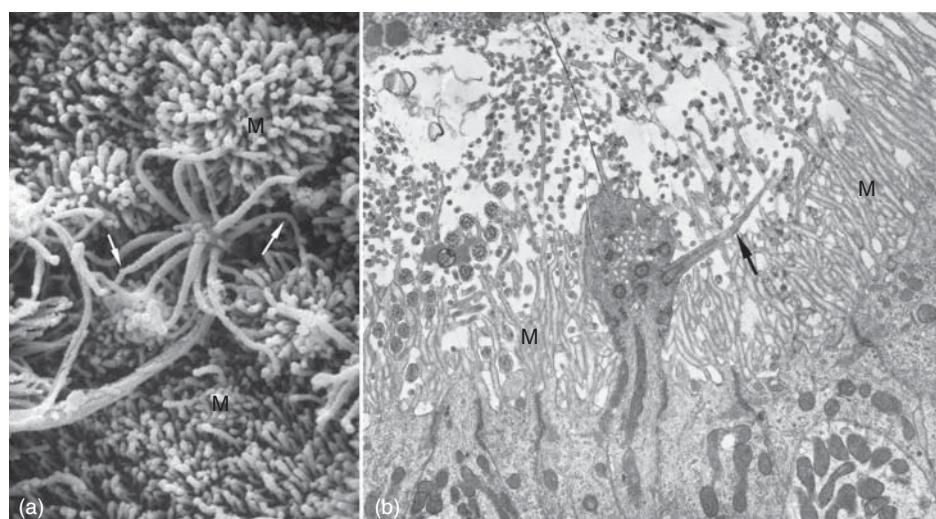

**Figure 4.6** Surface view of human nasal mucosa illustrating the morphological differences between the respiratory (R) and sensory olfactory cilia (O). The olfactory cilia extend over the mucosa surface forming a dense cilia network.

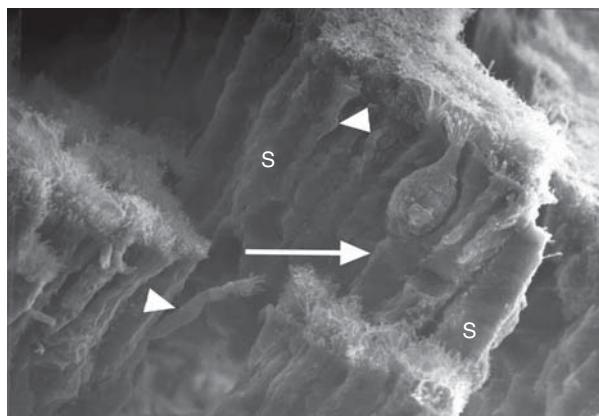

canines, rodents, and turtles. The function and cell lineage of the microvillar cell is unknown (Okano et al., 1967; Graziadei, 1973a; Moran et al., 1982; Morrison and Costanzo, 1990).

### 4.1.4 Basal Cells

The structure of the MOE has been compared to that of the developing neural tube of the embryonic CNS but the MOE only gives rise to one neuron type. Like the neural tube, the dividing MOE neuroblast stem cell layer is located basally. Olfactory basal cells are located in the lower epithelial compartment near the basal lamina (Figure 4.1). Two types of basal cells have been identified in vertebrates: horizontal and globose. Horizontal basal

**Figure 4.5** (A) Human olfactory epithelium illustrating a dendritic knob located between microvillar supporting cells (M). Olfactory dendrites can have 5–30 tapering ciliary processes (arrow). (B) Transmission electron micrograph of rodent olfactory dendritic knob. Gradually tapering sensory cilia (arrows) arise from basal bodies in the cytoplasm. Supporting cell microvilli (M).

cells (HBCs) contain tonofilaments and are immunoreactive to anti-cytokeratin antisera. Globose basal cells typically reside above the HBCs and are cytokeratin negative. Early studies by Graziadei and Monti-Graziadei and others showed that the basal cells contain a neuroblast population that constitutively divides to replace olfactory receptor neurons normally and following injury (Figure 4.8) (Graziadei and Monti-Graziadei, 1978; Graziadei and Monti-Graziadei, 1979; Costanzo, 1985; Huard et al., 1998; Schwob, 2002). Studies from several groups showed that the HBC is a relatively quiescent population that lacks neuronal markers and divides slowly, similar to the ependymal cells lining the post natal ventricles (Holbrook et al., 1995). The GBCs differ morphologically and biochemically: they are round, do not express

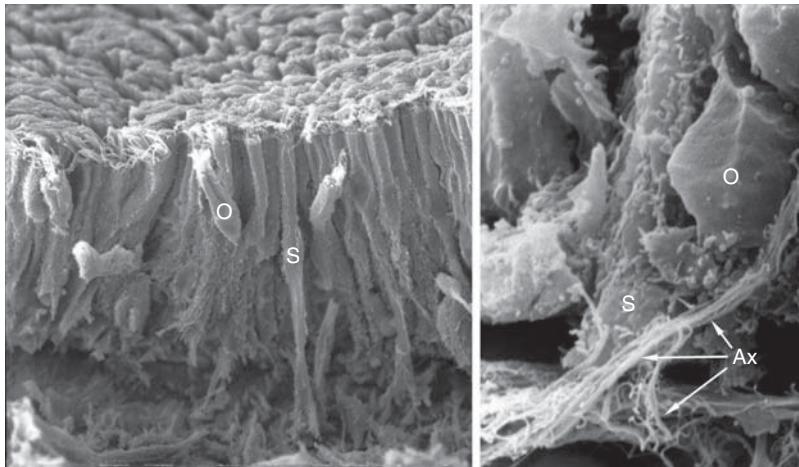

cytokeratin and give rise to a line of MASH-1 positive, transit amplifying cells. These in turn produce a second line of intermediate precursors, which subsequently divide and produce terminally differentiated ORNs (Caggiano et al., 1994; Beites et al., 2005; Nicolay et al., 2006). Thus, the GBCs are the proliferative cell population within the MOE and the HBCs may be regarded as the tissue stem cells (Mackay-Sim, 2010; Suzuki et al., 2013). The HBC lineage is thought to be of placode origin. Recently, it was demonstrated that the MOE contains neural crest derived cells (NCDC) that comingle with the placode and olfactory pit (Forni et al., 2011). Using a transgenic mouse strain that expresses EGFP-tagged NCDCs, Suzuki et al. (2013) observed labeled HBCs in adult MOE that were of both NCDC and placode origin. These observations, along with NCDCs recently discovered in post-natal inner ear (Freyer et al., 2011) and eye (Yoshida et al., 2006), suggest that NCDCs may have a common “back up” function as tissue stem cells in sensory organs. The findings that the MOE contains both placode and pluripotent neural crest cells is exciting and opens research avenues via which to examine NCDC potential in regenerative medicine.

#### 4.1.5 Supporting Cells

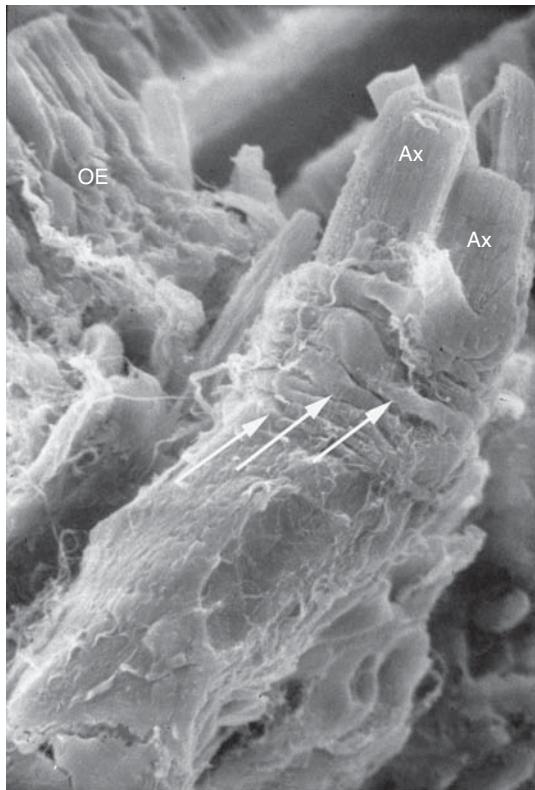

The supporting cell is a columnar cell that spans the epithelium. Supporting cell nuclei form the most superficial row of epithelial cell nuclei. Their apical surfaces project short microvilli into the overlying mucus (see Figure 4.5). Throughout their length, supporting cells are intimately associated with the olfactory neurons via intercellular bridges/appendages connecting the two cell types. In the basal region the supporting cell has a foot process that anchors it to the basal lamina (Figure 4.9) (Rafols and Getchell, 1983; Costanzo and Morrison, 1989; Morrison and Costanzo, 1989). Supporting cells express enzymes involved in metabolism of foreign compounds, suggesting a glia-like protective role of the neuronal environment. Recent studies demonstrated that defensins, a family of antiviral and antibacterial proteins, are expressed in the MOE (see below). Although additional studies are necessary to identify the cellular origin of defensins, it is tempting to speculate that supporting cells secrete these peptides in the MOE. Supporting cells are also phagocytic and, like CNS glia, provide structural support. The lineage of supporting cells is still unclear. Transplantation of GBCs into an experimentally degenerated MOE in mice gave rise to both olfactory neurons and supporting cells. However, some supporting cells labeled as neural crest-derived have been observed in the MOE, suggesting both placodal and neural crest origin (Chen et al., 2004; Forni et al., 2011).

**Figure 4.8** Light microscopy of olfactory epithelium 5 days following injury. Mitotic activity is located in the basal cell (globose) region of the neuroepithelium (arrow).

Olfactory receptor neuron (O); Small olfactory axon fascicles (Ax).

**Figure 4.10** Scanning electron micrograph of the lamina propria region. Olfactory axons (Ax) are surrounded by the cytoplasmic processes of the (arrows). Olfactory epithelium (OE).

#### 4.1.6 Olfactory Ensheathing Cells

The olfactory ensheathing cell (OEC) is a glia type cell associated with axons (Figure 4.10). Axon fascicles are surrounded by OEC cytoplasmic processes, which form a mesaxon for each fascicle (Figure 4.11). OECs express

**Figure 4.11** Fractured olfactory epithelium illustrates olfactory neurons (O) and basal lamina. Growing olfactory axon with a growth cone on the leading edge can be observed (arrow). From Morrison and Costanzo, 1989.

GFAP and S-100, cytoplasmic markers for CNS glia (Au and Roskams, 2003). For many years the origin of OECs and Schwann cells has puzzled investigators (Chuah and Au, 1991). Indirect evidence suggested similarities between these two cell types based on morphology and molecular markers. The recent studies by two separate groups (Forni et al., 2011; Katoh et al., 2011) showed that pluripotent neural crest cells are present in the olfactory placode and give rise to OECs. The neural crest also gives rise to Schwann cells. These results help explain the high

level of biological and molecular similarity between OECs and Schwann cells.

OECs have been shown to promote axon growth and recovery in several nerve lesion models, suggesting that their presence is responsible for the permissive and dramatic olfactory axogenesis (Mackay-Sim and St. John, 2011). A recent clinical study of canine spinal cord injury transplants showed unequivocally that transplanted OECs enhanced locomotor improvement (Granger et al., 2012). These exciting results suggest that OECs can mediate substantial change in function in local intraspinal tracts.

#### 4.1.7 Migrating Cells

As mentioned above, the olfactory placode is capable of generating a number of different cell types. There are also indications that migratory cell types present in the developing MOE are directed toward the developing telencephalon. Early observations by Bedford (1904) showed cells leaving the placode and forming cords within the adjacent mesenchyme. Later investigators described this mass of cells and axons as the “migrating mass” (Valverde et al., 1992). Some of these migrating cells are related to olfactory functions. Among these are OECs that play an important role in guidance of the migrating mass (Doucette, 1990; Chuah and West, 2002). Another cell type not directly related to olfaction but which migrates along MOE/VNO axons is the gonadotropin releasing hormone (GnRH1) cell. These cells are dependent on the guidance cues of developing peripherin-positive axons to transverse several complex terrains to ultimately reach the developing diencephalon. Gonadotropin releasing hormone neurons are a population of cells with a key role in vertebrate sexual development and behavior (Schwanzel-Fukuda and Pfaff, 1989; Wray et al., 1989).

Although these migrating cells are observed leaving the placodal epithelium, their origin has been unclear (Mendoza et al., 1982). Studies using a transgenic mouse model system examined the possible contribution of cranial neural crest derived cells. The olfactory placode and cranial neural crest are closely positioned to each other and mixing of the tissues has long been suggested (Couley and Le Douarin, 1985). Forni et al. (2011) used two complementary mouse systems to label NC and placode ectoderm contributions. They showed that pluripotent NC cells mingled with placode ectoderm and gave rise to olfactory ensheathing cells and GnRH1 expressing neurons.

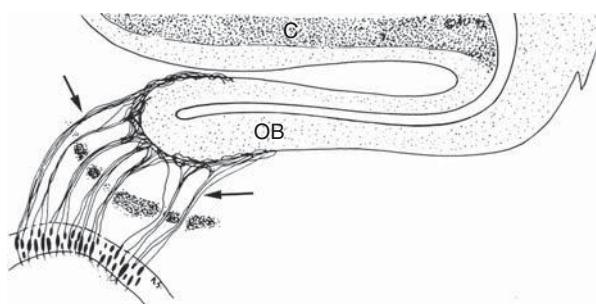

The developing vertebrate head relies a great deal on the interactions between the two ectodermal derivatives NC and cranial placodes. Previous studies have proven NC origin and cellular contributions to ectodermally derived cranial placodes (D'Amico-Martel and Noden, 1983). These findings not only offer new insights into olfactory development but also a rich field of investigation into GnRH1

neurons and the olfactory system, and could provide insight into NC defects and anosmia associated with normal and pathological development of the olfactory system.

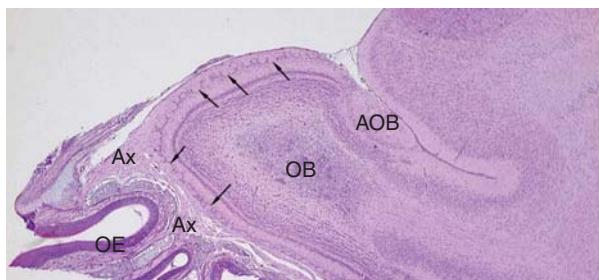

#### 4.1.8 Olfactory Nerve and Olfactory Bulb Formation

An axon process arises from the basal aspect of the olfactory receptor neuron. At its tip is a growth cone. The growing axon and growth cone must navigate through the mesenchyme to reach the telencephalon (Figure 4.12). The growth cone guides the axon by providing the motile force for their extension and by acting as exquisite sensors that detect and subsequently respond to a variety of environmental guidance cues. Growth cone associated cell surface receptors interpret these signals as attractive or repulsive forces (Mueller, 1999). The definitive cues that guide olfactory axon development and growth towards the telencephalon are not fully understood. No doubt guidance cues and signpost (e.g., semaphorins, slit, ephrin, and netrins) within the mesenchyme and possible chemotactic cues from the CNS direct and attract axon growth cones. One unique feature of the olfactory growth cone is the expression of a seven transmembrane olfactory receptor that plays a critical role for the axon to target the olfactory bulb (Feinstein and Mombaerts, 2004).

Pearson (1941), in his classic study on the development of the human olfactory nerve, noted that “the development of the olfactory bulb reminds one of Kipling's story *The Elephant's Child*.” Pearson was not suggesting that the axons were “pulling” part of the telencephalon to form the olfactory bulb, but that the olfactory axons influence bulb development. When the axons reach the telencephalon there is no evidence of olfactory bulb formation. After the axons grow into the brain, a protrusion from the telencephalon begins to develop, forming the rudimentary olfactory bulb. The olfactory axons increase in number, forming the presumptive olfactory nerve layer. They enter

**Figure 4.12** Diagram of olfactory axons growing from the nasal cavity reaching the developing olfactory bulb (OB). At the time olfactory axons reach the neural tube the olfactory bulb arises out of the ventral aspect of the telencephalon.

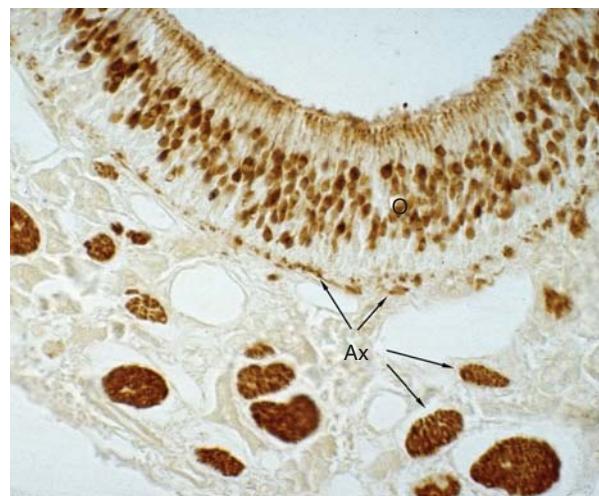

**Figure 4.13** Low power light micrograph of rodent olfactory primary neuraxis. Olfactory epithelium (OE). Olfactory axons (Ax). Olfactory bulb (OB). Accessory olfactory bulb (AOB). Glomeruli (arrows). (See plate section for color version.)

the developing olfactory bulb, ultimately forming the glomerular layer (Figures 4.12 and 4.13). A small population of axons penetrates the ventricular zone where they are thought to stimulate genesis of the olfactory bulb (Gong and Shipley, 1995). However, recent studies in mutant mice that lack an olfactory epithelium revealed that an olfactory bulb-like structure develops in the rostral telencephalon. The exact nature of the signal(s) that induce olfactory bulb formation are not fully understood and warrant further studies.

#### 4.1.9 Olfactory Marker Protein

Olfactory marker protein (OMP) is a widely recognized molecular marker of mature olfactory neurons (Margolis, 1972). It is the first powerful marker for fully differentiated olfactory receptor neurons and provides a key tool to investigate the dynamic relations between peripheral sensory neurons and central connections with the olfactory bulb. Olfactory marker protein is a low molecular weight soluble protein found almost exclusively in the mature olfactory neuron cell body, dendrites, and axon processes and is absent from the other cell components of the olfactory epithelium (Figure 4.14). OMP expression is developmentally regulated. Beginning at embryonic day 14 its expression reaches the adult level at postnatal day 30 (P30) and coincides with synapse formation on second-order olfactory bulb neurons (Farbman and Margolis, 1980; Graziadei et al., 1980).

Although OMP is present in a wide range of vertebrates and is highly conserved, its full function is still unclear. Genetic manipulations and deletion of OMP results in slower odorant response kinetics in EOG, single cell recordings, and calcium imaging (Lee et al., 2011; Kwon et al., 2009). Behaviorally, OMP<sup>-/-</sup> mice exhibit reduced odorant sensitivity and altered odor discrimination (Youngentob and Margolis, 1999; Youngentob et al., 2001). Developmentally, patch clamp recordings from the first postnatal month show functional changes with P30

**Figure 4.14** Olfactory marker protein immunohistochemistry of the rodent MOE. Mature olfactory receptor neurons (O) and axon fascicles of varying size (arrows) are OMP+. (See plate section for color version.)

showing greater odor sensitivity, indicating OMP may play a role in ORN maturity. Taken together, these observations illustrate that OMP exerts its molecular and cellular actions at multiple sites (Buiakova et al., 1996; Lee et al., 2011).

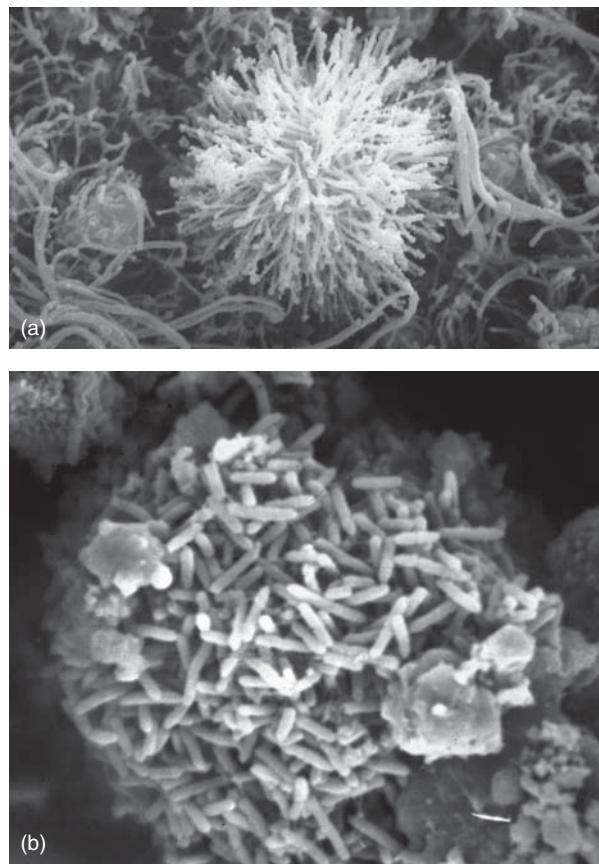

#### 4.1.10 Innate Immunity in the Main Olfactory Epithelium

Epithelia and leukocytes contribute to a physical and biochemical barrier called innate immunity in mammals, the first line of defense against pathogenic insult. Defensins are a family of small cationic peptides and have a wide range of antibacterial, antiviral, antifungal, and antiparasitic activity, being part of the biochemical barrier. Originally identified in the 1980s as part of the antibiotic arsenal of neutrophils, defensin and defensin-like peptides have since been found throughout the Metazoa, as well as in plants. The amino acid sequence among the 40 human defensins so far identified varies greatly but it is the highly conserved tertiary structure upon which the classification of these peptides is based. In the amino acid sequence, six cysteine residues are conserved and the pairing of these, which forms three disulfide bridges, is the basis for identifying  $\alpha$  and  $\beta$  subfamilies (reviewed in Ganz, 2003; Lehrer and Lu, 2012; Weinberg, 2012; Carvalho and Gomes, 2009; Gachomo et al., 2012). Marsupial and placental mammal expression of both  $\alpha$ - and  $\beta$ -defensins is highly compartmentalized. For example, Paneth cells express defensins that regulate intestinal flora (Cunliffe, 2003; Wehkamp et al., 2006). Down regulation of paneth cell  $\alpha$ -defensin expression and secretion is associated with inflammatory bowel disease (Crohn's disease) in the

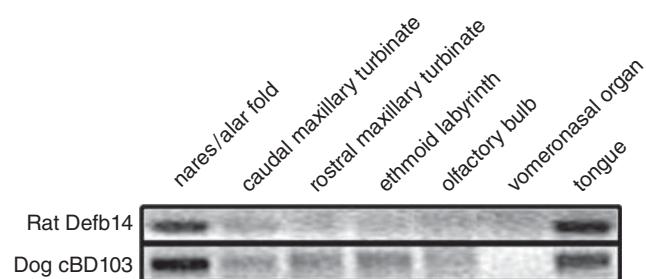

ileum (Fahlgren et al., 2003; Wehkamp et al., 2005; Gersemann et al., 2011). By contrast, colonic Crohn's disease is correlated with low  $\beta$ -defensins 2 and 3 (Wehkamp et al., 2002; Fellermann et al., 2006; Gersemann et al., 2008). More  $\beta$ -defensins than  $\alpha$ -defensins have been identified and  $\beta$ -defensins are thought to be evolutionarily more ancient. Primarily secreted by epithelial cells, some  $\beta$ -defensins are constitutively expressed, while others are induced by cytokines, pathogen associated molecular patterns (PAMPs), and pro- or anti-inflammatory cytokines (Hao et al., 2001; Harder et al., 2001; Joly et al., 2005; Batoni et al., 2006).

Defensins exert their antibiotic activity through disruption of the target's lipid bilayer and binding glycoproteins in the case of anti-viral activity (Kagan et al., 1990; Klotman and Chang 2006). Secondary effects may be derived from interactions with intracellular components such as liposomes, RNA, and DNA (Zasloff, 2002; Sahl et al., 2005) and chemoattractant properties, which recruit cells of the adaptive immunity system (Taylor et al., 2008). Antibiotic potency varies between defensins and depends upon environmental factors such as oxygen levels, salt concentrations, serum proteins, and proteases (Harder et al., 2001; Maisetta et al., 2008; Schroeder et al., 2011; Goldman et al., 1997). Unlike other innate immunity genes, some defensins show high copy number variation which, coupled with tissue specific expression and large variations in interindividual expression, may contribute to disease susceptibility and tissue specific pathogen resistance (Linzmeier and Ganz 2005; Vankeerberghen et al., 2005; Linzmeier and Ganz 2006; Wehkamp et al., 2006; Kisich et al., 2007; Milanese et al., 2009; Zanger et al., 2011).

The MOE is an avenue via which pathogens enter the CNS and defensins are variably expressed in all parts of the nasal cavity (Figures 4.15A and B) (Zanusso et al., 2003; Mori et al., 2005; Sjölander and Jonsson 2010). Human  $\beta$ -defensins (hBD) 1, 2, and 3 all show variable expression in rostral nasal tissues and secretions (Cole et al., 1999; Laudien et al., 2011). Of these three defensins, hBD3 is thought to be the most potent against a wide variety of pathogens and works synergistically with other antibiotic agents (Lee et al., 2002; Matthews et al., 1999). hBD3 is critical for oral keratinocyte-mediated killing of *Staphylococcus aureus*, a common opportunistic pathogen in both the oral and nasal cavities (Maisetta et al., 2003; Kisich et al., 2007). In the nasal cavity, hBD3 is mainly expressed in the *vestibulum nasi*, which is the colonization site of *S. aureus* (Laudien et al., 2011). In vivo, reduced cutaneous hBD3 expression is coincident with persistently elevated carriage of *S. aureus* in the nares, a risk factor for hospital-acquired, as well as recurrent, infections (Huang and Platt, 2003; Zanger et al., 2010; Zanger et al., 2011). Canine and rat hBD3 orthologues show similar expression

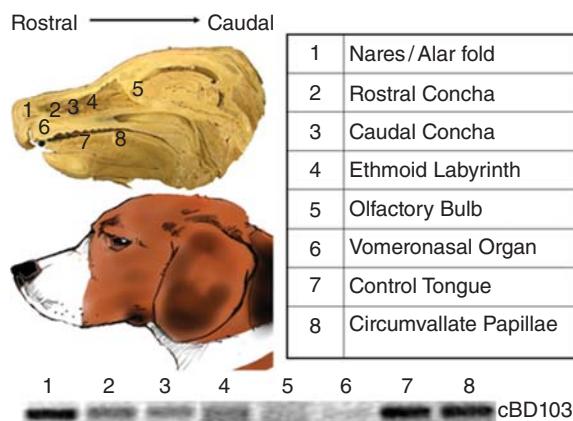

**Figure 4.15** Foreign particles and pathogens can reach the olfactory region and cause irritation/infection causing an inflammatory responses. (a) Pollen grain embedded on the surface of the olfactory mucosa. (b) Bacteria (*Edwardsiella ictaluri*) infection of olfactory mucosa.

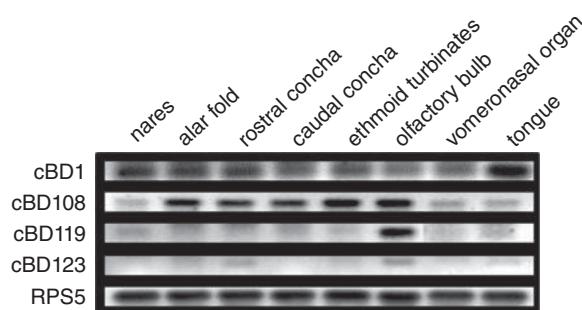

**Figure 4.16** RNA expression of rat  $\beta$ -defensin 14 and canine  $\beta$ -defensin 103 (human  $\beta$ -defensin 3 paralogs) in oronasal tissue.

patterns (Figure 4.16), with the highest hBD3 mRNA levels in stratified squamous epithelia. This suggests that hBD3 in nasal secretions may originate from the rostral tissues in the nasal cavity (Figure 4.17), offering limited protection to caudal tissues, including the olfactory neurons.

**Figure 4.17**  $\beta$ -defensin 103 (cBD103) RNA expression in canine olfactory bulb (brain) and oronasal tissues and their anatomic locations. cBD103 expression is representative of 15 dogs. However, some interindividual variation was visible, especially in the rostral and caudal concha samples.

**Figure 4.18** Canine  $\beta$ -defensin 1, 108, 119 and 123 RNA expression in the oronasal cavity and olfactory bulb (brain) of a single dog. Antibiotic activity and function in the innate immune system of the nasal cavity is not yet known. RPS5 is a reference gene.

Canine  $\beta$ -defensin (cBD) 1, 108, 119, and 123 transcripts were detected in nasal cavity respiratory epithelium, the MOE, and the olfactory bulb (Figure 4.18), indicating they may protect the caudal portions of the nasal cavity. Previous work has shown these cBDs are variably expressed in the trachea, lung, and skin (Erles and Brownlie, 2010; Leonard et al., 2012) but most of these  $\beta$ -defensins are not well characterized, so their role in the innate immunity of the nasal cavity and central nervous system remains to be elucidated.

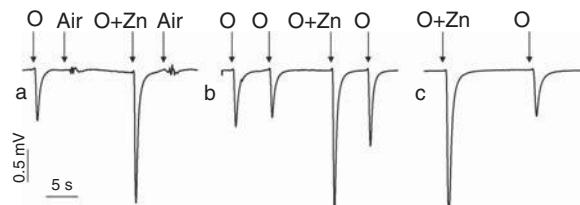

#### 4.1.11 Zinc Nanoparticles and Olfactory Receptor Neuron Signaling

Zinc is essential for normal physiological function and, in humans, is the second most abundant trace element (see Takeda, 2001 and references therein). The CNS

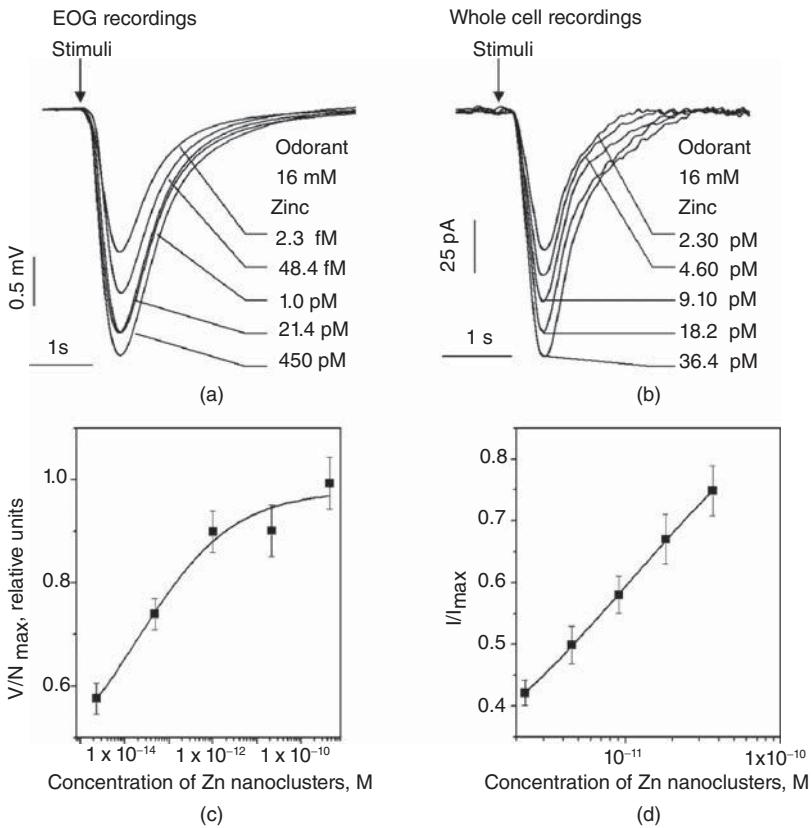

contains zinc and its local concentrations and subcellular segregation are tightly regulated (Howell and Frederickson, 1990; Christensen et al., 1992; Jo et al., 2000a; Danscher et al., 1985). Throughout the CNS, zinc ions are largely sequestered in synaptic vesicles and released into the synaptic cleft during signal transmission. These zinc-containing neurons are called zinc-enriched neurons (ZENs) and, in the forebrain, constitute a subpopulation of glutamatergic neurons. Changes in zinc concentration are associated with pathologies that include Alzheimer's disease, amyotrophic lateral sclerosis, depression, and epilepsy (reviewed in Bitanihirwe and Cunningham, 2009; Takeda and Tamano, 2009). In particular, perturbations in zinc concentrations caused by various agencies result in a decline of olfactory acuity or inappropriate responses to olfactory cues (Mackay-Sim and Dreosti, 1989; Takeda et al., 1999). The OB contains one of the largest populations of ZEN terminals in the brain and these are concentrated in the granule cell and glomerular layers (see Figure 4.13) (Jo et al., 2000b; Friedman and Price, 1984). ZENs synapsing on granule cells are centrifugal axons, just over half of which come from the anterior olfactory nucleus (Carson, 1984). The zinc positive axons in the glomerular layer are the terminals of main olfactory sensory neurons (Jo et al., 2000b). In both regions, zinc is a modulator of OB neuron activity (Ferraris et al., 1997; Trombley and Shepherd, 1996).

In the context of zinc's functions and spatial sequestration in the CNS generally, and the olfactory system specifically, Vodyanoy and coworkers began experiments with metallic (nonionic) zinc nanoparticles. Samoylov et al. (2005) isolated metallic nanoparticles from the blood of several vertebrate species. Subsequent analysis showed that zinc constituted a subset of these serum borne metals leading Vodyanoy (2010) to hypothesize that, given zinc's significant functions in the olfactory system, metallic zinc nanoparticles would affect signal transduction across the main olfactory sensory neuron membrane.

Odorants containing zinc clusters in nanomolar concentrations produced increased responses in both

**Figure 4.19** EOG recordings from rat olfactory epithelium. Responses were induced by a mixture of odorants (O) each at 16 mM; air; or odorants with zinc nanoparticles at 10 pM (O+Zn). Representative traces were obtained from one tissue sample with 10 contacts and 39 traces.

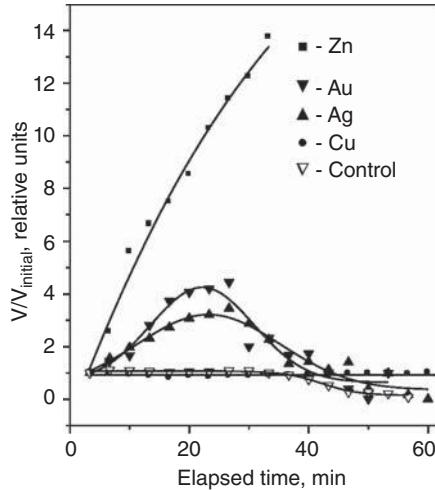

**Figure 4.20** EOG and single cells recordings from rat MOE exposed to odorant + zinc nanoparticles at constant odorant concentration. The stimulus was a 0.25 second (s) air pulse or odorant + zinc nanocluster. (a) Representative EOG traces in 4 tissues, 10 contacts, and 34 EOG recordings. (b) Whole cell current traces from olfactory neurons with holding potentials at  $-70$  mV. Downward direction represents inward current. Representative traces were obtained from 23 recordings and a total of 198 traces. (c) Normalized peak EOG voltage ( $V/V_{\max}$ ) plot of odorant + zinc particles and zinc nanocluster concentration. (d) Normalized peak negative current ( $I/I_{\max}$ ) plot of odorants + zinc particles and zinc nanocluster concentration.

EOG (Figure 4.19) and single-cell recordings made from freshly dissected MOE (Figure 4.20) (Moore et al., 2012; Viswaprakash et al., 2009) and in EOG recordings made from tissue-culture preparations (Viswaprakash et al., 2010). The increased responses were reversible (Figure 4.19) and dose dependent (Figure 4.20). Zinc particles alone elicited no response.

The same experiments were repeated with gold, silver, or copper nanoparticles at 5 nM in 16 mM odorant mixtures (Figure 4.21). Both gold and silver elevated EOG responses, although the relative amplitudes were smaller and their effective durations were attenuated relative to zinc. The metals' effects peaked at about 20 minutes and then began to decline, whereas zinc's effects continued to increase EOG amplitude. Silver nanoparticles in solution also increase EOG responses in a fish species at low concentration but at higher concentrations silver nanoparticles reduced EOG response amplitudes (Bilberg et al., 2011).

Tissues exposed to 5 nM copper nanoparticles with odorants responded at control levels to about 40 minutes. At that time, activity evoked by odorants alone began to decline but the tissue's response in the presence of copper nanoparticles continued at a constant level. This observation indicates that copper can modulate sensory neuron activity. However, we cannot conclude that copper is a functioning modulator in the odorant/receptor signal transduction complex *in vivo*.

**Figure 4.21** Relative EOG amplitudes showing metal effects on responses to a 16 mM odorant mixture delivered in 0.25 s puffs. The recording pipette contained zinc, gold, silver or copper nanoclusters at 5 nM or no metal as a control. The first trace for each metal was made immediately following contact. Subsequent traces were recorded at 200 s intervals. Representative data were recorded as follows. Zinc: 3 tissue samples, 4 contacts, 60 recordings, 450 traces; Gold: 1 tissue sample, 2 contacts, 28 recordings, 221 traces; silver: 2 tissues, 4 contacts, 58 recordings, 460 traces; copper: 1 tissue, 2 contacts, 23 recordings, 172 traces; control: 2 tissues, 37 recordings, 340 traces.

The supposition that copper is active at the MOE apical surface is not baseless since copper is involved in modulating OB neuron signaling activity (Trombley and Shepherd, 1996) and zinc and copper would have modulating functions throughout the olfactory system's primary neuraxis. It must be noted that the observations enumerated above concern the effects of metallic nanoparticles. Ionic forms of these metals inhibit olfactory responses: zinc ions in rats (Viswaprakash et al., 2009); silver ions in a carp species (Bilberg et al., 2011); and copper ions in a salmon species (Kennedy et al., 2012). This modulating behavior of copper nanoparticles at the MOE apical surface in vitro suggests that zinc and copper have functions throughout the primary neuraxis of the olfactory system and, in the MOE, mirrors the two metals' modulating effects in the OB reported by Trombley and Shepherd (1996).

Using a straightforward theoretical model, the binding stoichiometry of odorant and zinc displayed in single cell recordings can be calculated (Vodyanoy, 2010). Patch clamp data derived from a number of experiments yields a Hill coefficient suggesting that two odorant molecules are needed to activate one receptor/G<sub>olf</sub> complex. The Hill coefficient for zinc nanoclusters was approximately 0.5, which means that one zinc particle binds two receptors in a given receptor activation event. These values are consonant with theoretical and empirical observations reported by other investigators (Giraldo, 2008; Connors, 1987; reviewed in Kleene, 2008). Taken together, the best explanation for these data is that signal transduction across the sensory neuron membrane results from the dimerization of receptor molecules. The entire transduction complex would be composed of two receptor molecules, a zinc particle, and one G<sub>olf</sub> heterotrimer.

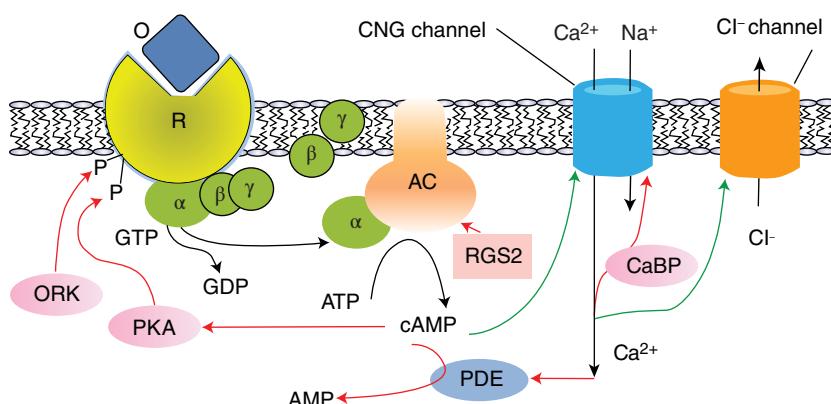

These findings corroborate reports of G protein-coupled receptor (GPCR) dimerization in general (reviewed by Milligan, 2004) and, more specifically, sensory system GPCR dimerization like that of rhodopsin in the vertebrate retina (Fotiadis et al., 2003). An early study of MOE proteins characterized a 19 kD band by sodium dodecyl sulfide polyacrylamide gel electrophoresis.

Gel filtration produced a native 38 kD homodimer and binding kinetics with the pepper-derived odorant 2-isobutyl-3-[<sup>3</sup>H]methoxypyrazine. Such observations suggested that the polypeptide was an odorant receptor with two odorant binding sites when dimerized (Pevsner et al., 1985). A second study by Dean and co-workers (2001) used a second method, the evolutionary trace, to analyze and model the pertinent helices in a number of GPCRs, including olfactory receptor homodimerization. More recently, insect receptors were shown to form heterodimers (Sato et al., 2008; Neuhaus et al., 2005). Finally, Wade et al. (2011) was able to establish stable heterologous human QR1740 receptor G-protein complex expression in the yeast *Saccharomyces cerevisiae*. Using bioluminescence resonance energy transfer together with immunoprecipitation and immunoblotting to analyze membrane fractions, Wade and co-workers demonstrated that, in the heterologous system, functional olfactory receptor units were homodimers. But contrary to Vodyanoy's (2010) calculated stoichiometry, as well as previous analyses, Wade et al. (2011) report a single odorant binding event necessary to precipitate signal transduction.

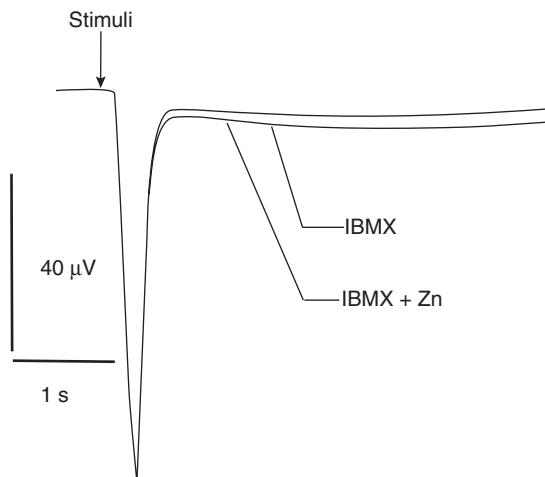

In vitro EOG signal amplification and single cell recordings facilitated by zinc nanoparticles is documented. The question then becomes where in the signal transduction cascade zinc has its effect? In general, odorant binding causes adenylate cyclase activation and subsequent synthesis of the second messenger cAMP (Figure 4.22). In turn, cAMP synthesis leads to the opening of nucleotide and calcium gated channels, which activate the sensory neuron. The signal is terminated by the phosphodiesterase catalyzed degradation of cAMP (reviewed by Kleen, 2008).

EOG responses are elicited without odorant from MOE tissue following application of the phosphodiesterase inhibitor 3-isobutyl-1-methylxanthine (IBMX). Addition of zinc nanoparticles does not affect IBMX-induced EOG responses indicating that zinc does not act on the ion channels (Figure 4.23) (Moore et al., 2012).

Since metallic zinc alone does not evoke a response, the effect is not at the level of cAMP production or activation

**Figure 4.22** In a generalized schematic of signal transduction, an odorant (O) binds a receptor molecule and the G-alpha ( $\alpha$ ) subunit activates adenylate cyclase (AC). AC activation produces cAMP the production of which opens the cyclic nucleotide gated calcium channels.

**Figure 4.23** EOG response induced by a pulse of 400  $\mu\text{M}$  IBMX with and without 4 nM zinc nanoparticles. The figure shows representative traces from 3 tissues and 25 recordings.

of adenylate cyclase. Taken together, these data indicate that zinc's site of action is the olfactory receptor/G-protein complex. Although zinc ions inhibited MOE response to odorants in the experiments outlined above, these observations do not contradict Turin's proposed model (1996) of odorant induced signal transduction at the MOE surface. One possibility is that the nanoparticles bind at the apical surface and release zinc ions (Vodyanoy, 2010). These ions would be the source of electrons that are involved in the tunneling proposed by Turin.

## Olfactory Receptor Function

KEIICHI YOSHIKAWA and KAZUSHIGE TOUHARA

### 5.1 INTRODUCTION

In the natural environment, a complex chemical space is constructed by a variety of compounds that are emitted from organisms and other sources. Such compounds include small volatile organic compounds, inorganic gases, and peptidic molecules, and are produced via multiple metabolic processes. These environmental compounds provide critical information for the survival of an animal, as they reflect the existence of food, predators, and conspecifics. Environmental compounds are specifically detected and processed by the mammalian olfactory system, a system that has a remarkable capacity to recognize and discriminate numerous compounds. The olfactory neural system begins within a large neuroepithelium termed the olfactory epithelium (OE) located in the roof, superior conchae, and septum of the nasal cavity (Figure 5.1). The OE contains millions of olfactory sensory neurons (OSNs) which extend ciliated dendrites to its surface. In addition, the OSNs project axons that synapse with second order neurons in the olfactory bulb (OB). The fundamental role of the OSNs is to detect environmental information and convey it to secondary neurons.

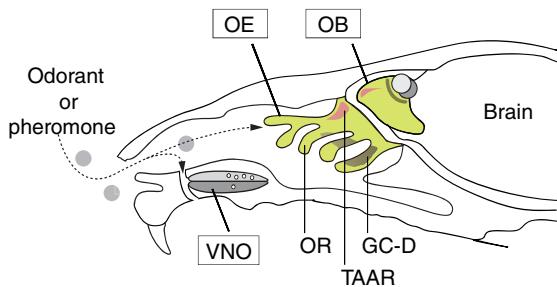

The underlying molecular basis of olfactory capacity is the large variety and number of olfactory receptors expressed on the sensory neurons. Olfactory receptors are defined on the basis that they are: (1) expressed in OSNs, (2) function to detect specific environmental chemical cues, and (3) initiate intracellular signal transduction which ultimately drives action potential generation in neurons. The discovery of the first mammalian olfactory receptor family, the odorant receptor (OR) family, initiated the molecular era of olfactory research. This achievement

has become the template for the identification of other types of mammalian olfactory receptors. Currently, three types of olfactory receptors have been shown to be expressed in a distinct subpopulation of OSNs. Each olfactory receptor detects specific cues and contributes to the remarkable capacity of olfaction. Detection of these specific cues provides animals not only with odor perception, but also several physiological and behavioral effects. This chapter discusses the expression, structure, signal transduction pathways, and ligand identity of each type of olfactory receptors, with an emphasis on their physiological function.

### 5.2 VERTEBRATE ODORANT RECEPTORS

#### 5.2.1 Discovery of the Odorant Receptor Multigene Family

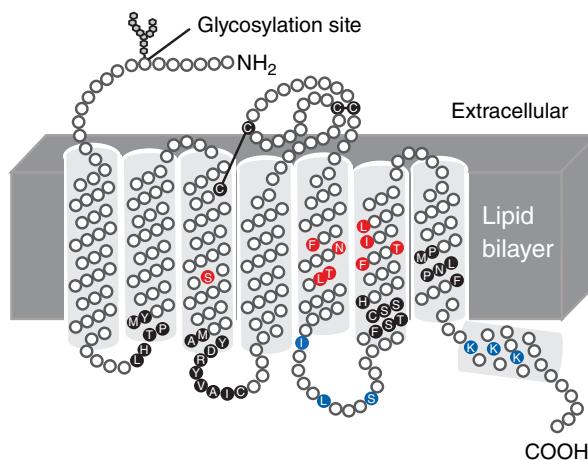

In 1991, Buck and Axel isolated and cloned OR genes based on three criteria (Buck and Axel, 1991). First, they assumed that ORs belong to the G protein-coupled receptor (GPCR) family. This was due to the finding that the activation of OSN by odorants resulted in the production of the G protein-mediated second messenger cAMP, which subsequently induced action potentials in the OSN (Nakamura and Gold, 1987; Pace et al., 1985). Second, ORs should be encoded by a multigene family with a capacity to distinguish numerous distinct odors. Third, ORs should be specifically expressed in the OE. The investigators then used a series of degenerate oligo-nucleotides designed according to conserved amino acid sequences in a variety of GPCRs to amplify the sequence of GPCRs expressed in rat OE. Resulting PCR products were then selected using the

**Figure 5.1** Schematic representation of the rodent olfactory system anatomy. Sagittal view of the rodent head showing the olfactory system. Stimulus molecules are transported into the nasal cavity, and reach two neuroepithelia known as the olfactory epithelium (OE) and the vomeronasal organ (VNO) epithelium. The vast majority of OSNs express ORs (green), whereas a distinct subpopulation of sensory neurons expresses TAARs (magenta) or GC-D (grey). The axons of OSNs project to a distinct area on the OB, termed glomeruli. Necklace glomeruli, where GC-D neurons project, are shown in gray, and axons of TAAR-expressing OSNs target to a distinct dorsal area of the OB (magenta). (See plate section for color version.)

second criterion of whether the product consisted of multiple related genes. Finally, the OE-specific expression of the candidate genes was verified, and described as a novel multigene family encoding putative OR. The identified genes encoded proteins that possessed common structural features in GPCRs. That is, the proteins contained seven putative trans-membrane regions, a glycosylation site in the extracellular N-terminal region, and putative disulfide bonds between the conserved cystein molecules in the extracellular loops (Figure 5.2).

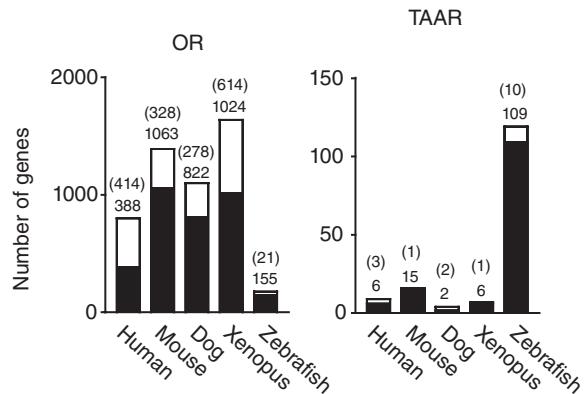

ORs are commonly distinguished from other GPCRs by several consensus motifs including a LHTPMY motif

**Figure 5.2** Molecular structure of the odorant receptor. The membrane topology of the OR is shown. Common amino acid sequences among ORs are shaded black. Key amino acid residues involved in odorant binding and G protein-coupling are shown in red and blue, respectively. (See plate section for color version.)

within the first intracellular loop, a MAYDRYVAIC motif at the end of trans-membrane segment 3 (TM3), FSTCSSH at the beginning of trans-membrane segment 6 (TM6) and PMLNPF in trans-membrane segment 7 (TM7) (Fleischer et al., 2009). These conserved motifs are thought to contribute to the maintenance of the normal conformational states of nascent OR proteins. ORs are also known to possess relatively variable amino acid residues within trans-membrane segments that are involved in ligand binding (Abaffy et al., 2007; Katada et al., 2005).

Using genome analysis, all tetrapod animals have been shown to express between 400 and 4,200 OR genes, including 20–60% pseudogenes (Nei et al., 2008; Niimura et al., 2014). In humans and the mouse, the number of intact OR genes is 396 and 1130, respectively (Figure 5.3). These numbers indicate that the OR gene family represents the largest gene family present in the entire genome. In each animal, OR genes are distributed throughout the genome and are generally found as small clusters. Phylogenetically, OR genes are categorized into nine classes known as  $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$ ,  $\varepsilon$ ,  $\zeta$ ,  $\eta$ ,  $\theta$ , and  $\kappa$ , each of which originated from distinct ancestral genes. Among the nine classes, the ORs identified in the genome of tetrapods are largely of the  $\alpha$  and  $\gamma$  classes. These classes are widely known as class I and class II ORs, respectively (Niimura and Nei, 2005). The remaining seven classes of ORs are expressed mainly in fish and amphibians. These findings suggest that these seven classes of OR are able to detect water-soluble compounds, whereas ORs of the  $\alpha$  and  $\gamma$  classes likely function to detect terrestrial volatile odorants (Nei et al., 2008). Two forms of OR nomenclature have been reported and include the Zhang and Firestein nomenclature (Zhang and Firestein, 2002), and the mouse genome informatics (MGI) nomenclature. The latter being the one most currently used.

**Figure 5.3** Total number of olfactory receptor genes in vertebrates. The black and white bars represent the number of intact genes and pseudogenes, respectively. The number shown above the bar indicates the number of intact genes and pseudogenes (parentheses). These findings were taken from Nei et al., 2008 and Niimura et al., 2014.

It took approximately seven years following the seminal discovery of the putative OR gene family for evidence of OR mediation of OSN response to odorants to be obtained. This long delay was largely due to difficulties in functionally expressing ORs in cell lines. Thus, the first verification of OR function was achieved using an *in vivo*-based approach where adenovirus-mediated over-expression of cloned OR I7, a rat orthologue of mouse Olfr2, in rat OSNs (Zhao et al., 1998). The infected rat OE showed a greater response to odorous aliphatic aldehydes. This suggested that the OR I7 gene encoded a receptor for aldehydes. A separate approach was based on the logic that a single OSN specifically expressed only one of a thousand OR genes, and that the OR should be responsible for responsiveness of the OSN to particular odorants. Thus, from an odorant responsive OSN, an OR gene was cloned using degenerate primers that recognized conserved sequence motifs (Malnic et al., 1999; Touhara et al., 1999). Subsequent demonstration that functionally cloned OR genes actually functioned as receptors for odorants was performed using adenovirus-mediated over-expression of OR in OSNs to verify their responsiveness (Touhara et al., 1999). The hallmark of these achievements was taking advantage of *in vivo* OSN machinery. These achievements also highlighted a lack of knowledge of the components responsible for functional expression of ORs in heterologous cells.

### 5.2.2 Development of Functional Assay Systems

The *in vivo*-based analysis of specific ORs was often complicated by the presence of endogenous ORs. In most cases, heterologous expression allows for a clear analysis of single receptor function. However, when an OR gene was exogenously introduced into cell lines, nascent OR protein was retained in the endoplasmic reticulum (ER) and subsequently degraded (Lu et al., 2003; McClintock et al., 1997). Consequently, the OR protein was not expressed on the cell surface membrane. Therefore, it was presumed that OSN contained specific molecular machinery that allowed for the expression of nascent OR protein at the cell surface, however, corresponding components did not exist in cell lines.

The first major success in heterologous expression of an OR was achieved in 1998. Krautwurst et al. (1998) designed a chimeric OR where the N-terminal sequence of the OR was extended with N-terminal 20 amino acids of bovine rhodopsin (Rho-tag). This strategy was based on a previous finding that rhodopsin could be expressed on the membrane of HEK293 cells, and that the N-terminal motif was required for membrane transport (Sung et al., 1991). These Rho-tagged OR proteins were successfully expressed on the cell surface of HEK293 cells and were activated by cognate ligands, resulting in intracellular signaling (Krautwurst et al., 1998). The activity of the

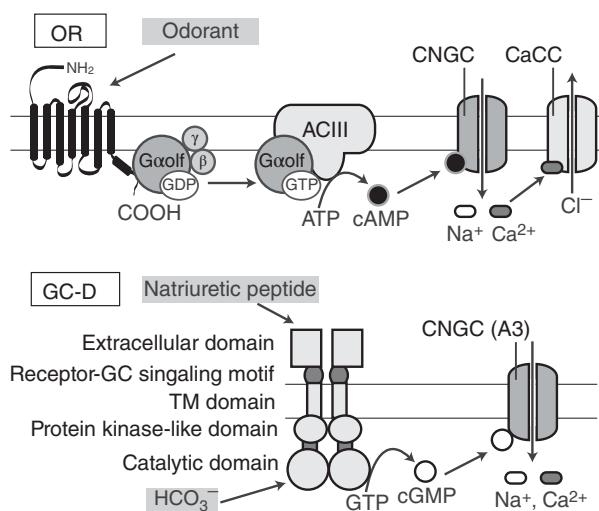

N-terminal epitope tag underlying the promotion of membrane expression was attributed to an increase in the glycosylation sites of the OR protein (Katada et al., 2004). A later study suggested that the ligand specificity and sensitivity of ORs were not modulated by the additional sequence (Zhuang and Matsunami, 2007). This approach paved the way for the characterization of numerous ORs. However, difficulties still remained in achieving heterologous expression for the large majority of ORs.

In 2004, trans-membrane proteins called receptor transporting proteins (RTPs) were discovered to act as chaperones of ORs from RNAs expressed in mouse OSNs (Saito et al., 2004). Receptor expression enhancing proteins (REEPs) were also identified in the OSNs, but were shown to exhibit lesser activity (Saito et al., 2004). Among the four members of RTP genes, RTP1 and 2 were found to be expressed in OSNs, and promoted membrane expression of ORs in heterologous cells. A more recent report demonstrated that RTP1 exhibited multiple roles in the expression of functional ORs (Wu et al., 2012). These functions included permitting the exit of ORs from the ER, trafficking ORs from Golgi to the cell membrane, and formation of co-receptors required for the modulation of OR activity. Collectively, RTPs are known to greatly enhance OR-mediated signaling in a heterologous cell.

Resistant to inhibitors of cholinesterase 8 homologue B (Ric-8B) also functions as a modulator of functional OR expression. Ric-8B is expressed in the OE and, when introduced into heterologous cells, amplifies the OR-mediated intracellular signaling (Von Dannecker et al., 2005; Von Dannecker et al., 2006; Yoshikawa and Touhara, 2009). Two distinct molecular mechanisms underlying Ric-8B activity have been proposed. The first mechanism involves the maintenance of G protein expression levels, while the second mechanism involves GPCR-dependent guanine nucleotide exchange factor (GEF) (Chan et al., 2011; Kerr et al., 2008; Nagai et al., 2010). Due to the short ligand-dwelling time of OR, an OR-ligand complex has a low probability of coupling with a cognate G protein in order to catalyze GDP-GTP exchange (Bhandawat et al., 2005). Ric-8B may work to increase the probability of coupling by ensuring adequate levels of G proteins on the cell surface, and to re-activate the small number of G proteins that have been previously activated by ORs. Although the precise physiological relevance of RTPs and Ric-8B in OSNs remains to be determined, the introduction of these factors in combination with the fusion of N-terminal epitope tags proved pivotal in overcoming the difficulties in the functional expression of OR in heterologous cells. To date, approximately 10% of murine ORs have been functionally expressed in heterologous cells and paired with their cognate ligands (Glatz and Bailey-Hill, 2011; Saito et al., 2009).

### 5.2.3 OR-Mediated Signal Transduction and Modulation of OR Activation

A fundamental role of ORs is to initiate intracellular signal transduction, a role that ultimately produces action potentials in the OSNs (Mombaerts, 2004). At the ciliary membrane of OSNs, an agonist-bound OR is coupled to the olfactory specific G protein  $\text{G}\alpha_{\text{olf}}$ , which subsequently activates adenylyl cyclase III (ACIII) OSNs, resulting in an intracellular increase in cAMP levels (Figure 5.4) (Breer et al., 1990; Kleene, 2008). The cAMP positively regulates the open probability of cAMP-sensitive cyclic nucleotide-gated (CNG) channels. These channels are heterotetramers comprised of four subunits termed CNGA2, CNGA4, and CNGB1b, with a stoichiometry of 2:1:1 (Nakamura and Gold, 1987; Zheng and Zagotta, 2004). The CNG channel causes calcium influx and subsequent opening of calcium-gated chloride ion channels (Kurashiki and Yau, 1993; Leinders-Zufall et al., 1997; Lowe and Gold, 1993). The membrane depolarization of OSNs caused by these ion permeations is the precipitating event for generation of action potentials in the OSNs. This signaling pathway is widely accepted as a canonical pathway, due to the anosmic phenotype of mice lacking the  $\text{G}\alpha_{\text{olf}}$ ,

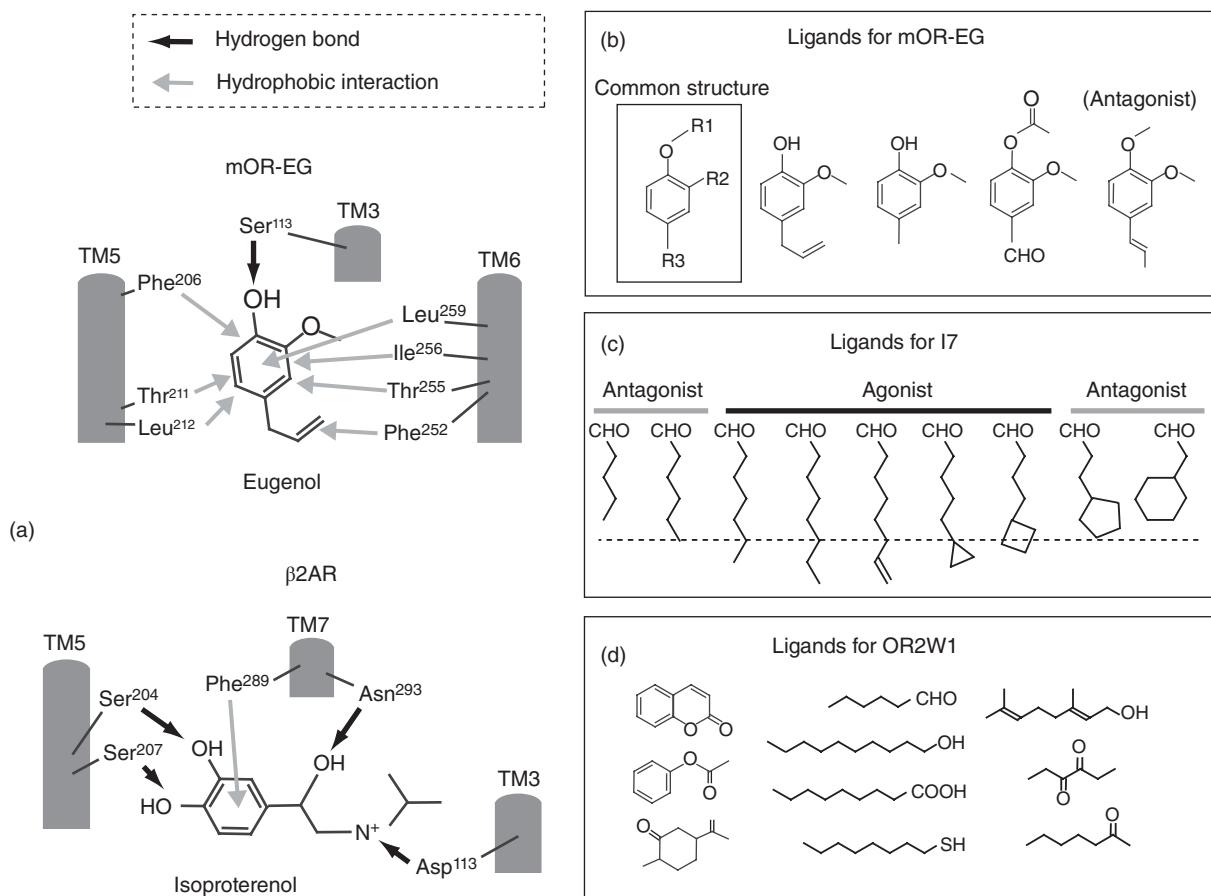

**Figure 5.4** Signal transduction mediated by olfactory receptors. (Upper panel) In OSNs, the OR activates signal components in order of heterotrimeric  $\text{G}\alpha_{\text{olf}}$  and ACIII. CNG channel (CNGC) is composed of CNGA2, CNGA4 and CNGB1b. Opening of the two types of ion channels, CNGC and a  $\text{Ca}^{2+}$ -dependent  $\text{Cl}^-$  channel, leads to membrane depolarization. (Lower panel) The GC-D exhibits the catalytic activity in response to extracellular binding natriuretic peptide or intracellular binding  $\text{HCO}_3^-$ . This results in an intracellular increase in cGMP that stimulates gating of the CNG channel complex, including the CNGA3 subunit. The opening of the CNG channel results in membrane depolarization via influx of  $\text{Ca}^{2+}$  and  $\text{Na}^+$ .

ACIII, or CNG channel (Belluscio et al., 1998; Brunet et al., 1996; Wong et al., 2000). More recent studies argue that anoctamin 2, also known as TMEM16B, contributes to OR-mediated signaling as a calcium-gated chloride ion channel in the OSNs (Reisert et al., 2003; Reisert et al., 2005; Stephan et al., 2009).

In addition to the established OR signaling pathways, recent studies have revealed several mechanisms thought to modulate OR activation and signal transduction in OSNs. In order to initiate signal transduction, ORs are localized on the cell surface of OSNs, most likely in conjunction with RTPs. Co-localization of OR with RTP1 on lipid rafts of a heterologous cell membrane is known to be essential for normal OR activation (Wu et al., 2012). RTPs may also form complexes with some ORs on the surface of the ciliated membrane and may modulate their signaling efficacy through orthosteric or allosteric mechanisms. A Gq-coupled receptor termed M3 muscarinic acetylcholine receptor (M3-R) has been shown to be expressed on the cilia of OSNs, and has the potential to modulate OR-mediated signaling (Li and Matsunami, 2011). When co-expressed with ORs in heterologous cells, M3-R may physically interact with various ORs in order to amplify their signal, but does not affect the expression level of OR proteins. Interestingly, the active state of M3-R further enhances OR-mediated signals, whereas inactive M3-R reverses this effect. Although the precise molecular mechanisms underlying these events remains unclear, the hypothesis that non-olfactory GPCRs modulate OR activity is supported by further observations, including the finding that the purinergic receptor P2Y, the G protein-coupled 2 (P2Y2) receptor, and the  $\beta 2$  adrenergic receptor ( $\beta 2\text{AR}$ ) enhance the function of some ORs (Bush et al., 2007; Hague et al., 2004). Ache and co-workers found that phosphoinositide-3-kinase (PI3K) inhibited OR-mediated signal transduction in OSNs (Ukhanov et al., 2011). Blockade of PI3K with inhibitors resulted in a significant enhancement of odorant-mediated calcium response of OSNs. This result is in line with previous observations that  $\text{PIP}_3$ , which is generated by PI3K, negatively regulates olfactory CNG channels (Brady et al., 2006; Zhainazarov et al., 2004). It would be interesting to determine whether acetylcholine or a hormonal compound that activates PI3K in OSNs is secreted in the OE under distinct physiological conditions such as nutritional changes and the estrus cycle.

### 5.2.4 Structural Basis of the Ligand Binding Mode and G Protein Coupling

The development of *in vitro* functional assay systems has allowed investigators to address various questions regarding how ORs bind to their cognate agonist and activate  $\text{G}\alpha_{\text{olf}}$  in OSNs. ORs are generally classified into class-A

**Figure 5.5** Ligand-binding and tuning modes of the odorant receptor. (a) Comparison of the ligand-binding mode of mOR-EG (upper schematic) versus that of  $\beta$ 2AR (lower schematic). For mOR-EG, binding of eugenol is achieved via numerous hydrophobic interactions and only one hydrogen bond with Ser<sup>113</sup>, whereas  $\beta$ 2AR forms four hydrogen bonds with isoproterenol. (b) Representative ligand repertoire of the mouse OR mOR-EG. (c) Ligand repertoire of I7. Dashed line shows length requirement for receptor activation. Short chain aldehydes are able to bind to I7 but are not able to activate. (d) An agonist repertoire of the relatively non-specific OR OR2W1.

family GPCRs which contain GPCRs including rhodopsin and  $\beta$ 2AR (Jacoby et al., 2006). GPCRs in the class-A family are activated by small ligands whose ligand binding sites are contained within a cavity formed by the seven trans-membrane domains. The agonist-bound activated GPCRs couple to cognate G proteins with their intracellular loops and C-terminus region (Liggett, 2002; Liggett et al., 1991; Nikiforovich et al., 2007). The structural basis of ORs shares similarity with that of the other members of class-A family GPCRs.

Computational docking simulation and rational receptor design in combination with site-directed mutagenesis resulted in the successful definition of odorant binding sites in the murine OR mOR-EG, also known as MOR174-9 or Olfr73 (Katada et al., 2005). Consistent with other class-A type GPCRs, ligand binding sites in the mOR-EG are mainly formed by several amino acid residues that reside in TM3, TM5, and TM6 (Figure 5.2).

A characteristic feature of the OR in the ligand binding mode is that the vast majority of the critical amino acid residues involved in odorant binding are hydrophobic (Katada et al., 2005). Thus, ORs associate with cognate odorants via weak hydrophobic interactions, in contrast to other GPCRs including  $\beta$ 2AR, that bind ligands mainly via electrostatic interaction (Figure 5.5a, (Klabunde and Hessler, 2002)). This weak ligand binding may in turn result in a relatively low affinity ( $\mu$ M order) and short life span of the OR-ligand complex (<1 ms) (Bhandawat et al., 2005). Despite the low affinity of ORs, mammalian species show extremely high sensitivity to many odorants (pM-nM order). This discrepancy may be attributed to the presence of the nasal mucus that covers the OSNs layer (Oka et al., 2006). The nasal mucus may play a role in trapping odorants and presenting them to the OSNs in a timely and spatially concentrated manner.

It has been proposed that a specific molecular basis of ORs may exist for the recognition of divalent sulfur-containing odorants. A recent study has shown that the presence of copper ion at a physiological level (30  $\mu\text{M}$ ) enhances the response of MOR244-3 (Olfr1509)-expressing HEK293 cells to a series of sulfur-containing odorants (Duan et al., 2012). This copper ion-induced enhancement was abolished when the H105 residue in MOR244-3 contained a mutation. Molecular modeling of MOR244-3 has predicted that H105 is located between TM2 and TM5 facing the extracellular side, thus representing a potential copper-associating amino acid residue. The authors of the study proposed the hypothesis that the complex of copper ions and divalent sulfur compounds exhibits a more appropriate size to match the binding site of ORs and present a more stable interaction with the ORs. This metal ion-mediated OR-ligand recognition may serve as the molecular basis which accounts for our high sensitivity to sulfur compounds such as the warning agent added to natural gas, 2-methyl-2-propanethiol.

When an OR binds to an agonist, the OR undergoes conformational change and consequently couples to G $\alpha$ olf (Kato and Touhara, 2009). Mutagenesis studies have revealed that OR-coupling to G $\alpha$ olf is achieved via a series of conserved amino acid residues located in the third intracellular loop and C-terminal domain (Figure 5.2), (Kato et al., 2008). The crystal structure of the OR is yet to be determined. Recent isolation of large quantities of ORs may aid in the construction of high-resolution crystal structures of ORs, and provide further insight into the structural basis of ORs in the future (Cook et al., 2009).

### 5.2.5 Ligand Selectivity

A variety of organic compounds that have a molecular weight of less than M.W. 300 and that contain a relatively hydrophobic motif are odorous to humans. A recent study suggests that the human nose has the potential to distinguish a trillion different odorants (Bushdid et al., 2014). Against the numerous odorants, each of the hundreds of ORs show a distinct breadth of molecular receptive range, from narrowly tuned to broadly tuned. Most ORs recognize a variety of compounds that share a common structural backbone or a functional group. For example, the mouse OR mOR-EG is activated by more than 25 compounds, most of which contain a phenol moiety in their chemical structure (Figure 5.5b), (Katada et al., 2005). These relatively selective ORs may also recognize compounds that are structurally similar to agonists as competitive antagonists (Figure 5.5c), (Oka et al., 2004; Peterlin et al., 2008). In contrast, a relatively non-specific OR, such as human OR2W1, is activated by some 37 compounds of 63 odorants tested that do not share a structural backbone or functional groups (Figure 5.5d) (Saito et al., 2009).

Generally, ORs exhibit a relatively broad ligand spectra compared with other GPCRs for hormones and neurotransmitters. This is most likely due to the finding that the ligand binding mode of ORs is based on weak hydrophobic interactions.

On the other hand, ORs also show high selectivity in the discrimination of closely related structures. MOR139-3 discriminates meta-cresol from the ortho and para geometric isomers (Yoshikawa and Touhara, 2009). MOR107-1 (Olfr323) recognizes the (–) enantiomer of fenchone, but not the (+) enantiomer, while MOR271-1 (Olfr168) is activated by the (+) enantiomer only (Saito et al., 2009). These broad but selective molecular receptive ranges appear to allow humans to recognize and discriminate between numerous odorants. It is worth noting that the ligand selectivity of ORs observed in the screening of synthetic odorant collections does not necessarily reflect the physiological context. Olfr288, which is able to recognize at least eight different synthetic lactone-derivatives, appears to be specifically tuned to (Z)-5-tetradecen-1-ol in the urine of male mice against a background of several exocrine gland secretions (Yoshikawa et al., 2013). Thus, although ORs apparently exhibit a relatively broad ligand spectrum against synthetic odorants, they may demonstrate significant selectivity in a natural environment.

An important question in olfactory research is whether odor quality is encoded in the periphery. It may be hypothesized that each OR is responsible for a distinct odor quality and that distinct OR-expressing OSNs are innervated by an individually tuned area of the brain. However, it has been demonstrated that a pair of odorants that represent different odor qualities can activate the same OR, whereas the same odorant can activate multiple ORs. These observations, and the fact that humans are able to recognize numerous odorants, led to the proposition of the combinatorial coding model. This model suggests that among the hundreds of ORs, an activated OR pattern is transmitted to higher brain areas to define an odor quality. Nevertheless, there are a few examples in which an odorant appears to be encoded by an extremely small number of ORs (Keller et al., 2007). OR7D4 is identified as a human OR for androstenone ( $5\alpha$ -androst-16-en-3-one). Large scale OR screening using a heterologous cell line suggested that detection of androstenone is achieved mainly by OR7D4. Muscone, a macrocyclic ketone with fascinating fragrance, is recognized mainly by MOR215-1 in mice and probably by OR5AN1 in humans (Shirasu et al., 2014). In the case of such a specific OR-ligand pair, the efficacy of the single OR-mediated signaling can directly affect the odor perception of individuals. Genetic variation of human OR7D4 includes two amino acid substitutions which impaired responsiveness to androstenone *in vitro* and led to reduced sensitivity in human subjects.

### 5.3 A NOVEL MEMBER OF THE VERTEBRATE OLFACTORY RECEPTORS IN THE OLFACTORY EPITHELIUM

The possibility that additional classes of olfactory receptors exist in the OE has also been suggested. This suggestion was based on previous findings. First, minor populations of OSNs do not possess the OR signaling component G<sub>olf</sub>, implying that these OSNs contain a different molecular mechanism for the recognition of environmental cues (Meyer et al., 2000). Second, the OE shows a remarkable ability to recognize diverse compounds beyond the small odorous molecules. It has been reported that major histocompatibility complex peptides induce calcium response in some OSNs of the OE (Spehr et al., 2006). In addition, the detection of a murine pheromone was thought to be achieved not only in the vomeronasal organ (VNO), an accessory olfactory system, but also in the OE (Boehm et al., 2005; Restrepo et al., 2004; Yoon et al., 2005). These observations suggest that some OSNs express novel types of receptors for peptides and/or pheromones.

#### 5.3.1 Trace Amine-Associated Receptors

In 2006, a second class of olfactory GPCRs, termed trace amine-associated receptors (TAARs), was identified as the receptor for volatile amines (Liberles and Buck, 2006). An enriched population of OSNs was isolated from the OE using cell sorting for endogenous  $\beta$ -galactosidase activity. The candidate genes encoding novel chemosensory GPCRs were then screened using real-time quantitative PCR with primers designed against GPCRs that did not include previously known chemosensory receptors. The identified TAAR genes encoded proteins that were classed into the class-A GPCR family, but were unrelated to ORs. Rather, TAARs were found to be distantly related to bioactive amine receptors such as the serotonin and dopamine receptors. The TAAR genes were identified in several vertebrate species including fish and human (Figure 5.3), (Gloriam et al., 2005; Nei et al., 2008). The total number of TAAR genes is thought to be smaller than that for the OR. One exception to this rule is the zebrafish, which has a similar number of intact genes encoding ORs (155 genes) and TAARs (109 genes). The human and mouse genome has been shown to contain 6 and 15 intact TAAR genes, respectively.

In the murine OE, TAARs (excluding TAAR1) are expressed in a minor population of OSNs in a mutually exclusive manner (Figure 5.1; Liberles and Buck, 2006). That is, an OSN expressing one particular TAAR gene does not co-express other members of TAARs. In addition, TAARs-expressing OSNs are unlikely to co-express

any ORs. Thus, it is conceivable that TAARs define the response specificity of a subset of OSNs. A recent study demonstrated that the TAAR-expressing OSNs innervate a distinct population of glomeruli from those connected with ORs-expressing OSNs (Johnson et al., 2012; Pacifico et al., 2012). In order to convert volatile amine-signal to an electrical signal in OSNs, TAARs may utilize a similar signal transduction mechanism to ORs. In OSNs, TAARs are co-expressed with G<sub>olf</sub>, suggesting active TAARs couple to G<sub>olf</sub> and initiate cAMP signaling (Liberles and Buck, 2006). This is supported by the finding that TAARs increase intracellular cAMP when expressed in a heterologous cell (Liberles and Buck, 2006). Furthermore, the electrical response in the OE to volatile amines was shown to disappear following disruption of genes encoding ACIII or the CNG channel (Brunet et al., 1996; Wong et al., 2000).

It had been presumed that TAARs are able to recognize volatile amines in the OE, as TAARs were originally shown to act as receptors for amines such as tyramine in the brain (Borowsky et al., 2001). Indeed, functional assays using a heterologous cell line provided evidence that TAARs recognize a series of odorous amines with unique selectivity and sensitivity (Liberles and Buck, 2006). Until recently, 7 of the 15 mouse TAARs (mTAAR1, mTAAR3, mTAAR4, mTAAR5, mTAAR7b, mTAAR7e and mTAAR7f) have been paired with 1–4 of the cognate amine agonists (Ferrero et al., 2012; Liberles and Buck, 2006). One of human TAARs has also been shown to recognize volatile amines (Wallrabenstein et al., 2013). TAAR-expressing OSNs can respond to volatile amines at nanomolar range (Pacifico et al., 2012; Zhang et al., 2013). Thus, TAAR repertoire mediates high sensitivity detection of volatile amines.

To address where TAARs bind to ligands, mutagenesis analysis on TAAR1 was conducted that focused on the potent endogenous agonist 3-iodothyronamine, which is a derivative of the thyroid hormone (Tan et al., 2009). This study suggested that the ligand-binding site of TAAR is located in a trans-membrane region, a finding that is consistent with recent works indicating that a key amino acid residue that defines ligand specificity is located in TM3 of TAARs (Ferrero et al., 2012). The ligand-binding site of a TAAR contains the charged amino acid residue aspartic acid that forms a salt bridge with an amine group located in the ligand. In addition, TAARs also contain several amino acid residues that may be involved in hydrogen bonding to the ligand, which is similar to the epinephrine-binding mode of  $\beta$ 2AR (Figure 5.5A).

In contrast to ORs, TAARs demonstrate a relatively low copy number throughout vertebrate species and a specific projection pattern to the OB. These findings imply that TAARs play an important role in olfaction. Some TAARs appear to be involved in the detection of chemosignals that trigger an innate behavioral response. The volatile amine 2-phenylethylamine, which is highly abundant in

the urine of carnivore species, acts as a key chemosignal for the avoidance of predators in rodents (Ferrero et al., 2011). 2-Phenylethylamine present in carnivore urine is finely recognized and discriminated by the mouse TAAR4. When mice smell 2-phenylethylamine in carnivore urine, they exhibit an avoidance behavior. TAAR4-deficient mice did not show avoidance behavior to 2-phenylethylamine (Dewan et al., 2013). Thus, TAAR4-expressing OSNs may contribute to the formation of a hard-wired aversion circuit. Thus, TAARs appear to play an important role in the detection of chemosignals utilized in intra-species chemical communication.

### 5.3.2 Guanylyl Cyclase D

In 1995, the olfactory-specific receptor guanylyl cyclase D (GC-D, *Gucy2d*) was cloned from the rat OE using degenerate primers that recognized conserved motifs within the guanylyl cyclase receptor (Fulle et al., 1995). The expression of GC-D transcripts was restricted to a small (less than 0.1%), randomly dispersed, population of OSNs located among the OR-expressing OSNs (Figure 5.1). GC-D-expressing OSNs demonstrated a typical bipolar morphology (Fulle et al., 1995; Zufall and Munger, 2010). That is, the cell body extended a single dendrite containing sensory cilia and a single axon. The axons of the GC-D neuron specifically projected to a set of interspersing glomeruli that form a “necklace” structure at the caudal area of the OB (Juifls et al., 1997). In addition, the GC-D neuron utilized a distinct signal transduction pathway when compared to the majority of OSNs that expressed ORs or TAARs. The GC-D neurons were also shown to lack canonical signaling components of ORs including Gaolf, ACIII, and the cAMP-sensitive CNG channel subunits CNGA2 and CNGB1b (Juifls et al., 1997; Meyer et al., 2000). Instead, these neurons were found to express the cGMP-specific CNG channel subunit CNGA3, cGMP-stimulated phosphodiesterase PDE2, and GC-D. This expression of signaling components suggests that GC-D neurons mainly utilize cGMP as a second messenger to mediate conversion of environmental signals to a neuronal response. We now know that GC-D neurons form part of the molecular basis of environmental cue detection, and transmit information to secondary neurons through intracellular cGMP signaling (Figure 5.4) (Zufall and Munger, 2010). The gene encoding GC-D is thought to have become a pseudogene early in primate evolution, indicating that the underlying molecular and cellular mechanisms do not exist in primates.

Today three chemosensory functions of GC-D neurons have been suggested through studies identifying different types of agonists including natriuretic peptides, carbon dioxide, and carbon disulfide. Early research in this field demonstrated that mammalian receptor guanylyl cyclases

functioned as receptors for hormonal natriuretic peptides, or functioned as a component of GPCR-dependent signaling via photoreceptor-specific GC-E and GC-F (Bennett et al., 1991; Kuhn, 2009; Potter et al., 2006). The natriuretic peptides were originally shown to be secreted from the atrium and ventricle of the heart in response to the expansion of blood volume (Dietz, 2005; Field et al., 1991; John et al., 1995). The hormonal activities of natriuretic peptides include the stimulation of salt excretion and the dilation of blood vessels to lower blood pressure. The natriuretic peptide target receptor guanylyl cyclase expressed in the vascular smooth muscle stimulates guanylyl cyclase activity (Potter et al., 2006). As a result, intracellular cGMP levels are elevated, eliciting physiological response via cGMP-regulated protein kinases, phosphodiesterases, and ion channels. One research group has demonstrated that olfactory GC-D neurons in the OE respond to two kinds of natriuretic peptides, uroguanylin and guanylyn, but not urodilatin (a GC-A agonist), and the heat stable enterotoxin STp (a GC-C agonist) (Leinders-Zufall et al., 2007). The response to the natriuretic peptides was found to disappear when GC-D neurons lacked an intact GC-D or CNGA3 gene, but not CNGA2, indicating that the response requires intracellular cGMP but not cAMP signaling. Both agonistic natriuretic peptides may be present within the excreted urine. Consistent with these findings, diluted urine was able to activate GC-D neurons, although it remains unclear as to whether the activity of urine was actually attributed to natriuretic peptides (Leinders-Zufall et al., 2007). Given the fact that nonvolatile compounds were able to gain access to a region where OSNs are scattered in the nasal cavity (Spehr et al., 2006), urinary natriuretic peptides were thought to most likely act as a physiological stimulant for GC-D neurons. Therefore, one function of the GC-D neurons may be to detect natriuretic peptides present within the urine of other individuals, and to obtain information about their metabolic status, for example water and salt balance.

It has also been suggested that GC-D neurons function as a sensor for atmospheric carbon dioxide concentration (Hu et al., 2007). Carbon dioxide is thought to serve as an important environmental cue for animals, as its levels are often associated with the presence of food, predators, and environmental stress. GC-D neurons exhibit intracellular calcium response to carbon dioxide at a threshold near 0.1%, with mice also able to recognize this concentration. Carbon dioxide-exposed GC-D neurons demonstrated an increased frequency of action potential firing, most likely due to the opening of CNG channels following intracellular cGMP increase. The responsiveness of GC-D neurons to carbon dioxide requires enzyme carbonic anhydrase II (CAII) expressed in GC-D neurons (Hu et al., 2007). Intracellular CAII is thought to metabolize carbon dioxide via the reversible reaction of  $\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{HCO}_3^- + \text{H}^+$  (Khalifah, 1971). It was previously demonstrated that

highly diffusible intracellular  $\text{HCO}_3^-$  in turn activated GC-D, resulting in an increase in intracellular cGMP levels. Heterologous expression of GC-D in HEK293T cells resulted in activation following the addition of  $\text{NaHCO}_3$  or  $\text{KHCO}_3$ , but not following pH change, resulting in intracellular cGMP increase (Sun et al., 2009).

More recently, it has been indicated that GC-D neurons exhibit sensitivity to carbon disulfide ( $\text{CS}_2$ ), an isoelectronic isomer of  $\text{CO}_2$  (Munger et al., 2010). The  $\text{CS}_2$ -responsiveness of GC-D neurons also requires CAII activity, suggesting that only  $\text{CS}_2$  metabolites may activate GC-D. It has been previously shown that the rats emit  $\text{CS}_2$  in their outward breath at a concentration of approximately 1 ppm (13  $\mu\text{M}$ ; Galef et al., 1988), and that this physiological concentration of  $\text{CS}_2$  is capable of inducing a response in GC-D neurons (Galef et al., 1988; Munger et al., 2010). It has been suggested that  $\text{CS}_2$  acts as a semiochemical that mediates social influences on food selection in the rodent (Galef et al., 1988). That is, rodents will exhibit an enhanced preference for a food after smelling food-derived odorants and  $\text{CS}_2$  from living conspecifics that have eaten that food. This response is termed the socially transmitted food preference (STFP) and is particularly important for rodents that are continuously faced with the problem of selecting appropriate foods. Although the underlying molecular mechanisms that mediate and form STFP are yet to be elucidated, a recent study has provided evidence that GC-D neurons mediate STFP via the detection of  $\text{CS}_2$  (Munger et al., 2010). Munger et al. investigated mice lacking GC-D and CNGA3. Disruption of these receptor components resulted in a reduced sensitivity of GC-D neurons to  $\text{CS}_2$  and a failure to form STFP. Thus, GC-D neurons appear essential for normal sensitivity to  $\text{CS}_2$  and acquisition of the STFP.

GC-D neurons exhibit sensitivity to  $\text{CS}_2$  at a sub-micromolar range, whereas the response threshold of carbon dioxide is more than 6.8 mM, a 10,000-fold lesser sensitivity than  $\text{CS}_2$  (Hu et al., 2007; Munger et al., 2010). Although sensitivity to both stimulants appears to be at a physiologically relevant level for when animals may be exposed via conspecific breathing or atmospheric air, the affinity of the GC-D neurons appears more highly tuned to  $\text{CS}_2$  than to  $\text{CO}_2$ . GC-D neurons also act as sensitive chemosensors that respond to the pM of natriuretic peptides ( $\text{EC}_{50} = 60\text{--}770 \text{ pM}$ ) (Leinders-Zufall et al., 2007). This finding is consistent with reports for other members of the guanylyl cyclase receptors that exhibit a dissociation constant at the pM range of natriuretic peptides (Bennett et al., 1991). The higher sensitivity to natriuretic peptides raises the question of whether natriuretic peptides act as a conspecific cue that GC-D neurons detect for the acquisition of STFP in a physiological context. Mice genetically or pharmacologically lacking CAII demonstrate a severely reduced sensitivity to  $\text{CS}_2$  and an impaired acquisition

of an artificial ‘ $\text{CS}_2$ -mediated’ food preference, but show normal sensitivity to natriuretic peptides (Munger et al., 2010). It would be interesting to examine whether pre-treatment with a pair of food odor and natriuretic peptides confers murine food preference, and whether CAII-deficient mice are able to detect social cues from living conspecifics and exhibit the food preference.

The structural basis of receptor guanylyl cyclase has also been extensively studied for GC-A, also known as natriuretic receptor-A (Kuhn, 2003). Receptor guanylyl cyclases including GC-D are single trans-membrane proteins that contain a ligand-binding extracellular domain, a trans-membrane domain and an intracellular catalytic domain (Figure 5.4). Two highly conserved motifs have been demonstrated in the extracellular juxtamembrane region, termed the receptor-GC signaling motif, and the intracellular protein kinase-like domain (Chinkers and Garbers, 1989; Liu et al., 1997; Wilson and Chinkers, 1995). The crystal structure of the extracellular domain indicates that GC-A binds to one natriuretic peptide as a homodimer (Ogawa et al., 2004). The dimeric extracellular domain consists of several key amino acid residues that interact with ligands via hydrogen bonds and hydrophobic interactions (He et al., 2006; Parat et al., 2008). The protein backbone of GC-A extracellular domains form a short parallel  $\beta$ -sheet with the C-terminal peptide backbone of natriuretic peptides. When a pair of extracellular domains binds to an agonist, receptor-GC signaling motifs are rotated (Ogawa et al., 2004). This extracellular conformational change may transmit to intracellular domains via trans-membrane helices and induce active conformation of two catalytic domains. Each intracellular protein kinase-like domain binds to ATP as a positive allosteric modulator which augments cyclase activity (Duda et al., 2009). For olfactory GC-D, a similar mechanism may function to detect natriuretic peptides and initiate intracellular signaling. In contrast, GC-D binds to the bicarbonate ion derived from carbon dioxide with the intracellular catalytic domain. This is indicated by the observation that targeted deletion of the extracellular domain or intracellular protein kinase-like domain of GC-D does not affect sensitivity to the bicarbonate ion, and that the recombinant catalytic domain alone shows an enhanced cyclase activity in the presence of this ion in HEK293T cells (Sun et al., 2009).

## 5.4 OLFACTORY RECEPTORS IN NON-OLFACTORY TISSUES

In 1992, one year after the discovery of the OR gene family, it was reported that mammalian ORs were also expressed in the testis (Parmentier et al., 1992). This finding raised the hypothesis that the largest family of chemoreceptors may serve some biological functions in tissues other than

in the OE. Similarly, TAARs have been shown to function in the recognition of volatile amine in the nose, while in the brain functions as a receptor for trace-amine. Further evidence has suggested that ORs are expressed in a variety of tissues including the brain, heart, kidney, and muscle (Feldmesser et al., 2006; Ferrand et al., 1999; Otaki et al., 2004; Pluznick et al., 2009; Zhang et al., 2004). A GPCR identified as a prostate specific G protein-coupled receptor (PSGR) was later classed into the OR family (OR51E2), (Neuhaus et al., 2009). In many cases, olfactory signaling components such as G $\alpha$ olf, ACIII, and CNG channel are co-expressed in non-olfactory tissues. The function of these ectopic ORs has been investigated. The human OR known as OR1D2 was found to be expressed in the testis, where it is used to aid in the recognition of human sperm to an odorant ligand and induce intracellular signaling that regulates sperm chemotaxis (Spehr et al., 2003). Similar findings have been observed in the mouse, where a ligand for MOR23 (Olfr16) was expressed in testis and found to regulate sperm motility (Fukuda et al., 2004). It is noteworthy that a recent study suggests that odorant recognition by sperm is mediated by a sperm-specific CatSper channel (Brenker et al., 2012). In murine muscle, ORs are expressed in myocytes during unique stages of muscle regeneration and regulate cellular migration (Griffin et al., 2009). PSGR is also known to regulate proliferation of human prostate cancer cells (Neuhaus et al., 2009). In the kidney, Olfr78 modulates blood pressure in response to short chain fatty acids produced by gut microbiota (Pluznick et al., 2013). Although the existence of endogenous ligands for the ectopic ORs has not been determined, the ORs appear to function in the detection of not only environmental volatile cues but also endocrine cues, and as a consequence regulate cell- or tissue-level function within the body. Intriguingly, one report has revealed that ORs expressed in a non-olfactory tissue were more highly conserved in animals than ORs expressed exclusively in the OE (De la Cruz et al., 2009). The acquisition of particular ligand selectivity may serve a selective advantage in the function of body tissues. These non-olfactory ORs are future targets of gene deletion studies that will help determine their physiological function. Understanding the precise function of the non-olfactory ORs may help pave the way for use of the OR family as novel targets for therapeutic agents.

## 5.5 CONCLUSIONS

Recent studies have significantly enhanced our understanding of the molecular mechanisms underlying the functional organization of the primary olfactory system. In the murine OE, multiple types of olfactory receptor have been identified including two GPCR families and one receptor enzyme. The pairing of olfactory receptors

with cognate ligands has revealed a wide range of olfactory cues including small organic compounds, peptidic molecules, and inorganic gases. The emerging large scale relationship between environmental chemical cues and olfactory receptor repertoires has also revealed not only a greater role for olfaction, but also a considerably complex fashion of odor coding. For example, mice recognize safe food through CS<sub>2</sub> detection at multiple neuronal inputs including GC-D, while ORs are required for food-related odor detection (Munger et al., 2010). Future studies that dissect the function of each olfactory receptor will aid in the clarification of the activation pattern of olfactory receptors against a chemical repertoire in a specific natural environment, and will help us to further understand olfactory coding strategies and the neuronal mechanisms underlying adaptive behaviors.

## Odorant Receptor Gene Regulation

AKIO TSUBOI and HITOSHI SAKANO

### 6.1 INTRODUCTION AND OVERVIEW

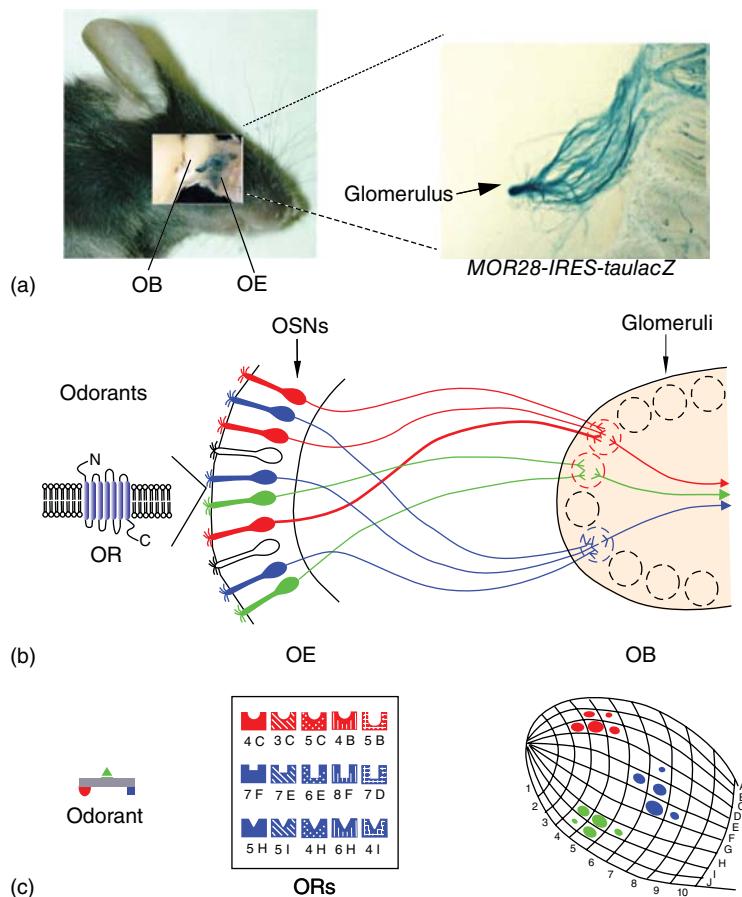

The main olfactory system recognizes a vast range of molecules that represent vital information about an animal's environment, including the location of prey and predators. Sensory information is specially encoded in the brain, forming neural maps that are fundamental for higher-order processing of sensory information. Molecular mechanisms of sensory map formation in the visual system in particular have been extensively studied. It is well established that axonal projection of retinal ganglion cells is instructed by multiple pairs of axon-guidance molecules that demonstrate graded expression in the retina and tectum (McLaughlin and O'Leary, 2005). The spatial organization of the projecting neurons in the retina is maintained and projected onto the target, preserving the nearest-neighbor relationship. By contrast, for olfactory map formation instructed by gene expression, our beginning of understanding such maps stemmed from the ground-breaking discovery of the odorant receptor gene family by Buck and Axel (1991).

In the *Mus musculus* olfactory system, there are ~1,000 functional odorant receptor (OR) genes comprising the largest multigene family of this species (Buck and Axel, 1991). These OR genes are clustered at about 50 different loci that are scattered among most of the chromosomes. Each olfactory sensory neuron (OSN) in the olfactory epithelium (OE) expresses only one member of the OR gene family in a mutually-exclusive and monoallelic manner. Because OSN axons of spatially dispersed cell bodies with the same neuronal identity converge on a pair of glomerular locations in the target olfactory bulb (OB) (Mombaerts et al., 1996), the odorant stimuli received

in the OE are converted to an olfactory map of activated glomeruli (Figure 6.1). Thus, the one neuron – one receptor rule forms the genetic basis for OR-instructed axonal projection. Much of the olfactory map formation appears to occur autonomously by axon-axon interaction, without involving target-derived cues (Sakano, 2010). Within the OB, the odor information coded in the olfactory map is processed in the local neuronal circuits and then conveyed by mitral and tufted cells to various areas of the olfactory cortex (Mori et al., 1999; Shepherd et al., 2004; Mori and Sakano, 2011). In this chapter, we review recent progress on the study of OR gene regulation and OR-instructed axonal projection of OSNs in rodents.

### 6.2 ORGANIZATION AND STRUCTURE OF THE ODORANT RECEPTOR GENES

A multigene family encoding OR molecules was first identified in rat, which consists of hundreds of related OR genes (Buck and Axel, 1993). In humans, only ~380 of the 800 OR genes have an intact open reading frame and are assumed to be functional (Glusman et al., 2001; Malnic et al., 2004). In the mouse, of ~1,400 OR sequences, some 20% are pseudogenes (Zhang and Firestein, 2002; Young et al., 2002; Zhang et al., 2004a; Godfrey et al., 2004). The mouse repertoire of ~1,100 functional OR genes is the largest multigene family that encompasses ~5% of all genes. Mouse ORs are grouped into ~230 subfamilies, based on the amino-acid identities of >40% (Zhang and Firestein, 2002). Vertebrate OR genes are divided phylogenetically into two different classes, I and II. The class I genes resemble the fish OR genes, while the class II genes

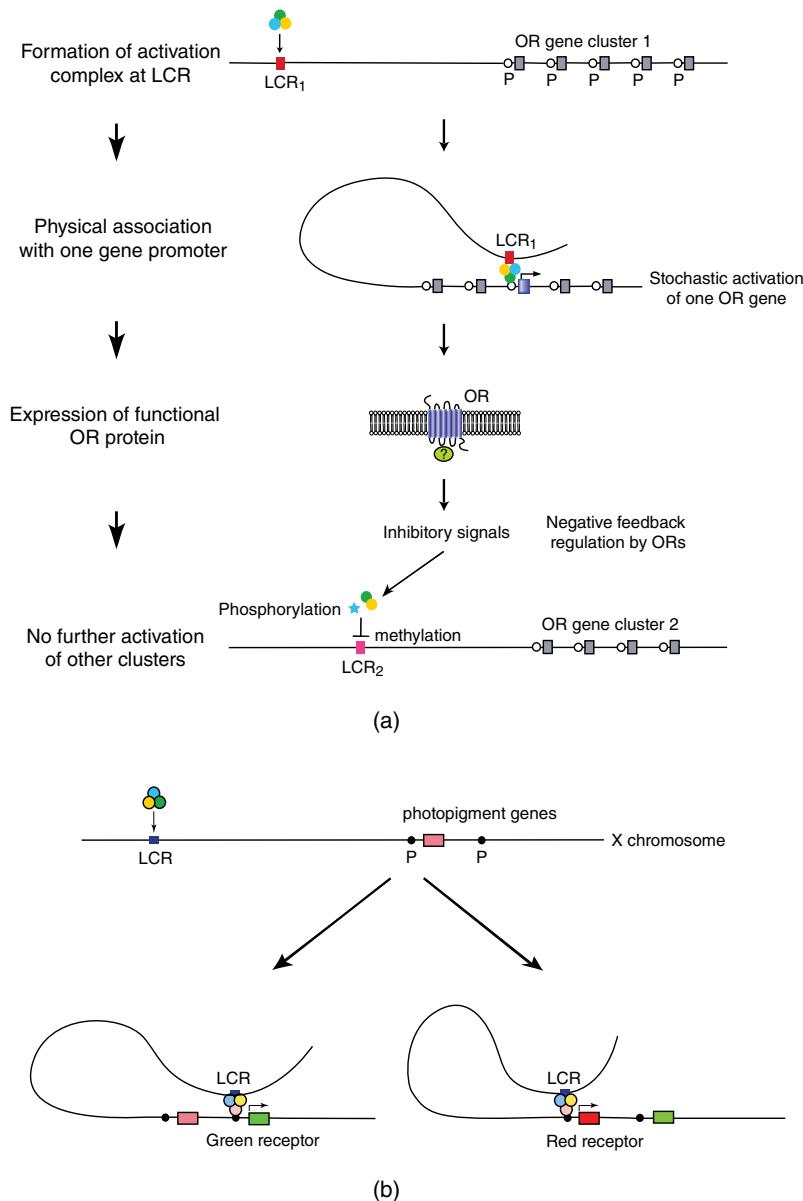

**Figure 6.1** Olfactory map in the mouse olfactory bulb. (a) Odorant receptor (OR)-instructed axonal projection of olfactory sensory neurons (OSNs). *MOR28*-expressing axons are stained blue with X-gal in the transgenic mouse, *MOR28-ires-tau-lacZ*. OSNs expressing the transgene converge their axons to a specific site, forming a glomerulus (arrow) in the olfactory bulb (OB). (b) Axonal segregation and olfactory map formation. OSN axons are guided to approximate destinations in the OB by a combination of dorsal-ventral (D-V) patterning and anterior-posterior (A-P) patterning. D-V projection occurs based on anatomical locations of OSNs in the olfactory epithelium (OE). A-P projection is regulated by OR-derived cAMP signals. The map is further refined in an activity-dependent manner during the early neonatal period. (c) Conversion of olfactory signals. In the OE, each OSN expresses only one functional OR gene in a monoallelic manner. Furthermore, OSN axons expressing the same OR species converge to a specific glomerulus in the OB. Thus each glomerulus represents one OR species. Because a given odorant typically activates multiple OR species and a given OR responds to multiple odorants, odorant signals received by OSNs in the OE are converted into a two-dimensional odor map of activated glomeruli with varying magnitudes of activity. (See plate section for color version.)

are unique to terrestrial vertebrates. The mouse OR genes are clustered at ~50 different loci spread over almost all chromosomes. Each cluster contains 1–189 OR genes, with an average intergenic distance of ~25 kilobases. Most OR genes are composed of 2–5 exons, where usually one exon encodes the entire protein. At least two-thirds of OR genes exhibit multiple transcriptional variants with alternative isoforms of noncoding exons (Young et al., 2003). Comparative analysis of the mouse and human OR genes revealed that coding homologies within the clusters are accounted for by recent gene duplication as well as gene conversion among the coding sequences (Nagawa et al., 2002). To maintain the integrity of the domain structure of the olfactory sensory map, gene conversion may have

played an active role in having the sequence similarities between the paralogs of the OR genes (Tsuboi et al., 2011).

### 6.2.1 Zonal Expression of Odorant Receptor Genes in the Olfactory Epithelium

In rodents, the OE can be divided into four distinct zones, based on the expression patterns of OR genes (Ressler et al., 1993; Vassar et al., 1993; Strotmann et al., 1994a, b; Tsuboi et al., 1999). The most dorso-medial zone of the OE is defined as zone 1 (Sullivan et al., 1996), also as dorsal (D) zone (Kobayakawa et al., 2007). D-zone OSNs are positive for O-MACS (Oka et al., 2003), but negative

**Figure 6.2** Mutually-exclusive expression of odorant receptor and photopigment genes. (a) In the odorant receptor (OR) gene system, the locus control region (LCR)-promoter (P) interaction alone would not preclude the activation of a second OR gene located in the other allele or in other OR gene clusters. Once a functional gene is expressed, the OR molecules transmit inhibitory signals to block the further activation of additional OR gene clusters. (b) In the human visual system, an LCR plays an important role in choosing either the red or green photopigment gene in a mutually exclusive manner in the cone cells of the retina. Stochastic interaction between the LCR and either promoter (P) ensures the mutually exclusive expression of the human photopigment genes encoded on the X chromosome. From Smallwood et al., 2002. (See plate section for color version.)

for OCAM (Yoshihara et al., 1997). Conversely, ventral (V) zone OSNs are negative for O-MACS, but positive for OCAM. The D zone is further divided into D<sub>I</sub> and D<sub>II</sub> zones based on the expressing OR gene classes described below (Mori and Sakano, 2011).

**6.2.1.1 Class I Odorant Receptors.** The class I ORs were first identified in fish (Ngai et al., 1993) and later found in amphibians (Freitag et al., 1995). They are assumed to recognize water-soluble odorous ligands. Class I ORs are also found in mammals, including human (Glusman et al., 2001; Malnic et al., 2004) and mouse (Zhang and Firestein, 2002; Young et al., 2002; Zhang

et al., 2004a; Godfrey et al., 2004). In the mouse, there are over 150 class I-OR genes, classified into 42 subfamilies (Zhang and Firestein, 2002; Zhang et al., 2004a). They are all clustered at a single locus on the mouse chromosome 7. Comprehensive *in situ* hybridization (ISH) revealed that almost all class I-OR genes are expressed specifically in D zone (Tsuboi et al., 2006), confirming the data from a high-throughput microarray analysis (Zhang et al., 2004b). It appears that they are coordinately regulated by a common locus control region (LCR) and/or promoter sequences (Figure 6.2). In the mutant mouse lacking the homeodomain protein Lhx2, class I expression becomes spared, while class II expression is abolished (Hirota et al., 2007).

**6.2.1.2 Class II Odorant Receptors.** In contrast to class I, class II OR genes account for a large share of the mammalian OR repertoire. ISH analyses with various OR gene probes demonstrated that each OR gene is expressed in a restricted area in the OE. It has been reported that OSNs expressing a given OR gene are confined to one of the four OE zones but are randomly distributed within the zone (Ressler et al., 1993; Vassar et al., 1993; Strotmann et al., 1994a, b Tsuboi et al., 1999). This appears to be true for D-zone specific class I genes. However, for most class II OR gene, the expression area is not always confined to one of the four conventional zones (Norlin et al., 2001; Iwema et al., 2004; Miyamichi et al., 2005). Expression areas appear to be specific to each OR gene and are arranged in an overlapping and continuous manner in the OE. It was demonstrated by DiI retrograde staining experiments that the dorsal/ventral arrangement of glomeruli in the OB is well correlated with the expression areas of corresponding ORs along the dorsomedial/ventrolateral (DM/VL) axis in the OE (Miyamichi et al., 2005). Thus, OR gene choice may not be totally stochastic, but rather it may be restricted by the OSN location in the OE. How does this positional information within the OE regulate OR gene choice? It is possible that this regulation is determined by cell lineage, resulting in the use of zone-specific transcription factors, e.g., Lhx2, Msx1 and Foxg1 (Hirota et al., 2007; Norlin et al., 2001; Duggan et al., 2008).

## 6.2.2 Single Odorant Receptor Gene Expression

In the mouse olfactory system, each OSN chooses for expression only one functional OR gene in a mutually-exclusive and monoallelic manner (Chess et al., 1994; Serizawa et al., 2000; Ishii et al., 2001). Such unique expression forms the genetic basis for the OR-instructed axonal projection of OSNs to the OB. How is the singular OR gene choice regulated and how is the one neuron – one receptor rule maintained in OSNs? Based on previous studies of other multigene families, three mechanisms have been considered for the choice and activation of OR genes: (a) DNA recombination, which brings a promoter and the enhancer region into close proximity; (b) gene conversion, which transfers a copy of the gene into the expression cassette; and (c) a regulatory DNA region, which interacts with only one promoter site. Irreversible DNA changes, such as recombination and gene conversion, had been attractive explanations for single OR gene expression because of the many parallels between the immune system and the olfactory system. However, these theories were dismissed after two groups independently cloned mice from postmitotic OSN nuclei and determined that the mice showed no irreversible DNA rearrangement in the OR genes (Eggan et al., 2004; Li et al., 2004).

### 6.2.2.1 Odorant Receptor Gene Choice.

Because the genetic translocation model appeared unlikely, another possibility was explored, namely a locus control region (LCR) that might regulate the single OR gene choice (Figure 6.2a). LCR is defined as a *cis*-acting regulatory region that controls multiple genes clustered at a specific genetic locus. The first example of an LCR was identified in the globin gene locus containing developmentally regulated and related genes (Grosveld et al., 1987). It has been assumed that transcription-activating factors bind to the LCR (holocomplex) that physically interacts with the remote promoter site by looping out the intervening DNA. In the globin gene system, an active chromatin hub structure has been reported, in which the LCR is in close proximity to the gene to be expressed (Carter et al., 2002; Tolhuis et al., 2002). One example of such an LCR in the mouse olfactory system, named *H* for the homology between the mouse and human DNA sequences, was identified upstream of the *MOR28* cluster containing seven murine OR genes (Nagawa et al., 2002; Serizawa et al., 2003). Deletion and mutation analyses of the *H* region further revealed that the 124-bp core-*H* region, which contains two homeodomain sequences and one O/E-like sequence, is sufficient to achieve the enhancer activity (Nishizumi et al., 2007). Based on the deletion analysis, another example of OR-gene LCR, named *P*, was identified between the *P3* and *P4* genes (Bozza et al., 2009; Vassalli et al., 2011; Khan et al., 2011). Both the homeodomain and O/E-like sequences are found in the *H* and *P* regions as well as in many OR-gene promoters (Vassalli et al., 2002; Hirota and Mombaerts, 2004; Rothman et al., 2005; Michaloski et al., 2006; Bozza et al., 2009; Vassalli et al., 2011). Homeodomain factors, Lhx2 and Emx2, and O/E family proteins are known to bind to their motifs in the OR gene promoter (Wang et al., 2004; Hirota et al., 2007; McIntyre et al., 2008). It is possible that these nuclear factors bind to the OR-gene LCRs and form a complex that remodels the chromatin structure near the cluster, thereby activating one OR promoter site at a time by physical interaction (Serizawa et al., 2003) (Figure 6.2a). This model is attractive because it reduces the likelihood of the simultaneous activation of multiple OR genes, from a probability of ~1,000 individual genes to ~50 LCR loci.

In the immune system, it has been reported that the LCR of the *IL-4* gene in naïve T helper cells interacts not only with the adjacent genes on chromosome 11, but also with the alternatively expressed *IFN-γ* gene on chromosome 10 (Spilianakis et al., 2005). Such an interchromosomal association of multiple gene loci may be a common feature of chromosomal organization for the coordinately regulated genes. Does the *H* region act on other OR gene clusters, not only in *cis* but also in *trans*,

like the *IL-4* LCR in T cells? Based on fluorescent *in situ* hybridization and chromosome conformation capture analyses of OSN nuclei, Lomvardas et al. (2006) reported that the single *trans*-acting LCR *H* may allow the stochastic activation of only one OR gene in each OSN. However, knockout studies of *H* contradict the single *trans*-acting LCR model for the OR gene choice (Fuss et al., 2007; Nishizumi et al., 2007). Targeted deletion of *H* abolished the expression of only three proximal OR genes in *cis*, indicating the presence of another LCR in the downstream region to regulate the four distal OR genes in the same *MOR28* cluster. Furthermore, in heterozygous ( $H^+/H^-$ ) knockout mice, the wild-type  $H^+$  allele could not rescue the  $H^-$  mutant allele in *trans*, indicating that *H* can act only in *cis* and not in *trans* (Nishizumi et al., 2007).

### **6.2.2.2 Negative Feedback Regulation to Maintain the One Neuron – One Receptor Rule.**

**Rule.** In the human visual system, an LCR plays an important role in choosing either the red or green photopigment gene in a mutually exclusive manner in the cone cells of the retina (Wang et al., 1999). It has been shown that stochastic interaction between the LCR and either of the two promoters ensures the mutually exclusive expression of the human photopigment genes that are encoded on the X chromosome (Smallwood et al., 2002) (Figure 6.2b). In contrast, in the OR gene system, the LCR-promoter interaction alone would not preclude the activation of a second OR gene located in the other allele or in other OR gene clusters. Therefore, it has been postulated that the functional OR proteins have an inhibitory role to prevent further activation of other OR genes (Serizawa et al., 2003; Lewcock and Reed, 2004). Transgenic experiments demonstrated that the mutant OR genes lacking either the entire coding sequence or the start codon can permit a second OR gene to be expressed (Serizawa et al., 2003; Feinstein et al., 2004; Lewcock and Reed, 2004; Shykind et al., 2004). Naturally occurring frameshift mutants of OR genes also allow the coexpression of a functional OR gene (Serizawa et al., 2003). It is known that a substantial number of pseudogenes are present in the mammalian OR gene families (~30% of total OR genes in mice and ~60% in humans). If an activated LCR has selected a pseudogene and has been trapped by its promoter, other clusters must undergo a similar process to ensure the activation of a functional OR gene (Roppolo et al., 2007). A pseudogene may help slow the process of OR gene activation and further reduce the likelihood of activating two functional OR genes. Thus rate-limited activation of an OR gene by *cis*-acting LCRs and negative feedback regulation by the OR gene product together appear to

ensure the maintenance of the one neuron – one receptor rule (Serizawa et al., 2003, 2004) (Figure 6.2a). However, the exact nature of the negative feedback signals has not been explored. Targets of the feedback signals are also issues for future studies. Promoters of OR genes, enhancers of OR gene clusters, and protein factors binding them could be silenced by OR-derived negative feedback signals. Histone modification could be another target of the feedback regulation.

It has been reported that forced expression of an OR gene with the Tet transactivation system can suppress the expression of endogenous ORs (Nguyen et al., 2007; Fleischmann et al., 2008). As the forced expression was found to be inefficient, researchers have proposed that the OR coding sequence has an inhibitory effect on transcriptional regulation. However, it has not been demonstrated that the suppressive effect would result from the DNA sequence and not the potentially toxic effects of OR overexpression. It is important to identify the essential nucleotide sequences responsible for the suppressive effects of functional ORs. In neonatal mice, a small fraction of OSNs express two functional OR species simultaneously, which are eventually eliminated in an activity-dependent manner (Tian and Ma, 2008). This form of negative selection has also been considered to be a fail-safe mechanism to ensure monogenic OR expression (Mombaerts, 2006).

OR-mediated negative feedback does not require G protein signaling (Imai et al., 2006; Nguyen et al., 2007). The involvement of G proteins in negative feedback regulation was tested using transgenic mice expressing a mutant-type OR, in which the DRY motif, essential for G protein signaling, was changed to RDY. This mutation completely abolished odor-evoked calcium responses in OSNs, indicating the loss of G protein signaling. However, OSNs expressing the mutant OR maintained the one neuron–one receptor rule. Seven-transmembrane receptors often utilize G protein-independent signaling pathways, such as those involving  $\beta$ -arrestin (Shenoy and Lefkowitz, 2011). Notably, the DRY motif is dispensable for  $\beta$ -arrestin-mediated seven-transmembrane-receptor signaling (Seta et al., 2002). Knockout studies will clarify whether  $\beta$ -arrestin-mediated signaling is involved in negative feedback regulation.

Recently, Magklara et al. (2011) reported that chromatin-mediated silencing is important to prevent multiple expression of OR genes in each OSN. They found that heterochromatic compaction of OR-gene clusters occurs before OR transcription via two trimethyl marks of H3K9me3 and H4K20me3. The enrichment for these silent marks is significantly reduced in an activated OR-gene region, which is marked instead with H3K4me3. It is assumed that although all OR-gene loci become silenced before OR-gene transcription, at a later stage, a limited

histone demethylase Lsd1 activity removes methylation of H3K9me3 from a stochastically chosen locus, activating its transcription (Lyons et al., 2013; Magklara et al., 2011). Once a functional gene is expressed, negative feedback signals may prevent the enzyme/selector from activating other OR-gene loci.

### 6.2.3 Regulation of Odorant Receptor-Instructed Axonal Projection

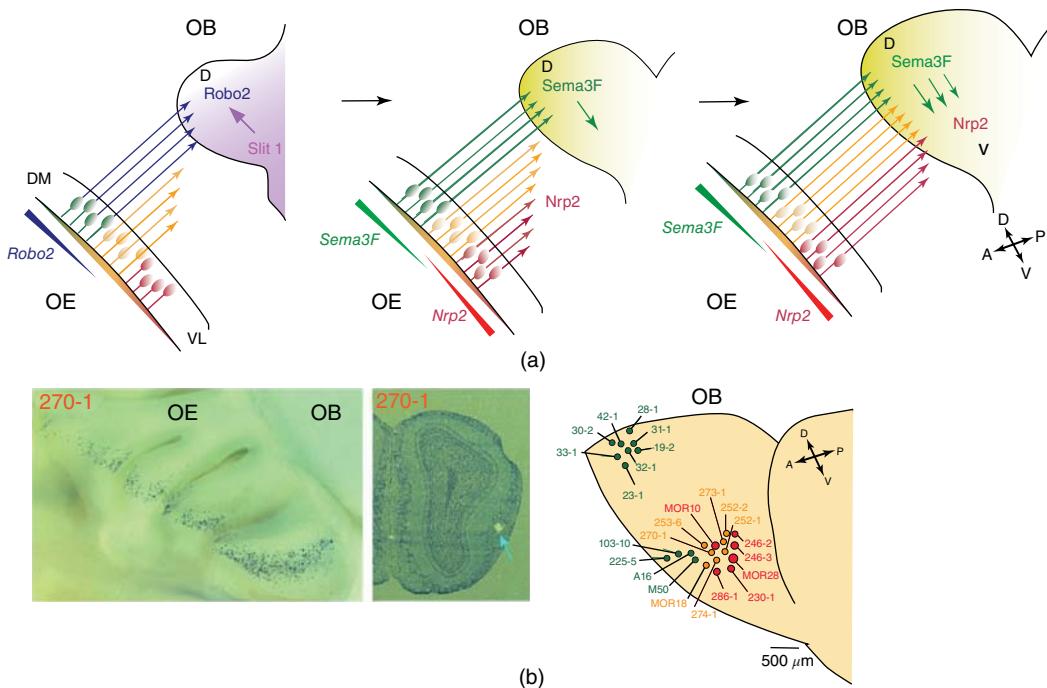

The olfactory map in the OB comprises discrete glomeruli, each representing a single OR species (Ressler et al., 1994; Vassar et al., 1994; Mombaerts et al., 1996) (Figure 6.3b). Coding-swap experiments of OR genes indicated the instructive role of the OR protein in OSN projection (Mombaerts et al., 1996; Wang et al., 1998; Feinstein and Mombaerts, 2004). Because OSNs expressing the same OR are scattered in the OE for anterior-posterior projection, topographic organization must occur during the process of axonal projection of OSNs. Unlike axonal projection in other sensory systems in which relative positional information is preserved between the periphery and the brain (Lemke and Reber, 2005; McLaughlin and O’Leary, 2005; Petersen, 2007), there is no such correlation for the projection along the anterior-posterior axis in the mouse olfactory system. Although OR molecules have been known to play an instructive role in projecting OSN axons to form the glomerular map, it has remained entirely unclear how this occurs at the molecular level. Intriguingly, OR molecules are detected in axon termini by tagging with green fluorescent protein (Feinstein and Mombaerts, 2004) or by immunostaining with anti-OR antibodies (Barnea et al., 2004; Strotmann et al., 2004). On the basis of these observations, it was suggested that the OR protein itself may recognize positional cues in the OB and also may mediate homophilic interaction of similar axons (Feinstein et al., 2004; Mombaerts, 2006). Although these models were attractive, recent studies argue against them. Instead of directly acting as guidance receptors or adhesion molecules, ORs regulate transcription levels of axon-guidance and axon-sorting molecules by OR-derived cAMP signals with levels uniquely determined by the OR species (Imai et al., 2006; Serizawa et al., 2006). In the mouse olfactory system, axon guidance/sorting molecules whose expression levels are regulated by ORs can be categorized into two different types (Sakano, 2010). One is type I, including Nrp1 and Plexin-A1, which is expressed at axon termini in a graded manner along the anterior-posterior axis in the OB. The other is type II, including Kirrel2 and Kirrel3, which is expressed at axon termini showing a mosaic pattern in the OB. In the knockout mouse for adenylyl-cyclase III, Nrp1 and Kirrel2 are downregulated, whereas Plexin-A1 and Kirrel3

are upregulated, suggesting that both type I and type II genes are under the control of cAMP signals. However, type II expression is regulated in an activity-dependent manner, whereas type I expression is independent from the neuronal activity. It is interesting to study how the same second messenger, cAMP, is capable of regulating two types of genes differently.

Recently, Nakashima et al. (2013) reported that the agonist-independent OR activity determines transcription levels of type I molecules, e.g., Neuropilin-1 and Plexin-A1, thereby regulating the anterior-posterior targeting of OSN axons. They demonstrated that  $G_s$ , but not  $G_{olf}$ , is responsible for mediating the agonist-independent OR activity. In contrast, expression of type II molecules, e.g., Kirrel2 and Kirrel3, is regulated by the ligand-induced OR activity using Golf. Nakashima et al. (2013) conclude that the equilibrium of conformational transitions set by each OR is the major determinant of expression levels of anterior-posterior targeting molecules.

#### 6.2.3.1 Positional Information of Olfactory Sensory Neurons in the Olfactory Epithelium Regulates Dorsal-Ventral Projection in the Olfactory Bulb.

In the dorsal region of the OE, OSNs expressing a given OR gene are distributed throughout D zone (Tsuboi et al., 2006). However, in the ventral region, OR genes exhibit spatially limited expression patterns along the DM-VL axis of the OE (Miyamichi et al., 2005). The relationship between the dorsal-ventral positioning of glomeruli and the locations of OSNs in the OE has been demonstrated by retrograde DiI staining of OSN axons (Astic et al., 1987; Miyamichi et al., 2005). These observations suggest that the anatomical locations of OSNs in the OE contribute to the dorsal-ventral positioning of glomeruli in the OB. In the OE, an axon-guidance receptor, Nrp2, and its repulsive ligand, Sema3F, are both expressed by OSN axons in a complementary manner to regulate dorsal-ventral projection (Takahashi et al., 2010; Takeuchi et al., 2010) (Figure 6.3a). Another set of repulsive signaling molecules, Robo2 and Slit1, are needed to restrict the first wave of OSN projection to the anterodorsal OB (Cho et al., 2007; Nguyen-Ba-Charvet et al., 2008). Expression levels of dorsal-ventral guidance molecules, such as Nrp2 and Sema3F, are closely correlated with the expressed OR species. However, unlike Nrp1 and Sema3A, which are involved in anterior-posterior positioning, the transcription of *Nrp2* and *Sema3F* is not downstream of OR signaling. If dorsal-ventral guidance molecules are not regulated by OR-derived signals, how are their expression levels determined and correlated with the expressed OR species? It appears that both OR gene choice and expression levels of *Nrp2* and *Sema3F* are commonly regulated by positional information within the OE. This regulation

**Figure 6.3** OR-gene expression in the OE contributes to the dorsal-ventral positioning of glomeruli in the OB. (a) Axonal extension of OSNs occurs sequentially along the dorsomedial-ventrolateral (DM-VL) axis of the OE as the OB grows from dorsal to ventral during development (Takeuchi et al. 2010). (Left panel) Dorsal-zone OSNs express Robo2 and project their axons to the prospective dorsal (D) domain of the embryonic OB. Repulsive interactions between Robo2 and Slit1 are needed to restrict early OSN projection to the embryonic OB. (Middle panel) In the OE, *Nrp2* and *Sema3F* genes are expressed in a complementary manner. (Right panel) *Sema3F* is deposited at the anterodorsal region of the OB by early arriving dorsal-zone axons and prevents the late-arriving *Nrp2*<sup>+</sup> axons from invading the dorsal region of the OB, resulting in projection to the ventral (V) domain. (b) A glomerular map generated by *in situ* hybridization (ISH) of OB sections. Axonal projection of OSNs occurs sequentially from the DM to the VL area in the OE, leading to establishment of the glomerular order in the OB along the D-V axis. Representative data for MOR270-1 were shown in the whole-mount ISH of the OE (left) and the radioisotope ISH of OB section (center). The glomerular map is schematically illustrated in the right on the basis of OB-ISH data. From Takahashi et al., 2010. (See plate section for color version.)

is likely determined by cell lineage, resulting in the use of specific sets of transcription factors, which can explain the anatomical correlation along the DM-VL axis of the OE.

### 6.3 CONCLUSION

In the mammalian olfactory system, each OSN activates only one functional OR gene in a mutually-exclusive and monoallelic manner. Such unique expression forms the genetic basis for the OR-instructed axonal projection of OSNs to the OB. Thus, the one neuron – one receptor rule is essential for the conversion of olfactory signals received in the OE into the olfactory map in the OB. Two examples of OR-gene LCRs, *H* and *P*, have been reported for the *MOR28* cluster (Serizawa et al., 2003) and *P3* cluster (Khan et al., 2011). Like the LCR in other gene systems, physical interaction between the LCR and promoter probably enables the expression of only one OR gene within the cluster. Double *in situ* hybridization experiments demonstrated

that the mutant OR genes, which contain the entire coding deletion or frameshift sequence, can permit a second OR gene to be expressed. Although it was recently reported that chromatin-mediated silencing is important for the single OR expression (Magklara et al., 2011), an inhibitory role has been postulated for the functional OR protein that may prevent a histone-demethylation enzyme/selector from activating another allele (Lyons et al., 2013). Stochastic activation of an OR gene by LCR and negative-feedback regulation by the OR gene product, together, may ensure the maintenance of the one neuron – one receptor rule in the mammalian olfactory system.

## Neurogenesis in the Adult Olfactory Epithelium

ALAN MACKAY-SIM, JAMES ST JOHN, and JAMES E. SCHWOB

### 7.1 INTRODUCTION

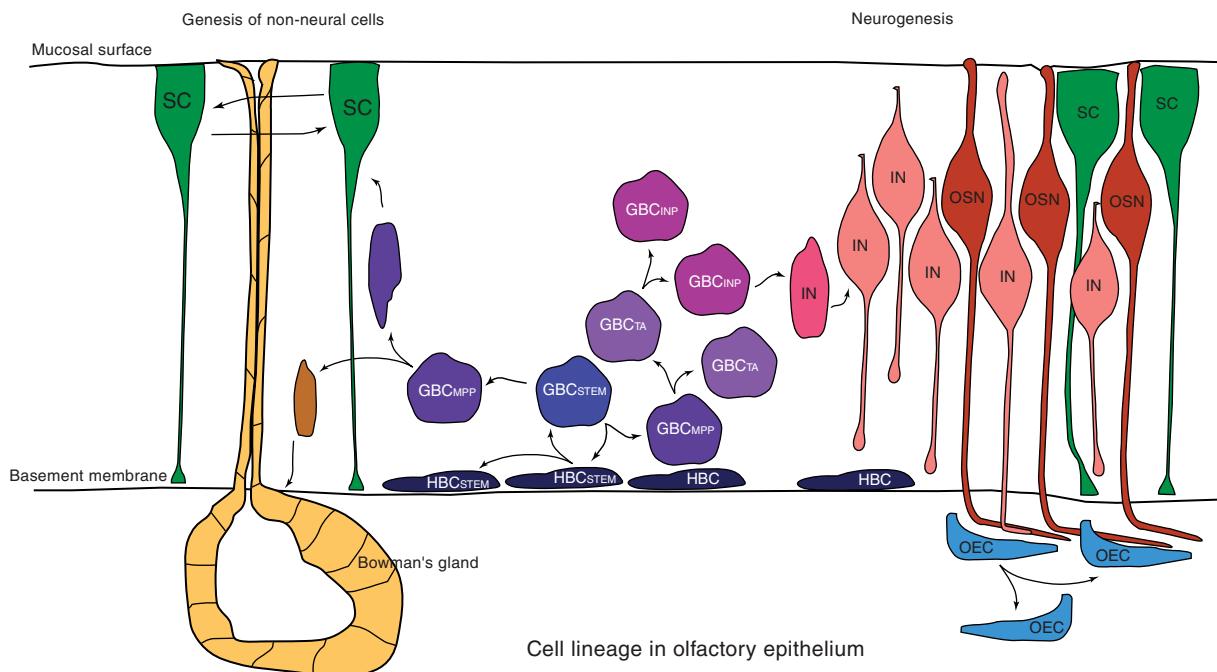

It is now recognized that neurogenesis occurs in a number of sites within the adult brain, even in the brain of aged humans (Eriksson et al., 1998). Neurogenesis has long been recognized as a property of the adult olfactory epithelium. Indeed, neurogenesis in this tissue is robust enough to replenish piecemeal or replace wholesale the neuronal population to such an extent that structure and function are restored after injury severe enough to compromise or destroy the sense of smell. Olfactory sensory neurons regenerate in humans (Wolozin et al., 1992; Murrell et al., 1996), even into old age (Holbrook et al., 2011), making the olfactory system one of the most continually variable regions of the human nervous system.

### 7.2 NEUROGENESIS IN ADULT OLFACTORY EPITHELIUM

#### 7.2.1 Overview of Cell Types in Olfactory Mucosa

The olfactory epithelium is a pseudo-stratified, columnar epithelium containing three cell compartments: the superficial supporting cells, the medially located sensory neurons, and the basal cells (see Chapter 4). The supporting cells, including sustentacular cells and several variants of microvillar cells, can be identified by a number of antigens including the anonymous monoclonal antibodies SUS1 (Hempstead and Morgan, 1983) and SUS4 (Goldstein and Schwob, 1996), as well as more defined markers, such as

keratin 18, E-cadherin, and transcription factors (more on this below) (Guo et al., 2010; Packard et al., 2011a, b). The mature sensory neurons are identified by their expression of olfactory marker protein (OMP; Danciger et al., 1989). Below the sensory neurons and blending in with the basal cells below are the immature sensory neurons, which are identified by expression of GAP43 and  $\beta$ -tubulin type III (Verhaagen et al., 1989; Roskams et al., 1998). The basal cells of the olfactory epithelium have traditionally been divided into two categories on the basis of morphology: horizontal basal cells (HBCs) and globose basal cells (GBCs). Under the electron microscope HBCs resemble the basal cells of the adjacent respiratory epithelium, appearing highly differentiated, with a dark cytoplasm, forming a flattened monolayer along the basal lamina with which they make hemidesmosomal connections (Holbrook et al., 1995). HBCs envelop the olfactory axons as they exit the epithelium and are identified immunologically by their expression of a variety of antigens including keratins 5 and 14, ICAM-1, and a surface glycoprotein that binds to the lectin BS-I (Holbrook et al., 1995). GBCs, more superficially located than HBCs, are round cells with large nucleus and sparse cytoplasm and are not seen in respiratory epithelium (Goldstein and Schwob, 1996). All GBCs (and some immature neurons) are immunologically labelled with the monoclonal antibodies GBC1-3 (Goldstein and Schwob, 1996); the antigen recognized by GBC3 was identified as the immature form of the non-integrin laminin receptor (Jang et al., 2007). The GBC population is heterogeneous and can be subdivided further based on expression of transcription factors, as described below. The GBC population also includes a

**Figure 7.1** Cell lineage in olfactory epithelium. The globose basal cell population (GBC) contains a multipotent stem cell ( $\text{GBC}_{\text{STEM}}$ ) that can proliferate and produce all neural and non-neuronal cells of the olfactory epithelium, including the Bowman's gland cells (GC) and duct cells, supporting cells (SC) and olfactory sensory neurons (OSN). Supporting cells can divide *in situ*. Globose basal cells may form a hierarchy from multipotent proliferating progenitors ( $\text{GBC}_{\text{MPP}}$ ) through transit amplifying cells ( $\text{GBC}_{\text{TA}}$ ) to immediate neuronal precursors ( $\text{GBC}_{\text{INP}}$ ) which leave the cell cycle after dividing, to differentiate into immature neurons (IN). The horizontal basal cell ( $\text{HBC}_{\text{STEM}}$ ) is a quiescent stem cell whose asymmetric division provides another horizontal basal stem cell and a multipotent globose basal cell stem cell ( $\text{GBC}_{\text{STEM}}$ ). The horizontal basal cell may only be active after massive epithelial damage to maintain their population. Olfactory ensheathing cells (OEC) in the lamina propria can divide *in situ*. They may be derived from an epithelial stem cell.

"third-type" of basal cell located above the HBC layer but extending a slender process to contact the basal lamina at an adherens-type junction (Holbrook et al., 1995). These have been interpreted as an intermediate form between HBCs and GBCs, and their existence has been cited as evidence that HBCs give rise to GBCs (Graziadei and Monti Graziadei, 1979) but the same histological data could be interpreted as a transition in the opposite direction. As discussed below, in the normal adult olfactory epithelium these transitions are probably rare events. Figure 7.1 shows an overview of the cell types in the olfactory epithelium and the lineage relations between them.

### 7.2.2 Replacement of Sensory Neurons in the Adult Olfactory Epithelium

After the early reports of basal cell mitosis in mouse olfactory epithelium (Nagahara, 1940) and regeneration of olfactory sensory neurons after zinc sulfate lesion in monkey (Schultz, 1941), there followed numerous reports confirming these observations in a variety of vertebrates: frog (Smith, 1951), fish (Westerman and von Baumgarten,

1964), cat and dog (Andres, 1966), lamprey (Thornhill, 1970), and mouse (Smart, 1971). Proliferating cells and their progeny can be identified at different times after an animal is injected with thymidine analogs that label cells synthesizing DNA during the cell cycle. At early survival periods after injection of  $^{3}\text{H}$ -thymidine in the mouse, the dividing cells are located in two layers of the epithelium – most are among the basal cells, close to the basement membrane, with a few located apically among the supporting cells (Moulton et al., 1970; Graziadei and Monti Graziadei, 1979). With increasing periods after injection of  $^{3}\text{H}$ -thymidine, the labelled basal cells migrate away from the basement membrane until their nuclei lie in the mid-zone of the epithelium in the region of the sensory neuron nuclei (Moulton et al., 1970; Graziadei and Monti Graziadei, 1979). These observations are consistent with basal cells giving rise to neurons and, under the electron microscope, there appear to be transitional cell types whose morphology suggests that they are immature neurons (Graziadei, 1973; Graziadei and Monti Graziadei, 1979). The rate of basal cell mitosis is inversely proportional to epithelial thickness, indicating regulatory mechanisms at work within the epithelium (Mackay-Sim

and Patel, 1984). Quantitative analyses show that 70–80% of the labelled cells are lost from the epithelium between 14 and 21 days after migrating into the neuronal layer (Moulton et al., 1970; Mackay-Sim and Kittel, 1991a), but labelled cells in the neuronal layer survive for 3 months (Moulton et al., 1970; Mackay-Sim and Kittel, 1991b) or longer (Hinds et al., 1984). Retrograde labelling by injection of colloidal gold provided direct evidence that olfactory neurons remain connected to the olfactory bulb for at least 3 months (Mackay-Sim and Kittel, 1991b). To survive, neurons must find synaptic space at the bulb and dendritic space at the epithelial surface (Breipohl et al., 1986; Mackay-Sim and Kittel, 1991b). Olfactory neuron survival is dependent on contact with, and trophic support from, the olfactory bulb (Schwob et al., 1992). Cell death is an integral part of neurogenesis during embryonic development and analysis of cell death in the adult olfactory epithelium indicates that all cell types undergo apoptosis, not just mature sensory neurons (Mahalik, 1996). Cell death can occur within one day of birth (Carr and Farbman, 1993), indicating that apoptosis in the olfactory epithelium is an integral and early part of neurogenesis in the adult olfactory epithelium. Olfactory neurogenesis is regulated by endocrine, autocrine, and paracrine factors similar to those operating during embryonic organogenesis (Breipohl et al., 1986).

### 7.2.3 Multipotent Stem Cells in the Olfactory Epithelium

Tissues capable of repair and regeneration are thought to contain a proliferating “stem” cell whose progeny become the functionally mature cells of the tissue. “Tissue-resident” or “adult” stem cells are usually defined as a “self-renewing” population (they proliferate to maintain their number) which is “multipotent” (their progeny can make all the cell types of the tissue). Tissue-resident stem cells are thought to divide “asymmetrically” to produce another stem cell and a proliferating daughter cell often called a “multipotent progenitor” or “transit amplifying” cell, to indicate that this daughter cell population has lost the ability to self-renew and, with each cell division, the progeny become more committed along a certain lineage of differentiation. In the olfactory neuron lineage, the final dividing cell is known as the “immediate neuronal precursor” (Figure 7.1). In the olfactory epithelium, advances are being made in discriminating among the basal cells, all the cells in lineage from the “true” stem cell (the self-renewing cell giving rise to multipotent progeny) through to mature sensory neuron.

The fact that neurons are born in normal olfactory epithelium and can be restored following epithelial injury provides *prima facie* evidence for the existence

of neural stem cell(s) in the olfactory epithelium. Certainly, the GBC population contains cells committed to making neurons: direct analysis of genetically labelled GBCs and their progeny using a replication-incompetent retrovirally-derived vector (RRV), demonstrated that the dividing GBCs cells are only capable of producing other GBCs or neurons (Caggiano et al., 1994; Schwob et al., 1994a). This and evidence *in vitro* makes it clear that the immediate neuronal precursor is a proliferating GBC (Graziadei and Monti Graziadei, 1979; Calof and Chikaraishi, 1989; Goldstein and Schwob, 1996; Newman et al., 2000). This then establishes a lineage from GBC to mature sensory neuron but does not identify the stem cell, nor shed light on whether it is capable of making other cell types of the epithelium (Figure 7.1). The multipotent capacity of the stem cells is demonstrated by the use of toxic agents that cause the death of most cell types in the olfactory epithelium, not just the sensory neurons (e.g., zinc sulphate; Harding et al., 1978). Methyl bromide gas is selectively toxic to the olfactory epithelium. It is administered at small doses by passive inhalation for 6–8 hours and causes widespread destruction of neurons, supporting cells, glands, and duct cells, but spares many or even most GBCs and HBCs (Schwob et al., 1995). Despite this widespread destruction, the epithelium regenerates all cell types including neurons, supporting cells, basal cells, and Bowman’s duct/gland cells (Schwob et al., 1995). Use of this model and lineage analysis to trace the genetically labelled progeny of the remaining basal cells indicated that there may be two multipotent progenitors, one that gives rise to non-neuronal cells only (supporting cells, Bowman’s gland cells and duct cells) and another that gives rise to basal cells, neurons, and supporting cells (Huard et al., 1998). Additionally, it was concluded that the multipotent cell giving rise to the non-neuronal cells is a Bowman’s gland duct cell and the other multipotent, neural lineage cell is a GBC (Huard et al., 1998). In these studies the dividing cells are genetically labelled by transduction with the RRV, applied intranasally. In rats, GBCs are the most superficial and also the most highly proliferative cell type that survives MeBr lesion and are infectable 1 day after exposure (Schwob et al., 1995), making them the most likely target for RRV transduction after intranasal infusion. These experiments take us further down the lineage from immediate neuronal precursor to multipotent progenitors but do not identify whether there is a self-renewing stem cell giving rise to these two multipotent progenitors.

HBCs were proposed as stem cells based on histological analysis after epithelial reconstitution (Rehn et al., 1981). Quantitative analysis of the undamaged epithelium suggested that the stem cell resides on the basement membrane in the location of the horizontal basal cell (Mackay-Sim and Kittel, 1991a), but this hypothesis remained inconclusive. This is because the asymmetrically

dividing cells were slowly dividing and located on the basement membrane, where they were not identified as horizontal basal cells, immunologically or morphologically (Mackay-Sim and Kittel, 1991a). Additional experiments in vitro also suggested that neurons can arise from horizontal basal cells (Mahanthappa and Schwarting, 1993; Satoh and Takeuchi, 1995), but the progenitors were identified with a single basal cell antibody (keratin) and the progeny with a single neuronal antibody (NCAM) (Mahanthappa and Schwarting, 1993; Satoh and Takeuchi, 1995). Without accounting for other potential cells in the cultures (GBCs, supporting cells), the neurons may have arisen from unidentified cells but ascribed to the keratin-positive HBCs. The role of HBCs remained moot even after the retroviral labeling experiments of undisturbed epithelium (Caggiano et al., 1994; Schwob et al., 1994a) because the animals were killed too early to observe the division of a horizontal basal cell with a cell cycle period of about 50 days (Mackay-Sim and Kittel, 1991). The contribution of HBCs as multipotent progenitors was demonstrated unequivocally using lineage tracing with genetically labelled cells (Leung et al., 2007). HBCs express keratin-5 (K5). Transgenic mice carried a reporter gene (*LacZ*) that was expressed only by cells expressing K5 and only when they were administered the drug Tamoxifen, such that the reporter gene was transcribed into protein ( $\beta$ -galactosidase) in the K5-expressing cells and their progeny. The K5 cells and progeny could be identified in tissue sections through a color reaction catalyzed by  $\beta$ -galactosidase. By administering the Tamoxifen (to switch on the labeling) after methyl bromide exposure to damage the olfactory epithelium, it was shown that K5-expressing HBCs could reconstitute all the cell types, both neuronal and non-neuronal, of the olfactory epithelium (Leung et al., 2007). A second study used a similar reporter gene in K5-positive HBCs with sensory neuron damage by olfactory bulbectomy and came to essentially the same conclusions (Iwai et al., 2008).

These studies showed that HBCs were *sufficient* to give rise to all cells. After epithelial damage not all the epithelial cells were labeled (Leung et al., 2007; Iwai et al., 2008) and in the undisturbed epithelium, despite extensive labeling of HBCs, there were only a few patches of labeled cells to indicate that HBCs had contributed to the cells above them in the epithelium (Leung et al., 2007; Iwai et al., 2008). These observations indicate that HBCs, although sufficient, were *not necessary* for regeneration of the epithelium, either undisturbed or after olfactory bulbectomy (Iwai et al., 2008) or chemical damage (Leung et al., 2007). This leaves open the question as to whether there are two multipotent progenitors, the HBC and a GBC. The stem cell potential of GBCs was specifically explored by a series of experiments using cell transplantation techniques in combination with genetic lineage tracing. In the first experiment, proliferating cells

of the rat olfactory mucosa (i.e., mainly GBCs; Schwartz Levey et al., 1991) were genetically labeled by infection with RRV after olfactory bulbectomy (Goldstein et al., 1998). These cells were then transplanted into the olfactory epithelium of MeBr-lesioned hosts and their fate was followed histologically. The descendants of these presumed GBCs included HBCs, GBCs, neurons and supporting cells (Goldstein et al., 1998). In a second study, GBC-2 antibody immunoreactivity was used to select GBCs and immature neurons from the normal, undamaged mouse epithelium by fluorescence-activated cell sorting (Chen et al., 2004b). These cells were infused intranasally into MeBr-lesioned hosts and their fate was followed by their expression of GFP or  $\beta$ -galactosidase (Chen et al., 2004b). The descendants of these GBCs included GBCs, neurons, sustentacular cells, duct/gland cells, and even respiratory columnar epithelial cells, i.e., every epithelial cell type *except* HBCs (Chen et al., 2004b). In contrast to this multipotency, sustentacular, and duct/gland cells sorted from the normal mouse epithelium using the antibody SUS-4 gave rise only to themselves (Chen et al., 2004b) and HBCs sorted from normal mouse epithelium using the lectin BS-I failed to engraft, suggesting that HBCs isolated from normal epithelium lacked the potency expected of stem cells (Chen et al., 2004b). Recent experiments show that some GBCs are very slow cycling (Guo et al., 2010), a feature taken as ancillary evidence for “stemness” (Cotsarelis et al., 1989; Mackay-Sim and Kittel, 1991; Potten, 1998). These experiments demonstrate that GBCs, like HBCs, satisfy the criteria for stemness, namely multipotency and self-renewal. As discussed above, each cell type can give rise to the other, indicating that both can be considered “stem cells” to all the cell types in the olfactory epithelium, although the transplantation experiments demonstrate that the GBCs are a mixed population of stem cells, multipotent proliferating progenitors, and immediate neuronal precursors (Figure 7.1).

In summary, the transplantation experiments above demonstrate that GBC stem cells are active in the normal epithelium and during sensory neuron replacement after damage to the olfactory epithelium. The lineage tracing experiments confirm this: in the normal epithelium the HBCs were labeled, with little contribution to other cell types; after bulbectomy (Iwai et al., 2008) or MeBr lesion (Leung et al., 2007), the HBCs contributed to all epithelial cell types. Even so, much of the epithelium remained unlabeled, indicating that GBCs continue to contribute to repair, as confirmed by combined lineage tracing and transplantation (Chen et al., 2004b). From these studies it seems probable that the GBC stem cell is constitutively active and the HBC stem cell is quiescent, requiring specific activation. This hypothesis was tested directly using transgenic mice similar to those used

previously (Leung et al., 2007) allowing us to identify HBCs and their progeny after transplantation into unlabeled hosts (Schnittke, Herrick, and Schwob, manuscript in preparation). It was found that transplanted HBCs did not show multipotency if they were derived from normal epithelium, in accordance with previous transplantation results (Chen et al., 2004b). However, if the donor olfactory epithelium was exposed to MeBr lesion 18–48 hr prior to HBC harvest, the HBCs contributed to all cell types in the host epithelium, consistent with previous lineage-tracing results (Leung et al., 2007). These observations demonstrate directly that HBCs must undergo a kind of “activation” *in situ* by some type of lesion-dependant signal in order to proliferate and become multipotent. GBCs do not require prior activation by a lesioned environment, but immediately function as multipotent following transplantation and engraftment (Chen et al., 2004b).

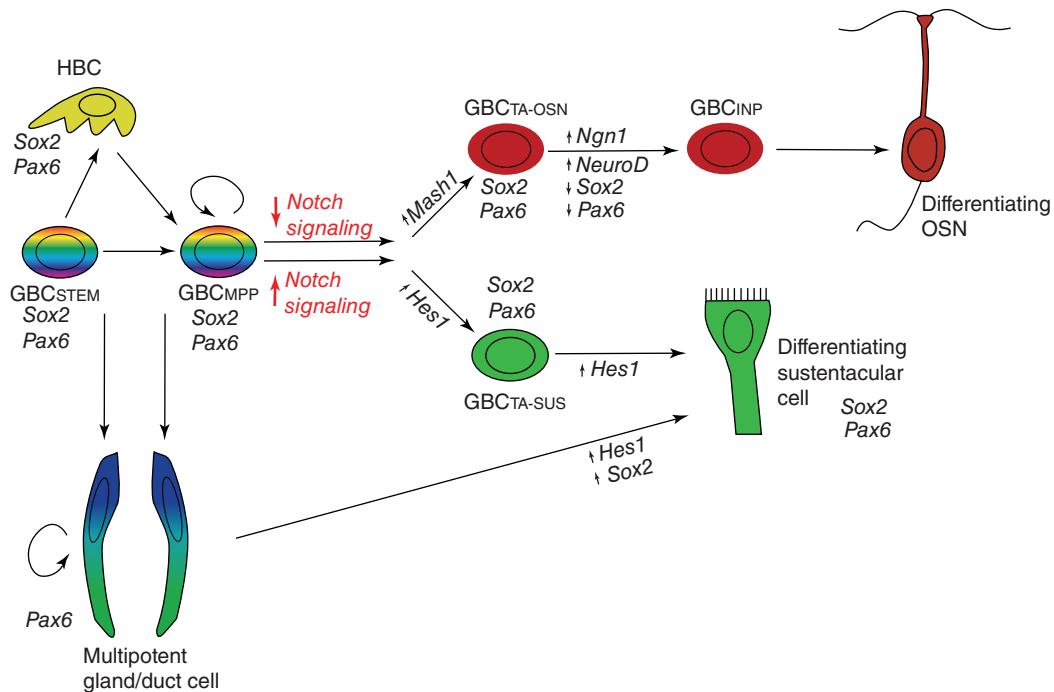

Taken together, the best current formulation for understanding the nature of stem cells in the olfactory epithelium is the existence of two kinds of tissue stem cell – a quiescent, reserve population (HBCs), and a more facultative population (GBCs). Each of these stem cells can generate the other, as well as all other neuronal and non-neuronal cell types in the adult olfactory epithelium. It is significant that genetic deletion of the transcription factor *p63* eliminated HBCs but did not prevent the development of GBCs, and all the other cells of the olfactory epithelium, including neurons, and their projection onto the olfactory bulb (Packard et al., 2011a). Furthermore, considering that HBCs emerge after GBCs during development (Packard et al., 2011), it is possible that HBCs are originally a GBC-derived population of quiescent stem cell that is removed from the cell cycle until re-activated by signals released during severe damage to the olfactory epithelium. Recent data indicate that down-regulation of the transcription factor *p63* is necessary and sufficient to activate HBCs. Within 18 hours of unilateral MeBr exposure, *p63* levels in HBCs are reduced in the lesioned side compared to the unlesioned side (Schnittke, Packard, and Schwob, manuscript in preparation). During the next day, some HBCs proliferate and lose all detectable *p63* expression (while remaining identifiable by labeling for K5, K14, and ICAM-1/CD54). When harvested at this time point, the HBCs are functionally multipotent following transplantation, indicating that loss of *p63* activates return to multipotency. Conversely, RRV-driven expression of *p63* prevents activation and multipotency (Schnittke and Schwob, manuscript in preparation). It is proposed that *p63* acts to promote HBC cell renewal and inhibits its differentiation (Fletcher et al., 2011), which is consistent with the finding that downregulation of *p63* releases this inhibition to activate a multipotent state. Specific molecular signals sustaining quiescence of HBCs, or

causing their activation during epithelial damage, have yet to be identified but they may include those described below.

### 7.2.4 Globose Basal Cell Lineage in Olfactory Neurogenesis

It should be emphasized that GBC cells form a heterogeneous population in terms of function within a hierarchy of cells from stem cell through to immediate neuronal precursor (Figure 7.1). GBCs are histologically very similar but can be distinguished from each other on the basis of the expression of a group of transcription factors, including well-known members of the basic helix-loop-helix (bHLH) family of transcription factors. Figure 7.2 is a heuristically useful model of the flow of cells during normal neurogenesis and during the reconstitution of the epithelium following injury. Needless to say, there is much that is not understood about the details of the process.

According to this model, the stages include: (1) multipotent stem cells ( $\text{GBC}_{\text{STEM}}$ ) (Chen et al., 2004b), (2) multipotent progenitors ( $\text{GBC}_{\text{MPP}}$ ) with the capacity to generate multiple epithelial cell types in response to direct epithelial injury (Goldstein et al., 1998; Huard et al., 1998; Chen et al., 2004b), (3) transit amplifying cells, which are apparently committed to making neurons ( $\text{GBC}_{\text{TA}}$ ; Guillemot et al., 1993; Gordon et al., 1995), and (4) immediate neuronal precursors, which undergo a final division and differentiate into neurons ( $\text{GBC}_{\text{INP}}$ ; Calof and Chikaraishi, 1989; Cau et al., 1997). Based on expression analysis and genetic epistasis, the transcription factors that can be used to separate the groups are Sox2 (a HMG transcription factor; Kawauchi et al., 2009; Guo et al., 2010), Pax6 (paired box), Ascl1 (bHLH; formerly known as Mash1; Guillemot et al., 1993; Cau et al., 1997), Neurog1 (bHLH; Cau et al., 1997; Cau et al., 2002), and NeuroD1 (bHLH; Cau et al., 1997; Packard et al., 2011a, b). Sox2 and Pax6 appear earliest in development and during regeneration; they are universally co-expressed by the residual GBCs 1 day after MeBr lesion, when the progenitor cells are multipotent (Guo et al., 2010). Ascl1 and then Neurog1 and NeuroD1 appear sequentially, followed by the differentiation of post-mitotic daughters into immature olfactory neurons (Cau et al., 1997; Manglapus et al., 2004). Ascl1 was identified as a marker for the transit amplifying stage based on the proliferation of that subpopulation of GBCs in advance of the enhanced proliferation caused by neuronal death and on the reduction of olfactory neurogenesis in Ascl1 knockout animals (Gordon et al., 1995). Epistasis in Ascl1 knockout epithelium and the timing of expression in normal embryos and lesioned-recovering adult epithelium indicate that Neurog1 and NeuroD1 expression are expressed downstream of Ascl1 (Cau et al., 1997; Manglapus et al., 2004). Further analysis suggests that Neurog1

**Figure 7.2** Stem cell-progenitor cell relationships in the adult olfactory epithelium. In this model, the heterogeneous population of GBCs includes stem cells (GBC<sub>STEM</sub>), committed multipotent precursors (GBC<sub>MPP</sub>), neuron-committed transit amplifying cells (GBC<sub>TA-OSN</sub>) and immediate neuronal precursors (GBC<sub>INP</sub>) that give rise to olfactory sensory neurons (OSN). Different GBCs are distinguished by the expression of a limited number of transcription factors (*Sox2*, *Pax6*, *Ngn1*, *NeuroD*, *Mash1*, *Hes1*, *p63*). After damage to the epithelium, *Notch* signaling, and the upregulation of *Hes1*, directs some of the multipotent GBCs toward a sustentacular fate (GBC<sub>TA-SUS</sub>). Multipotent gland/duct cells are also capable of making sustentacular cells, although the signals required are not yet clear. The HBCs, a reserve stem cell population, are set aside when the transcription factor *p63* is expressed and are activated to function in recover after epithelial injury when *p63* is suppressed. At several points along the pathway, the stem and progenitor cells have a capacity to give rise to and renew themselves, at least to a limited extent.

is slightly upstream of NeuroD1, but shows substantial overlap with it (Cau et al., 2002; Manglapus et al., 2004; Packard et al., 2011a). All olfactory neurons apparently derive from a NeuroD1-expressing stage in the progenitor progression, based on genetic lineage tracing and expression of NeuroD1 by proliferating GBCs (Packard et al., 2011a). *Sox2* and *Pax6* perdure through the Ascl1 (+), transit-amplifying stage, but both are undetectable in immediate neuronal precursor-stage GBCs marked by either NeuroD1 or Neurog1 (Guo et al., 2010). Interestingly, the patterns of gene expression by the GFP-labelled immediate neuronal precursors and immature neurons in mice expressing a Neurog1-GFP transgene are virtually identical between normal epithelium and post-bulbectomy epithelium when proliferation is accelerated (Krolewski et al., 2012). This finding suggests that the Neurog1<sup>+</sup> GBCs are downstream of the cell that is responsible for the acceleration of proliferation following bulb ablation.

Additional evidence can be adduced for the identification of *Sox2*<sup>+</sup>/*Pax6*<sup>+</sup>/Ascl1<sup>-</sup> cell as the multipotent progenitor (GBC<sub>MPP</sub>). One day after MeBr lesion, some

identified GBCs labeled with RRV (Huard et al., 1998) express the neuroinhibitory bHLH transcription factor, Hes1, and then shift apically and differentiate into Hes1-expressing sustentacular cells (Manglapus et al., 2004). This finding accounts for the generation of sustentacular cell-only clones following RRV-LacZ infection or GBC transplantation. Hes1 is one of the canonical targets for up-regulation by Notch signaling in both vertebrates and invertebrates, a pathway that is commonly used to switch progenitor cells between fates, especially neuronal versus non-neuronal (Kageyama and Ohtsuka, 1999). Indeed, Hes1 up-regulation is often used as an indirect measure of Notch activation. To test whether Notch signaling was responsible for the switch between generating neurons versus sustentacular cells, two vectors were used to modify Notch signaling: RRV encoding a constitutively active form of Notch1 (the Notch1 intracellular domain or NICD) and another encoding a dominant negative version of Mastermind-like (dnMAML), a co-factor required for activation of transcription following Notch signaling. Infection with RRV-dnMAML prevented the generation

of sustentacular cells, such that infected clones were composed of neurons and, on occasion, non-HBC basal cells (Guo, Schnittke, and Schwob, manuscript in preparation). In contrast, RRV-NICD prevented the generation of neurons and produced clones that were extremely large and uniformly composed of sustentacular-like cells of a primitive, K18-expressing epithelial cell (*ibid*). Taken together, the data suggest strongly that Notch signalling is involved in the regulation of neuron production versus generation of sustentacular and other non-neuronal cells by multipotent GBCs (GBC<sub>MPP</sub>). Although firmly based on available data, the model in Figure 7.2 is still incomplete in describing the lineage relationships during neurogenesis and the production of non-neuronal cell types in the adult olfactory epithelium. There may also be differences during development. For example, some Ascl1<sup>+</sup> GBCs or early GBC-like progenitors on the way to becoming GBCs express *p63* and may go on to make HBCs (Packard et al., 2011b).

### 7.2.5 Ectomesenchymal Stem Cell in Olfactory Mucosa

In addition to the basal cells of the olfactory epithelium, the human olfactory mucosa contains a stem cell that is described as an “ectomesenchymal” stem cell, with properties of both mesenchymal and neural stem cells (Delorme et al., 2010). This stem cell is grown in vitro from the whole mucosa, including cells from both epithelium and the underlying lamina propria (Murrell et al., 2005; Delorme et al., 2010). It can be cultured in “neurospheres,” in common with other neural stem cells, but is capable of differentiating into neurons, astrocytes, and oligodendrocytes, as well as a wide range of non-neural cell types, including cardiac and skeletal muscle, chondrocytes, osteocytes, liver cells, and fat cells (Murrell et al., 2005; Murrell et al., 2008; Murrell et al., 2009; Delorme et al., 2010; Wetzig et al., 2011). After transplantation into the chick embryo, olfactory stem cells from mouse and human olfactory mucosa contributed to heart, liver, kidney, and nervous system (Murrell et al., 2005). When transplanted into the bone marrow of irradiated adult rat, olfactory stem cells contributed to all blood lineages (Murrell et al., 2005). A “mesenchymal-like” stem cell was isolated from embryonic rat olfactory mucosa with cellular markers that are also present in the lamina propria (Tome et al., 2009). Adult mouse and human lamina propria cultures yield multipotent stem cells in the absence of cells from the olfactory epithelium (unpublished observations), but definitive identity of a lamina propria stem cell is still lacking. It is possible that the “ectomesenchymal” stem cell in adult olfactory mucosa is derived from the ectomesenchymal stem cell

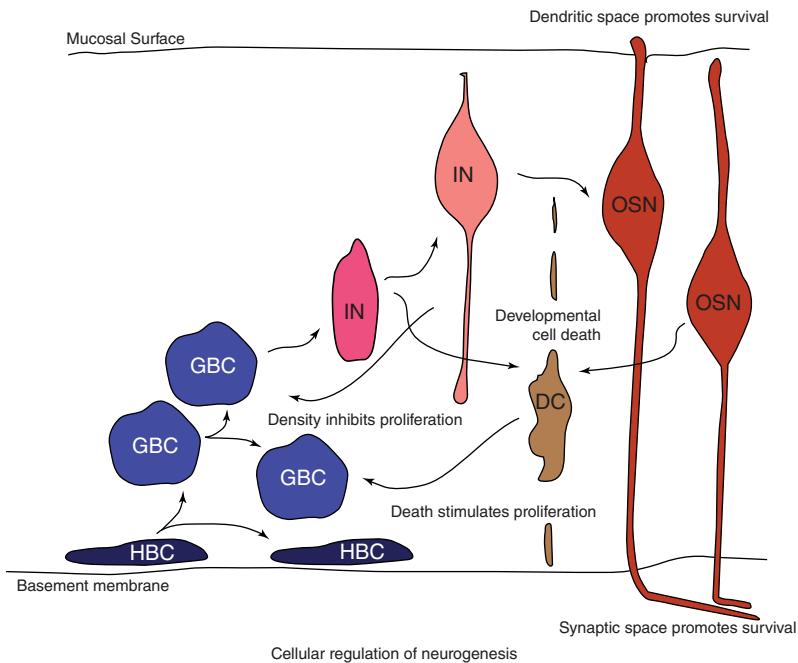

that migrates out from the cranial neural crest during embryogenesis. These multipotent cells give rise to multiple neural and non-neural tissues of the head, including neurons and glia of the peripheral nervous system, smooth muscle, bone, cartilage, corneal endothelium, and dental pulp. The olfactory ensheathing cells in the olfactory mucosa are derived from neural crest (Barraud et al., 2010; Forni et al., 2011) and there is some evidence for contributions to the olfactory placode by the neural crest in mouse (Katoh et al., 2011). A neural crest origin of stem cells in adult olfactory mucosa may help explain their multipotent capacity, although definitive evidence for a neural crest origin of olfactory mucosa stem cells is still lacking.

### 7.2.6 Summary

Life-long neurogenesis, now accepted to be integral to the adult brain, was first demonstrated in the adult olfactory epithelium. As shown in Figures 7.1 and 7.2, there is now a deep understanding of the cell lineage of olfactory neurogenesis from stem cell to differentiated sensory neuron and the other cell types of the olfactory epithelium. It is apparent that both HBCs and GBCs have the capacity of multipotent stem cells, with HBCs likely to be a quiescent population requiring activation by epithelial damage to re-enter the multipotent lineage. In the lamina propria below the epithelium there is another multipotent ectomesenchymal stem cell. A major outstanding question is whether there is a direct lineage relationship between the neural stem cell of the olfactory epithelium and the multipotent ectomesenchymal stem cell in the lamina propria.

## 7.3 REGULATION OF OLFACTORY NEUROGENESIS

Early analyses of olfactory neurogenesis were interpreted to mean that the neurons “remain in the epithelium as mature functional elements for approximately 25 days” (Moulton, 1975; Graziadei and Monti Graziadei, 1979; Samanen and Forbes, 1984). Along with this concept of a short-lived sensory neuron, there came to be an assumption that turnover of sensory neurons from basal cell mitosis was a “predetermined … genetic characteristic” (Graziadei and Monti Graziadei, 1978). Contrary to this oft-cited view, there is now overwhelming evidence that olfactory neurogenesis is a highly regulated and homeostatic process that in some respects reflects aspects of embryonic development in other parts of the nervous system. Under this hypothesis neurogenesis in the adult olfactory epithelium follows rules that govern brain development (Breipohl et al., 1986): (1) cell death occurs at all stages of neuronal development; (2) developing neurons are over-produced;

**Figure 7.3** Cellular regulation of neurogenesis in vivo. Neurogenesis is regulated by extrinsic factors (epithelial damage, toxins, olfactory bulb ablation) causing cell death which, in turn, stimulates proliferation of the basal cell progenitors and neuronal precursors (HBC, GBC). Cell death (DC, dying cell) is also caused by intrinsic developmental factors (hormones, growth factors, dendritic and synaptic space) that affect maturation and survival of developing neurons (IN). Basal cell proliferation is inhibited by the density of immature neurons. These dynamic processes involve many paracrine and autocrine signals which eventually select a few neurons to undergo final maturation. Once mature, the olfactory sensory neuron (OSN) lives until damaged by extrinsic factors.

**Table 7.1** Regulation of basal cell proliferation in vivo.

Experiment	Stimulus	Effect on Basal Cell Proliferation	Possible Regulatory Pathway
Olfactory nerve cut	Death of neurons	Increased	Proliferating factor released from dying cells
Chemical destruction of neurons	Death of neurons	Increased	Proliferating factor released from dying cells
Destruction of olfactory bulb mitral cells	Death of neurons	Increased	Lack of trophic factor from synaptic target
Naris occlusion, open side	Increased usage, loss of neurons	Increased	Proliferating factor released from dying cells
Naris occlusion, closed side	Reduced usage, no cell death	Decreased	Lack of proliferating factor, increase in inhibitory factor
Epithelial thickness	Increase in immature neuron density	Decreased	Increase in inhibitory factor

(3) developing neurons pass through a “critical period” during which they must find synaptic space at their target, or die; (4) successful neurons are dependent on their target for survival; and (5) mature neurons are not programmed to die but may die from external influences. Figure 7.3 and Table 7.1 summarize the cycle of neurogenesis and some of the regulating factors.

During neurogenesis in the adult olfactory epithelium autocrine and paracrine signals and cell–cell contact maintain or induce different cell types. Signals potentially arise within the epithelium, lamina propria, and olfactory bulb. Furthermore, because the surface density of sensory neuron dendrites is controlled and stable (Mackay-Sim et al., 1988;

Mackay-Sim and Kittel, 1991a), it is possible that signals may be present in the mucus, acting as target-derived factors for the dendrites.

Neurogenesis is stimulated by death of the sensory neurons (Nagahara, 1940; Graziadei, 1973) followed by restoration of olfactory function (Harding et al., 1978). Long-term sensory neuron survival requires synaptic contact with the olfactory bulb (Schwob et al., 1994b) and loss of the synaptic targets in the olfactory bulb stimulates basal proliferation for more than a year (Weiler and Farbman, 1999). Neurogenesis is affected by usage, as shown by experiments in which the naris is sealed unilaterally in early development (Farbman et al., 1988) or in adulthood

(Maruniak et al., 1989). Neurogenesis is regulated by the density of immature neurons, as shown by an inverse correlation between basal cell proliferation and epithelial thickness in the salamander. Quantitative analysis of the cell types in this epithelium demonstrated that the only cell type whose numbers increased with epithelial thickness was the immature neuron (Mackay-Sim et al., 1988). This led to the conclusion that the developing neurons exert an inhibitory influence on basal cell proliferation (Mackay-Sim et al., 1988). In agreement is evidence that the rate of proliferation in vitro was reduced when precursor cells were co-cultured with sensory neurons (Mumm et al., 1996). Cell death in the normal undisturbed epithelium is apoptotic (Magrassi and Graziadei, 1995) and can occur as early as one day after cell birth (Carr and Farbman, 1993), such that apoptotic cells can be horizontal basal cells, globose basal cells, immature neurons, and mature neurons (Holcomb et al., 1995; Mahalik, 1996). The apoptotic cascade can be induced by activation of the cell surface receptors Fas and TNF receptor-1 by their ligands FasL and TNF- $\alpha$  (Farbman et al., 1999). Neurogenesis is reduced with age in the human olfactory epithelium (Naessen, 1971; Nakashima et al., 1984; Nakashima et al., 1985).

## 7.4 MOLECULAR REGULATION OF OLFACTORY NEUROGENESIS

Regulation of proliferation, differentiation, survival, and death during olfactory neurogenesis requires multiple factors operating in multiple signaling pathways. All cells in epithelium and lamina propria may play roles in maintaining sensory neuron number and survival. For example, the supporting cells could monitor the local density of sensory neurons because they surround the dendrites of the sensory neurons (Breipohl et al., 1974; Graziadei and Monti Graziadei, 1979) and may release factors to regulate proliferation of basal cells or differentiation of neuronal precursors and immature neurons supporting cells. Similarly horizontal basal cells wrap around the axons as they leave the epithelium (Holbrook et al., 1995) and the ensheathing cells do so when they enter the lamina propria and guide them to the olfactory bulb (Doucette, 1984; Gong et al., 1994). Either of these cell types could regulate neuronal survival and differentiation. Broadly speaking, there are two types of signals that could regulate olfactory neurogenesis at the local or cellular level: diffusible and fixed. Growth factors are diffusible signals that can have paracrine or autocrine actions. Fixed signals include physical interactions via direct cell surface contacts and indirect contacts through the extracellular matrix. Extracellular signals have not been extensively investigated in olfactory neurogenesis—much more is known about growth factors.

### 7.4.1 Growth Factors and Receptors Present in Olfactory Epithelium

A long list of growth factors and their receptors have been identified in the olfactory epithelium (Table 7.2), although the cell types that express them are not always known. The exceptions are CNTF (basal cells and neurons; Buckland and Cunningham, 1999), dopamine (mucus; Lucero and Squires, 1998), dopamine D2 receptor (basal cells and neurons; Feron et al., 1999; Koster et al., 1999), EGF receptor and TGF $\alpha$  (horizontal basal cells and supporting cells; Farbman et al., 1994; Holbrook et al., 1995; Farbman and Buchholz, 1996; Krishna et al., 1996), FGF2 (supporting cells, neurons, basal cells; Matsuyama et al., 1992; Gall et al., 1994; Goldstein et al., 1997; Chuah and Teague, 1999; Hsu et al., 2001), GDNF (neurons; Buckland and Cunningham, 1999), IGF binding proteins 2–4 (mucus; Federico et al., 1999), p75<sup>NTR</sup> (supporting cells and horizontal basal cells in the human; Feron et al., 2008; Hahn et al., 2005; Minovi et al., 2010), TrkA (supporting cells and horizontal basal cells; Feron et al., 2008; Roskams et al., 1996; Miwa et al., 1998), TrkB and TrkC (neurons; Roskams et al., 1996; Feron et al., 2008), NGF (neurons; Williams and Rush, 1988; Aiba et al., 1993; Roskams et al., 1996; supporting cells, neurons, immature neurons, globose basal cells; Feron et al., 2008), BDNF (horizontal basal cells; Buckland and Cunningham, 1999; supporting cells, neurons, immature neurons Feron et al., 2008), NT3 (supporting cells, neurons, immature neurons; Feron et al., 2008), NT4 (all cell types in epithelium; Feron et al., 2008), Neuregulin1 isoforms (lamina propria) and ErbB receptors (GBCs and immature neurons; Salehi-Ashtiani and Farbman, 1996; Donovan and Schwob, manuscript in preparation). The variety of growth factors and receptors present in the olfactory epithelium and the variation in expression by the different olfactory cell types suggests a rich complexity in the regulation of olfactory neurogenesis.

### 7.4.2 Growth Factor Functions in Olfactory Neurogenesis

Defining the actions of growth factors can be very difficult. For example, does the growth factor act directly or via a neighboring cell? Does the putative target cell have the appropriate receptors? Is an increase in sensory neurons in vitro the result of a growth factor action on progenitor proliferation or differentiation, or neuronal survival or death? Generalizing from the literature is further complicated by the variety of culture systems, cell types, species, and culture media. Consequently the conclusions drawn from most studies about growth factor actions should be considered as “working hypotheses” until the various complexities are explored. Nonetheless converging data suggest distinct and

**Table 7.2** Growth factors, receptors, binding proteins and synthetic enzymes present in olfactory epithelial cells, identified immunologically, using *in situ* hybridisation or RT-PCR. Papers include adult and developing tissues and some primary cultures of adult epithelial cells. ATP, dopamine, nitric oxide and vitamin A are not peptide growth factors but have growth factor-like actions in olfactory cell cultures. ActR, Activin receptor; BDNF, brain derived growth factor; BMP, bone morphogenic protein; BMPR, bone morphogenic protein receptor; CNTF, ciliary neurotrophic factor; D2, dopamine D2 receptor; DA, dopamine; EGF, epidermal growth factor; EGFR, epidermal growth factor receptor; FGF, fibroblast growth factor; FGFR, fibroblast growth factor receptor; GDNF, glial cell line-derived growth factor; GFR, GDNF receptor; GGF, glial growth factor; IGF, insulin-like growth factor; LIF, leukocyte inhibitory factor; NDF, Neu differentiation factor; NGF, nerve growth factor; NO, nitric oxide; NOS, nitric oxide synthase; NPY, neuronal protein Y; NRG, neuregulin; NT3, neurotrophin 3; p75<sup>NTR</sup>, p75 neurotrophin receptor; PDGF, platelet-derived growth factor; PDGFR, platelet-derived growth factor receptor; P2XR, purine receptor type 2X; PYY, protein YY; RA, retinoic acid; RAR, retinoic acid receptor; RXR, retinoid X receptor; TGF, transforming growth factor; Trk, tyrosine kinase.

definable roles in olfactory neurogenesis for EGF family factors, FGF2, TGF $\beta$  family factors, LIF, NO, and ATP (Figure 7.4).

EGF and TGF $\alpha$  stimulate proliferation of horizontal basal cells (Satoh and Takeuchi, 1995; Farbman and Buchholz, 1996; Feron et al., 1999c). TGF $\alpha$ , but not EGF, is expressed in the olfactory epithelium and their cognate receptor (EGFR) is also present on horizontal basal cells and supporting cells (Farbman et al., 1994; Holbrook et al., 1995; Farbman and Buchholz, 1996; Krishna et al., 1996). Neuregulins, other members of the EGF family, are implicated in olfactory neurogenesis. The neu differentiation factors (NDF $\beta$ -1, -2, and -3) stimulate proliferation of olfactory ensheathing cells and the ensheathing cells, GBCs and immature neurons express ErbB2 receptors (Pollock et al., 1999). Another neuregulin, glial growth factor 2 (GGF2), is weakly proliferative and induces differentiation of ensheathing cells and is expressed by them (Chuah et al., 2000).

In vitro, FGF2 stimulates proliferation of a globose basal cell neuronal precursor (DeHamer et al., 1994; Newman et al., 2000), a globose basal cell-like cell line (Goldstein et al., 1997), and a human olfactory progenitor cell line (Ensoli et al., 1998). FGF2 induced differentiation in explant cultures of mouse and human olfactory epithelium (MacDonald et al., 1996; Murrell et al., 1996), but this is an indirect effect of stimulation of globose basal

cell proliferation (Newman et al., 2000). These observations are consistent with in vivo delivery of FGF2 both intraperitoneally (Nakamura et al., 2002) and intranasally (Nishikawa et al., 2009). FGF2 also stimulated proliferation of ensheathing cells (Chuah and Teague, 1999), and the related FGF1 stimulates ensheathing cell differentiation (Key et al., 1996).

Several members of the TGF $\beta$  family of growth factors are implicated in olfactory neurogenesis. TGF $\beta$ 2 induces differentiation of neuronal precursors (Mahanthappa and Schwarting, 1993), a keratin-positive basal cell line (Satoh and Takeuchi, 1995) and the globose basal cell (Newman et al., 2000). In vivo experiments (Mackay-Sim and Patel, 1984) and in vitro experiments (Mumm et al., 1996) indicated that neurons or immature neurons exert an inhibitory effect on basal cell proliferation. It is possible that this inhibition is mediated via BMPs and their receptors. BMPs 2, 4, and 7 can inhibit proliferation of neuronal precursors in vitro (Shou et al., 1999). BMP receptor subtype Ib is present in embryonic olfactory epithelium (Zhang et al., 1998), mRNA for BMP receptor subtypes Ia, Ib, and II are present in adult olfactory epithelium (Hsu and Mackay-Sim, unpublished). In the embryo, BMPs 2, 4, and 7 are expressed by cells in the lamina propria beneath the olfactory epithelium and noggin, a BMP antagonist, inhibited olfactory neurogenesis in embryonic cultures and low concentrations of BMP4 promoted survival of newly

**Figure 7.4 Growth factor regulation of cell proliferation and neurogenesis.** A working hypothesis of growth factor interactions that maintain neurogenesis in olfactory epithelium. See text for details.

generated olfactory receptor neurons (Shou et al., 2000). These results suggest both anti-proliferative and neuronal survival roles for BMPs, at least during embryogenesis. Another member of the TGF $\beta$  family, GDF11, also arrests the cell cycle of olfactory progenitors (Wu et al., 2003). *GDF11*-deficient mice have more olfactory progenitors and neurons (Wu et al., 2003), whereas mice deficient in a GDF11 antagonist, follistatin, have decreased neurogenesis (Gokoffski et al., 2011). *Foxg1* is a transcription factor that negatively regulates TGF $\beta$  family signaling. *Foxg1*-deficient mice have deficient follistatin signaling, and like the follistatin deficient mouse have fewer olfactory progenitors and sensory neurons (Kawauchi et al., 2009a). This phenotype is rescued by mutations in *GDF11*, leading to the conclusion that *Foxg1* inhibits GDF11 signaling via follistatin (Kawauchi et al., 2009a). It is proposed that GDF11 inhibits and follistatin stimulates expansion of the immediate neuronal precursors, but a second follistatin binding factor, activin betaB, inhibits expansion of earlier stages in the lineage, namely stem cells and early progenitors (Gokoffski et al., 2011).

The cytokine, LIF, regulates proliferation of olfactory progenitors during regeneration after injury to the olfactory epithelium. Olfactory bulbectomy transiently induces *LIF* mRNA in injured sensory neurons (Bauer et al., 2003) and globose basal cells (Nan et al., 2001). Bulbectomy also induces expression of mRNA for the LIF receptor, *LIFR*, and downstream signaling molecules STAT3 and Cyclin

D1 (Getchell et al., 2002b). Bulbectomy normally stimulates progenitor proliferation in the olfactory epithelium, but this fails to occur in the LIF-deficient mouse (Bauer et al., 2003). In vitro, LIF stimulates proliferation neuronal precursors (Satoh and Yoshida, 1997) and inhibits sensory neuron maturation (Moon et al., 2002). Recent evidence demonstrates that the effects of LIF are mediated via the diffusible factor, nitric oxide (NO) (Sulz et al., 2009; Lopez et al., 2012). Nitric oxide synthase (NOS) is induced in olfactory epithelium after bulbectomy (Roskams et al., 1994). In vitro, NO induced proliferation of basal cells and blockers of inducible-NOS inhibited proliferation and promoted differentiation into sensory neurons, effects that were reversed by a NO donor (Sulz et al., 2009). LIF induced expression of LIFR and iNOS in horizontal basal cells and globose basal cells and stimulated proliferation of neural progenitors (Lopez et al., 2012). The proliferative effect of LIF was prevented by a LIFR blocking antibody and by an inhibitor of iNOS, with both effects reversed by a NO donor (Lopez et al., 2012). Taken together these experiments suggest that damage to the olfactory sensory neurons induces expression of LIF, which then stimulates proliferation of globose basal cells, the neuronal progenitors, and inhibits differentiation of sensory neurons via induction of iNOS and production of NO. Because NO diffuses readily through tissues, this mechanism would spatially enhance the transient effect of LIF release from affected sensory neurons. After damage to the olfactory epithelium, LIF is released by macrophages in the olfactory

mucosa (Getchell et al., 2002b) and iNOS is induced in olfactory ensheathing cells (Harris et al., 2009), further amplifying this signaling pathway.

Purines such as ATP are involved in regeneration of the sensory neurons after epithelial injury. The purinergic P2X receptor is found in basal cells, and blocking PTX receptors inhibits the injury-induced proliferation of basal cells (Gao et al., 2010). Intraperitoneal and intranasal ATP and purinergic agonists induced proliferation of progenitors in the olfactory epithelium, an effect that was reversed by purinergic antagonists and similar results were obtained in vitro (Jia et al., 2009). The mechanism of ATP-induced proliferation may act via several growth factor signaling pathways. ATP-induced expression in olfactory epithelium of TGF $\alpha$ , FGF2, and NPY via purinergic receptors (Jia et al., 2011). The ATP-induced proliferation was blocked by inhibitors of EGFR and FGFR, indicating that ATP signaling acts via the well documented TGF $\alpha$  and FGF2 actions in the olfactory epithelium. NPY is expressed by supporting cells, sensory neurons and some olfactory ensheathing cells (Doyle et al., 2012). NPY-deficient mice have fewer olfactory neurons but more MASH1-positive globose basal cells (Doyle et al., 2012). The number of neurospheres generated from olfactory mucosa is reduced compared to wild-type mice in NPY-deficient and Y1 receptor-deficient mice (Doyle et al., 2008). In the neonatal olfactory epithelium, purinergic receptor agonists induced release of NPY in slice cultures (Kanekar et al., 2009) and in the adult olfactory epithelium, ATP promoted NPY synthesis and increased the number of NPY-positive cells (Jia and Hegg, 2010). This was blocked with purinergic receptor antagonist, which also blocked the effect of ATP on basal cell proliferation (Jia and Hegg, 2010). The emerging picture from these results is that cellular damage to the olfactory epithelium releases ATP into the extracellular milieu and this then induces proliferation of neuronal progenitors via the EGF, FGF2, and NPY signaling pathways. PYY, a molecule in the NPY family may also play a role in neurogenesis (Doyle et al., 2008; Doyle et al., 2012).

Other peptide growth factors are implicated in olfactory neurogenesis, although their functions are less well defined. IGF-I is present in human olfactory mucus (Federico et al., 1999) and infusion of IGF-I into the external nares increased the thickness of the olfactory epithelium and increased the number of proliferating cells (Pixley et al., 1998). In vitro, IGF-I reduced GBC proliferation and promoted morphological differentiation of neurons (McCurdy et al., 2005). Of the neurotrophins, BDNF and NT-3, but not NGF, increased the numbers of immature neurons in primary cultures of olfactory neurons (Holcomb et al., 1995; Roskams et al., 1996; Liu et al., 1998). BDNF induces proliferation and survival of neuronal precursors,

effects that were blocked by atrial C-type natriuretic peptide (Simpson et al., 2002). Given the distribution of the neurotrophin receptors (see above), it is not surprising that sensory neurons were not affected by the presence of NGF because they lack its receptors TrkA and p75<sup>NTR</sup> (Feron et al., 2008). It is interesting to note that in co-cultures of neurons and ensheathing cells withdrawal of NGF resulted in a dramatic decrease in neuron number (Bakardjieva, 1997). This may have been an indirect effect via loss of the ensheathing cells, which express the low affinity NGF receptor (see below). The Wnt signaling pathway is a major regulator of embryonic brain development. Several Wnt signaling molecules were expressed in the adult olfactory epithelium, including agonists (Wnt2, Wnt3a, Wnt7b), an antagonist (Sfrp1), a receptor (Fzd), and signaling pathway molecules (Axin1, Tcf7l2; Wang et al., 2011). Wnt signaling inhibitors disrupted neurogenesis after epithelial damage with significant reductions in olfactory sensory neurons and neuronal progenitors, indicating that Wnt signaling may be necessary for progenitor proliferation (Wang et al., 2011). In vitro, Wnt activators increased the number of immature neurons and reduced the number of non-neuronal cell types, leading to the suggestion that Wnt promotes neuronal differentiation (Wang et al., 2011).

Dopamine induced apoptosis and differentiation of an olfactory cell line (Coronas et al., 1997a) and promoted differentiation in explant culture of olfactory epithelium of the adult mouse (Feron et al., 1999c). In human explant cultures, dopamine inhibited mitosis and induced apoptosis (Feron et al., 1999c). These effects were mediated via the dopamine D2 receptor (Feron et al., 1999c), which is present in the neuronal layer of the olfactory epithelium (Feron et al., 1999c; Koster et al., 1999). Dopamine is present in the mucus above the epithelium (Lucero and Squires, 1998). Dopamine modulates electrical properties of sensory neurons (Vargas and Lucero, 1999) via adenylyl cyclase (Mania-Farnell et al., 1993; Coronas et al., 1999) and hence could signal that the developing dendrite has reached the epithelial surface. Dopamine is also present in the olfactory bulb at the site of axon termination (Halasz et al., 1977; Davis and Macrides, 1983), and it could act there as a signal to the developing neuron that its axon has reached its target. It is possible, therefore, that dopamine may act continually as a trophic factor at both ends of the active sensory neuron.

Retinoic acid (vitamin A) is involved in many aspects of neural development. The many components of retinoic signaling are present in the olfactory epithelium: receptors (RAR $\alpha$ , RAR $\beta$ , RXR $\alpha$ , RXR $\beta$ , and RXR $\gamma$ ; Zhang, 1999; Yee and Rawson, 2005), synthetic enzymes (RALDH 1–3; Peluso et al., 2012), binding proteins (CRABP I and II; Asson-Batres et al., 2003) and degrading enzyme (Cyp26B1; Hagglund et al., 2006). Vitamin A deficiency increases proliferation of basal cells (Asson-Batres

et al., 2003a, b) and retinoic acid induced differentiation of an immortalized olfactory progenitor cell line into OMP-positive neurons (Lakard et al., 2007) and induced neurite outgrowth of olfactory neurons (Whitesides et al., 1998). The direction of retinoic acid signaling appears to be from supporting cells and lamina propria fibroblasts onto sensory neurons and basal cells because the synthetic enzymes are found in the former (Asson-Batres and Smith, 2006; Peluso et al., 2012) and the receptors are found in all cell types (Yee and Rawson, 2005; Oztopatli et al., 2012). Cyp26B1, the retinoic acid degrading enzyme, was found in some sensory neurons (Hagglund et al., 2006). Expression of a dominant-negative retinoic acid receptor ( $\text{RAR}\alpha$ ) in sensory neurons during development led to their premature death (Hagglund et al., 2006; Oztopatli et al., 2012) and after epithelial damage, retroviral transduction with the same dominant-negative retinoic acid receptor after epithelial damage blocked the reappearance of mature OMP-positive sensory neurons (Peluso et al., 2012). Epithelial damage and treatment with retinoic acid increased the number of  $\text{RAR}\alpha$ -positive supporting cells and basal cells (Yee and Rawson, 2005). These experiments suggest that retinoic acid signaling regulates differentiation of neuronal progenitors into sensory neurons and that this signaling operates via supporting cells.

### 7.4.3 Macrophages and Olfactory Neurogenesis

The olfactory mucosa, including the olfactory epithelium, is populated by macrophages and dendritic cells, the surveillance cells of the immune system (Getchell et al., 2002b; Ruitenberg et al., 2008). Macrophages respond dynamically to tissue damage. Recruitment of macrophages to the epithelium after damage is essential for regeneration. When macrophage recruitment was reduced after bulbectomy, apoptosis was increased whereas epithelial thickness, proliferation, and sensory neuron numbers were all reduced (Borders et al., 2007). Bulbectomy increased levels of macrophage attractant chemokines MIP-1 $\alpha$  and MCP-1 and their receptors CCR1 and CCR2 – all found on resident and infiltrating macrophages (Getchell et al., 2002c). *MIP-1 $\alpha$* -deficient mice had reduced recruitment of macrophages to the epithelium after bulbectomy that was reversed by *MIP-1 $\alpha$*  treatment (Kwong et al., 2004). Macrophage infiltration and activation and neuronal progenitor proliferation were all reduced after bulbectomy in mice deficient of the macrophage scavenger receptor, which mediates binding of macrophages to apoptotic cells (Getchell et al., 2006). Macrophages and dendritic cells in the olfactory epithelium express another chemokine receptor, CX3CR1 and they depend on its ligand, fractalkine/CX3CL1, for intraepithelial migration (Ruitenberg et al., 2008). CX3CR1-deficient

mice have increased death of sensory neurons after bulbectomy (Blomster et al., 2011). This was associated with increased recruitment of macrophages into the damaged epithelium and increased levels of proinflammatory cytokines (TNF $\alpha$  and IL6), despite diminished macrophage phagocytic activity (Blomster et al., 2011). Taken together these studies demonstrate the importance of macrophages in regulating regeneration of the olfactory epithelium after damage to the sensory neurons.

### 7.4.4 Olfactory Ensheathing Cells and Neurogenesis

The remarkable capacity for neurogenesis is partly dependent on the olfactory ensheathing cells (OECs), the glia that surround the sensory axons to form the olfactory nerve fascicles from the epithelium to the olfactory bulb (Doucette, 1984; Doucette, 1989; Marin-Padilla and Amieva, 1989; Doucette, 1990; Valverde and Lopez-Mascaraque, 1991; Franceschini and Barnett, 1996). In the lamina propria they surround local fascicles of olfactory axons that become increasingly larger towards the olfactory bulb (Doucette, 1990). Upon reaching the bulb, the olfactory nerve defasciculates; presumably with the aid of the OECs of the outer nerve fibre layer (Doucette, 1989). The axons then refasciculate according to their odorant receptor type, prior to targeting to their topographically appropriate glomerulus and a process in which the OECs of the inner nerve fibre layer are thought to contribute (Doucette, 1989; Mombaerts et al., 1996; Au et al., 2002).

OECs are heterogeneous in morphology, gene expression, protein expression, and functions associated with their location in the olfactory nerve or olfactory bulb. In the olfactory nerve, two types are distinguished by distinct cytoplasmic densities under the electron microscope (Cuschieri and Bannister, 1975; Doucette, 1989; Valverde et al., 1993) and immunologically, whereby some express S-100 protein and glial acidic fibrillary protein (GFAP) and others express only GFAP (Pixley, 1992). In the nerve and outer nerve fibre layer of olfactory bulb, OECs express p75<sup>NTR</sup> (Vickland et al., 1991; Pixley, 1992; Turner and Perez-Polo, 1992; Gong et al., 1994; Mombaerts et al., 1996; Roskams et al., 1996), S100 (Pixley, 1992), brain lipid binding protein (BLBP; Vincent et al., 2008), and polysialylated neural cell adhesion molecule (E-NCAM) (Franceschini and Barnett, 1996). OECs in the inner nerve fibre layer of olfactory bulb express low levels of S100B, but not p75<sup>NTR</sup>, and a subset expresses TROY and NPY (Ubink and Hokfelt, 2000; Hisaoka et al., 2004; Morikawa et al., 2008). Microarray studies demonstrate that OECs from olfactory nerve outside the olfactory bulb expressed higher levels of genes involved in modulating the extracellular matrix; OECs from the outer nerve layer of the olfactory bulb expressed higher levels of genes

contributing to modulating the extracellular matrix, cell sorting and neural development; and OECs from the inner nerve layer of the olfactory bulb expressed higher levels of genes that regulate axon guidance (Guerout et al., 2010; Honore et al., 2012).

In the healthy adult, OEC proliferation is limited but after olfactory bulbectomy OECs rapidly proliferate throughout the olfactory nerve pathway and from precursors within the basal layer of the olfactory epithelium (Chehrehasa et al., 2012). Newly formed OECs migrate into the lesion cavity in the skull and enable the regenerating axons to grow and extend on the pre-formed surface of OECs (Chehrehasa et al., 2010). Time-lapse imaging analysis *in vitro* reveals that OECs from olfactory nerve predominantly adhere to each other whereas OECs of the olfactory bulb display a mix of repulsion and adhesion (Windus et al., 2007; Windus et al., 2010). OEC behaviour is regulated by extracellular matrix (Tisay and Key, 1999), affecting sensory neurons via soluble factors and by direct contact. Olfactory sensory neurons preferentially grow on OECs (Chuah and Au, 1994; Tisay and Key, 1999; Windus

et al., 2011), which form a substrate for neuronal migration (Windus et al., 2010; Windus et al., 2011). OECs produce numerous growth factors that would assist olfactory neurogenesis including NGF (Woodhall et al., 2001; Lipson et al., 2003), BDNF (Woodhall et al., 2001; Lipson et al., 2003), FGF1 (Key et al., 1996), FGF2 (Matsuyama et al., 1992; Gall et al., 1994; Chuah and Teague 1999), GDNF (Woodhall et al., 2001; Lipson et al., 2003), CNTF (Guthrie et al., 1997; Lipson et al., 2003), Neurotrophin (NT)-4/5, and VEGF (Mackay-Sim and Chuah, 2000; Boruch et al., 2001; Woodhall et al., 2001; Wewetzer et al., 2002; Au and Roskams, 2003).

#### 7.4.5 Summary

There are clearly many molecular signals regulating proliferation, differentiation, survival and death in neurogenesis in the adult olfactory epithelium (Table 7.3, Figure 7.4). The picture is still incomplete because there are still many growth factors and receptors in the olfactory epithelium for

**Table 7.3** Growth factors that have proven active *in vitro* and *in vivo* that act on different cell types in olfactory mucosa. “Growth factor” is used here to encompass all extracellular signalling molecule affecting neurogenesis.

Growth Factor	Cell Type	Action	Reference
ATP	Neuronal precursors	Stimulates proliferation	Jia et al., 2011
BDNF	Mature neurons	Promotes survival	Newman et al., 2000
BMP 2/4/7	Neuronal precursors	Inhibits proliferation	Shou et al., 1999; Shou et al., 2000
BMP4	Immature neurons	Promotes survival	Shou et al., 2000
CX3CL1	Macrophages	Promotes recruitment	Blomster et al., 2011
Dopamine	Immature neurons	Promotes differentiation	Feron et al., 1999c
EGF / TGF $\alpha$	Horizontal basal cells	Stimulates proliferation	Farbman et al., 1994; Farbman and Buchholz 1996; Newman et al., 2000
	Supporting cells	Stimulates proliferation	Farbman and Buchholz 1996; Newman et al., 2000
FGF2	Globose basal cell neuronal precursors		DeHamer et al., 1994; Newman et al., 2000; Nishikawa et al., 2009
	Olfactory ensheathing cells	Stimulates proliferation	Chuah and Teague 1999
GDF11	Neuronal precursors	Inhibits proliferation	Wu et al., 2003
GGF2	Olfactory ensheathing cells	Stimulates proliferation	Chuah et al., 2000
IGF-I	Immature neurons	Promotes differentiation	McCurdy et al., 2005
LIF	Neuronal precursors	Promotes proliferation	Lopez et al., 2012
MIP1 $\alpha$	Macrophages	Promotes recruitment	Kwong et al., 2004
NO	Neuronal precursors	Stimulates proliferation	Sulz et al., 2009; Lopez et al., 2012
NRG	Olfactory ensheathing cells	Stimulates proliferation	Pollock et al., 1999
NT3	Olfactory ensheathing cells	Stimulates proliferation	Bianco et al., 2004
PDGF	Mature neurons	Promotes survival	Newman et al., 2000
RA	Immature neurons	Promotes differentiation	Whitesides et al., 1998; Lakard et al., 2007
	Neuronal precursors	Inhibits proliferation	Asson-Batres et al., 2003b
TGF $\beta$ 2	Globose basal cell neuronal precursors	Promotes differentiation	Mahanthappa and Schwarting 1993; Newman et al., 2000
TH	Immature neurons	Promotes survival	Mackay-Sim and Beard 1987
Wnt	Neuronal precursors	Stimulates proliferation	Wang et al., 2011
	Immature neurons	Promotes differentiation	Wang et al., 2011

which functional roles are not yet defined (Table 7.2). Regulation of cell lineage and neurogenesis would occur locally in a cell-type and time-dependent manner, involving cells within the epithelium, lamina propria, and olfactory bulb.

## 7.5 CLINICAL APPLICATIONS FROM OLFACTORY NEUROGENESIS

Olfactory mucosa can be sampled in humans without affecting the sense of smell (Lanza et al., 1993; Feron et al., 1998), thus offering access to stem cells, neural progenitors, neurons, and olfactory ensheathing cells. This convergence of biological properties and practical accessibility are leading to clinical applications in transplantation repair of the injured spinal cord (Mackay-Sim and St John, 2011) and in drug discovery for brain diseases (Mackay-Sim, 2012). Deeper understanding of olfactory neurogenesis may help to unravel the cause of esthesioneuroblastomas, which originate from the olfactory epithelium. These tumors present a highly heterogeneous cellular composition indicating that they may derive from a multipotent GBC stem cells with evidence for HBC-like differentiation, sustentacular-like cells, and other cells with a phenotype intermediate between olfactory neurons and Bowman's duct/gland cells. Such cells have their own sub-territory within the tumor, indicating that they may derive from multipotent GBC stem cells (Holbrook et al., 2011).

### 7.5.1 Transplantation Repair of the Spinal Cord

Olfactory ensheathing cells were chosen as candidates for repair of the injured spinal cord because of their role in assisting neurogenesis in the olfactory mucosa and their ability to integrate with the central nervous system (Doucette, 1990; Ramon-Cueto and Nieto-Sampedro, 1994; Li et al., 1997; Li et al., 1998; Ramon-Cueto et al., 1998). There are now numerous studies demonstrating the efficacy of olfactory ensheathing cell transplantation for the repair of the injured rodent spinal cord (Mackay-Sim and St John, 2011). Importantly for clinical translation, olfactory ensheathing cells from the nose of adult rats demonstrated that autologous transplantation could assist functional recovery after complete spinal cord transaction (Lu et al., 2001; Lu et al., 2002). Additionally, olfactory ensheathing cells from the human nose induced functional recovery after transplantation into the contused spinal cord of the rat (Gorrie et al., 2010). There are numerous ways in which olfactory ensheathing cells contribute after transplantation into the injured spinal cord: provision of growth factors (Woodhall et al., 2001; Chung et al., 2004); direct physical contact (Li et al., 2004); stimulation of axon

sprouting (Chung et al., 2004); and myelination (Imaiizumi et al., 1998).

A Phase I clinical trial demonstrated that intra-spinal cord transplantation of autologous olfactory ensheathing cells is feasible, with no adverse outcomes over an observation period of three years (Feron et al., 2005; Mackay-Sim et al., 2008). Another clinical approach has been to transplant whole pieces of autologous olfactory mucosa into the injured spinal cord after surgical removal of the injured cord tissue (Lima et al., 2006). This method was safe in most patients, although significant adverse events were reported (Lima et al., 2006; Chhabra et al., 2009). Some patients noted improvements in locomotor function after olfactory mucosa transplantation, but such improvements were not universal (Lima et al., 2006; Chhabra et al., 2009). In these studies there was no control group, as expected in an efficacy trial. Obviously olfactory mucosa pieces contain many cell types other than olfactory ensheathing cells, including stem cells, which may contribute to recovery of the injured spinal cord.

### 7.5.2 Olfactory Stem Cell Models of Brain Diseases

Autopsy specimens of olfactory mucosa from patients show immunohistological evidence of pathological changes in Alzheimer's disease (Talamo et al., 1989) including increased frequency of  $\beta$ -amyloid aggregates and dystrophic tau-positive neurites (Lee et al., 1993; Crino et al., 1995; Arnold et al., 2010) and markers of oxidative stress (Perry et al., 2003). "Neuroblasts" can be grown in continuous culture from autopsy specimens of human olfactory mucosa (Wolozin et al., 1992) and, in Alzheimer's disease, these show elevated levels of the precursor to  $\beta$ -amyloid protein (Wolozin et al., 1993) and increased oxidative stress (Ghanbari et al., 2004) compared to neuroblasts from people without the disease. Olfactory mucosa from schizophrenia patients has different proportions of cells staining for immature and mature neuronal markers at autopsy (Arnold et al., 2001) and olfactory mucosa cultures have altered cell proliferation and altered tissue adhesion, not seen in tissue from controls or patients with bipolar disorder (Feron et al., 1999b; McCurdy et al., 2006). Neurodevelopmental abnormalities are also reported in biopsy specimens from patients with Rett's syndrome (Ronnett et al., 2003).

Olfactory stem cells can be grown from human biopsy tissue either as neurally restricted progenitors (Roisen et al., 2001) or as more broadly multipotent stem cells (Murrell et al., 2005; Delorme et al., 2010). Olfactory stem cells are grown as self-renewing "neurospheres" that can differentiate into neurons, astrocytes, and oligodendrocytes (Roisen et al., 2001; Murrell et al., 2005). Olfactory neurosphere-derived cells from patients and

controls can be grown in continuous culture to investigate cellular and molecular aspects of the effects of disease on the nervous system (Mackay-Sim, 2012). In Parkinson's disease, olfactory neurosphere-derived cells show evidence of oxidative stress in their gene and protein expression, in several metabolic assays, and in reduced activity of the *NRF2* signaling pathway (Matigian et al., 2010; Cook et al., 2011). Olfactory neurosphere-derived cells from patients with schizophrenia have altered gene and protein expression and metabolic function in cell signaling pathways associated with neurodevelopment (Matigian et al., 2010). Closer analysis of schizophrenia patient-derived cells reveals dysregulation of the cell cycle including increased levels of cyclin D1, a shorter cell cycle period and an increased proliferation rate (Matigian et al., 2010; Fan et al., 2012). Gene expression differences from control cells of patient-derived cells were disease-specific for schizophrenia and Parkinson's disease (Matigian et al., 2010) and additionally, there were disease-specific differences in the variability in gene expression, indicating an additional level of dysregulation as a consequence of schizophrenia and Parkinson's disease (Mar et al., 2011). Olfactory cell cultures are also instructive for understanding monogenic diseases. Neuroblasts from olfactory epithelium of two patients with fragile X mental retardation had no FMR1 protein, consistent with their genetic mutation and protein expression in their leukocytes (Abrams et al., 1999). Similarly, olfactory ectomesenchymal stem cells derived from olfactory mucosa of patients with familial dysautonomia show the expected reduction in protein levels of the affected gene (*IPKAPB*) and have promise in testing small molecules to correct the condition (Boone et al., 2010).

### 7.5.3 Future Clinical Applications

Olfactory function is commonly lost with age (Doty et al., 1984), although it may be due to ageing-associated disease, rather than ageing itself (Mackay-Sim et al., 2006). This is associated with olfactory nerve fibrosis, replacement of olfactory by respiratory epithelium, and olfactory epithelium that lacks neurons and GBCs, but retains HBCs (Holbrook et al., 2005). Potential therapeutic strategies include activation of HBCs to proliferate and re-enter the multipotent cell lineage and even transplanting autologous HBCs or GBCs after generating them *in vitro* from small biopsies. A deeper understanding of the stem cells in the olfactory mucosa may also lead to clinical applications for transplantation outside the olfactory system. For example, human olfactory neurosphere-derived cells can promote functional recovery after transplantation into the injured rat spinal cord (Xiao et al., 2005), transplantation into the parkinsonian rat (Murrell et al., 2008) and after

transplantation into the injured intervertebral disc (Murrell et al., 2009).

## 7.6 CONCLUSIONS

Olfactory neurogenesis is a continuing, regulated process that is similar in many respects to neurogenesis in the embryonic nervous system. It is noteworthy that although neurogenesis continues throughout adult life, the rate of basal cell proliferation declines in old age and there is a significant decrease in olfactory function in aging humans. The regulation of olfactory neurogenesis is not completely understood; there are a large number of candidate factors whose function is unknown but whose presence is inferred by the expression of appropriate receptors in the epithelium. Apart from its intrinsic interest in scientific terms, understanding olfactory neurogenesis is becoming important now for its potential clinical applications in diseases of brain development and in nervous system repair.

## ABBREVIATIONS

---

ActR	Activin receptor
Ascl-1	Achaete-scute like 1 (formerly known as Mash1)
BDNF	brain-derived growth factor
BMP	bone morphogenic protein
BMPR	BMP receptor
CNTF	ciliary neurotrophic factor
Cre-ERT2	Cre recombinase fused with the selectively tamoxifen-sensitive estrogen receptor
D2	dopamine D2 receptor
DA	dopamine
EC	ensheathing cell
EGF	epidermal growth factor
EGFR	epidermal growth factor receptor
FACS	fluorescence-activated cell sorting
FGF	fibroblast growth factor
FGFR	fibroblast growth factor receptor
GAP43	growth associated protein 43
GBC	globose basal cell
GDNF	glial cell line-derived growth factor
GFAP	glial fibrillary acidic protein
GFP	enhanced green fluorescent protein
GFR	GDNF receptor
GGF	glial growth factor HBC horizontal basal cell
HBC	horizontal basal cell
IGF	insulin-like growth factor
IGFBP	insulin-like growth factor binding protein

---

IGFR	insulin-like growth factor receptor
IN	immature neuron
LIF	leukocyte inhibitory factor
MeBr	methyl bromide
MN	mature neuron
NCAM	neural cell adhesion molecule
NDF	Neu differentiation factor
Neurog1	Neurogenin 1
NGF	nerve growth factor
NO	nitric oxide
NOS	nitric oxide synthase
eNOS	endothelial NOS
iNOS	inducible NOS
nNOS	neuronal NOS
NPY	neuronal protein Y
NT3	neurotrophin 3
OMP	olfactory marker protein
p75 <sup>NTR</sup>	p75 neurotrophin receptor
PDGF	platelet-derived growth factor
PDGFR	platelet-derived growth factor receptor
P2XR	purine receptor, type 2X
PPY	protein YY
RA	retinoic acid
RAR	retinoic acid receptor
RXR	retinoid X receptor
RRV	replication-incompetent retrovirus
TGF	transforming growth factor
TNF	tumour necrosis factor
Trk	tyrosine kinase

# Chapter 8

---

## Anatomy and Neurobiology of the Main and Accessory Olfactory Bulbs

MATTHEW ENNIS and TIMOTHY E. HOLY<sup>1</sup>

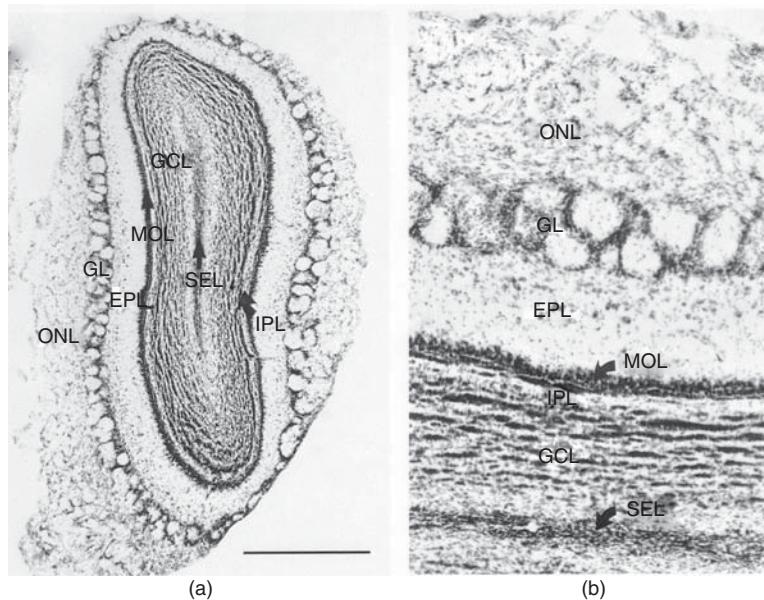

### 8.1 INTRODUCTION

The olfactory system of most mammals, excluding humans, consists of two parallel components, the main and accessory olfactory systems. They operate in parallel and are largely separate anatomically and functionally. The main olfactory system primarily processes volatile odors that enter the nasal cavity during respiration. Odors are transduced by nasal epithelium olfactory receptor neurons (ORNs) and are then relayed to, and synapse in, the main olfactory bulb (MOB). In contrast, the accessory olfactory system processes non-volatile odors, transduced by vomeronasal receptor neurons in the vomeronasal organ and transmitted to the accessory olfactory bulb (AOB). In tandem, the two systems underlie our sense of “smell” which is critical for flavor perception, food selection, and identification of conspecifics, predators, and prey. Odors produce strong and lasting memories in humans, and exert potent control of animal behavior. This chapter focuses on olfactory processing in the mammalian MOB and AOB. Knowledge in both structures has undergone explosive growth over the last two decades. We focus primarily on these advances; readers are referred to other sources that review earlier primary literature (Mori, 1987; Shepherd, 1972; Shipley et al., 1996; Ennis et al., 2007). Due to late developmental maturation in the olfactory system we emphasize findings from mature or post-weaning ages.

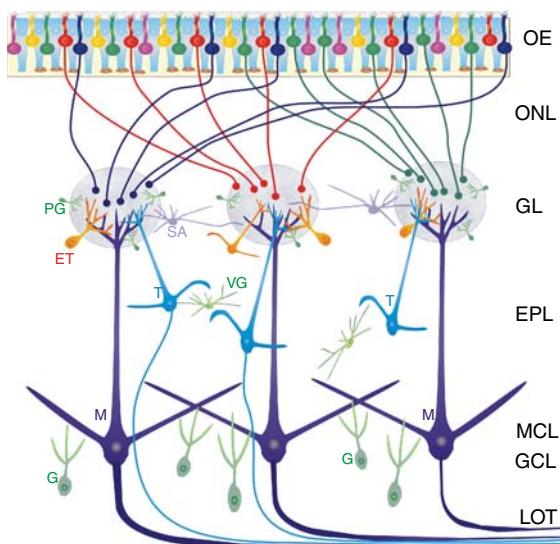

### 8.2 MAIN OLFACTORY BULB (MOB)

The rodent MOB is a cylindrical structure connected by a slender peduncle to the anterior pole of the brain. The MOB is laminated with the layers forming concentric circles (Figures 8.1, 8.2); from superficial to deep these are the: olfactory nerve layer (ONL), glomerular layer (GL), external plexiform layer (EPL), mitral cell layer (MCL), internal plexiform layer (IPL), granule cell layer (GCL), and the subependymal layer/subventricular zone. Odors are transduced by ORNs (Chapters 5 and 6), giving rise to action potentials that travel along olfactory nerve (ON) fibers and synapse in spherical shaped glomeruli in the GL. ORNs expressing the same odorant receptor project to one or two glomeruli located on the medial and/or lateral side of each MOB (Figure 8.2; Ressler et al., 1993, 1994; Vassar et al., 1994; Mombaerts et al., 1996; Wang et al., 1998; Potter et al., 2001; Treloar et al., 2002; Wang et al., 1998). Within the glomeruli, ORN axons synapse with mitral and tufted cells (M/TCs) – the MOB output neurons – and with intrinsic neurons, juxtaglomerular cells (JGCs) (Pinching and Powell, 1971a; Shepherd, 1972; Najac et al., 2011). ORNs utilize glutamate as their primary neurotransmitter (Sassoè-Pognetto et al., 1993) and the initial olfactory sensory input to MOB is excitatory. ORN terminals also contain carnosine, zinc, and copper that may function as neuromodulators (Sassoè-Pognetto et al., 1993; Ennis et al. 2007). The relatively cell sparse EPL contains tufted cells (TCs), interneurons, and an extensive network of dendrodendritic synapses formed

<sup>1</sup>We acknowledge grant support for portions of this chapter that refer to research of the authors: PHS Grants DC003195, DC008702, DC005964, DC010381, and NS068409.

**Figure 8.1** Architecture of the MOB. (a) and (b): Coronal sections (Nissl stain) of the rat MOB at low (a) and high (b) magnifications. Abbreviations: SEL, subependymal layer. Scale bar = 1 mm.

**Figure 8.2** Basic circuitry of the MOB. Abbreviations: G, granule cell; M, mitral cell; T, tufted cell, OE, olfactory epithelium; VG, van Gehuchten cell. (See plate section for color version.)

between M/TC and GCs. The thin MCL contains MC somata as well as GCs. The IPL is relatively thin and cell sparse, while the GCL contains the largest number of cells, primarily granule cells using the inhibitory transmitter gamma-aminobutyric acid (GABA).

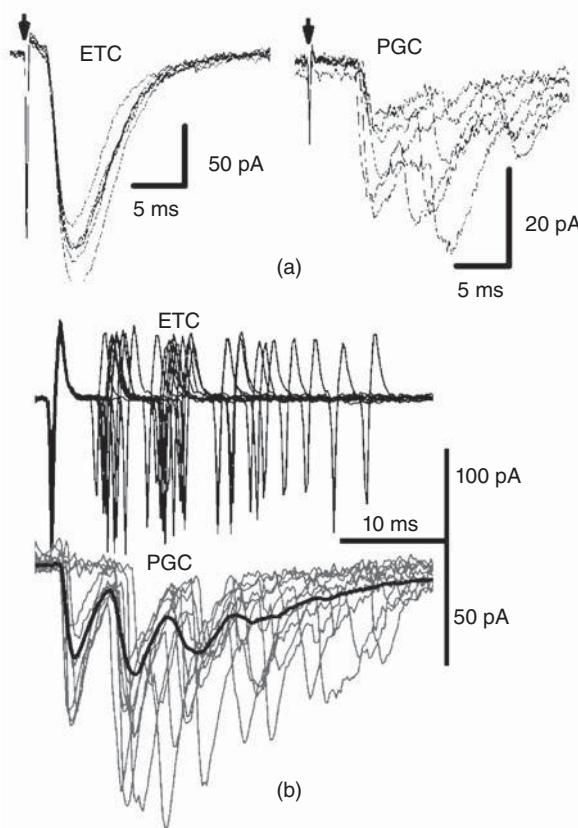

### 8.2.1 Glomerular Layer (GL)

Glomeruli have long been considered to represent fundamental units of olfactory processing. In line with this, each glomerulus: (1) receives input from a homogeneous ORN population expressing the same odorant receptor;

(2) contains a dedicated population of intrinsic and output neurons organized in a columnar like arrangement; and (3) exhibits unique odor input response properties (Wachowiak and Shipley, 2006; Willhite et al., 2006).

**8.2.1.1 GL Neurons.** GL neurons comprise three primary classes collectively referred to as JGCs: external tufted cells (ETCs), periglomerular cells (PGCs) cells, and (3) short axon cells (SACs) (Pinching and Powell, 1971a). The vast majority are interneurons with local connections in the GL, although some ETCs project outside of MOB (Ennis et al., 2007).

**EXTERNAL TUFTED CELLS (ETCs)** Like their deeper M/TC cousins, ETCs extend a single apical dendrite that arborizes in one glomerulus and receive monosynaptic ORN input (Pinching and Powell, 1971b, c; Hayar et al., 2004a, b; Liu and Shipley, 2008a, b); only ~6% of ETCs have apical dendrites in two glomeruli. ET/M/TCs contain glutamate and form excitatory dendrodendritic synapses with PG and SACs, and in turn receive inhibitory synapses from PGCs (Pinching and Powell, 1971b, c). The apical dendrites of ET/M/TCs located within the same glomerulus are coupled by connexin protein-based gap junctions that function as bidirectional electrical synapses important in synchronizing intraglomerular activity (Ennis et al., 2007). Some ETCs cells have secondary dendrites that extend into the EPL, and some also appear to have axons that may synapse with PG or SACs (Hayar et al., 2004a). ETCs recorded in slices exhibit spontaneous rhythmic spike bursts at frequencies ranging from ~0.5–11 Hz

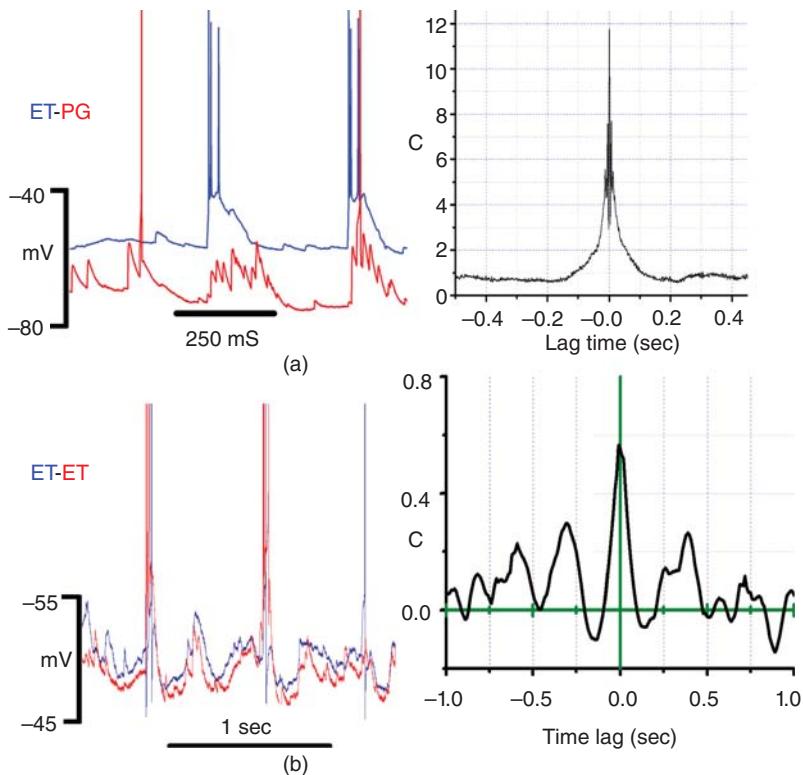

**Figure 8.3** (a) Voltage-clamp traces showing of ON-evoked synaptic responses (EPSCs) in ET and PGCs. Right, ON stimulation (arrow) produced short, constant latency EPSCs in an ETC, indicative of monosynaptic input. Left, ON stimulation evoked longer, variable latency EPSCs in a PGC, indicative of di- or poly-synaptic responses. (b) ETCs monosynaptically excite PGCs. Dual recordings from an ETC (cell-attached recording mode, upper trace) and a PGC (whole-cell voltage clamp mode, lower traces). Spontaneous ETC spike bursts (10 superimposed bursts) are accompanied by phase-locked bursts of EPSCs in the PGC (black line is the average of 135 traces).

(Hayar et al., 2004a, b, 2005; Liu and Shipley, 2008a, b) (Figures 8.3, 8.4), a range overlapping the 2–12 Hz theta frequencies of rodent sniffing (see Section 8.7.2). ETCs with secondary dendrites in the EPL do not appear to rhythmically burst, indicating that there may be at least two ETC subtypes (Antal et al.; 2006). ETC rhythmic bursting is generated intrinsically and involves a number of voltage-dependent currents, but especially important in burst initiation is a TTX-sensitive slowly inactivating or persistent  $\text{Na}^+$  current (Hayar et al., 2004a, b; Liu and Shipley, 2008a, b). ETCs respond monosynaptically to ON stimulation with a short latency excitatory postsynaptic potential or current (EPSP/EPSC) or a spike burst (Figure 8.3; Hayar et al., 2004a, b, 2005; Liu and Shipley, 2008a, 2008b).

**PERIGLOMERULAR CELLS (PGCs)** PGCs, the largest GL neuronal population, comprise multiple subtypes that are all thought to be inhibitory. Their dendrites are typically restricted to a small subregion in 1–2 glomeruli (Hayar et al., 2004a, b; Shao et al., 2009; Kiyokage et al., 2010). Only a relatively small subpopulation (30%) receive ORN synapses (Shao et al., 2009; Kiyokage et al., 2010). Their dendrites receive synapses from ET/M/TC dendrites and in turn make reciprocal inhibitory synapses back onto the parent ET/M/TC dendrite or onto those of other ET/M/TCs (Kasowski et al., 1999; Toida et al., 1998, 2000; Hayar et al., 2004b). Most PGC cells are GABAergic (Ennis et al., 2007; Shao et al., 2009). The GL contains a population of dopamine (DA) cells that were classically described as a subset of GABAergic PGCs (Halász et al., 1977; Kosaka et al., 1985; Gall et al., 1987; Ennis et al., 2007). Recent studies (see below) however, indicate that most if not all DA-GABA cells in the mouse are SACs. PGCs also stain for other neurochemical markers or neuropeptides (Ennis et al., 2007; Kosaka and Kosaka, 2011). PGCs are thus neurochemically heterogeneous and not surprisingly exhibit varying electrophysiological properties (Puopolo and Belluzzi, 1998; McQuiston and Katz, 2001; Pignatelli et al., 2005; Puopolo et al., 2005). However, most PG and SACs recorded in slices typically have low spontaneous spike activity even though they receive barrages of spontaneous glutamatergic EPSP/EPSCs (Figures 8.3, 8.4) (Hayar et al., 2004a, b; Shao et al., 2009; Kiyokage et al., 2010). In vivo, PGCs exhibit broader odor tuning (respond to more odorants) than ET/M/TCs (Tan et al., 2010).

**SHORT AXON CELLS (SACs)** SACs are distinguished by dendrites that seem to harvest information from multiple glomeruli (Aungst et al., 2003; Hayar et al., 2004a). Like PGCs, most (70%) do not receive direct ORN synaptic input but instead receive excitatory input from ET/M/TCs dendrites (Hayar et al., 2004b; Kiyokage et al., 2010). They extend axons up to 1–2 mm in the GL providing an anatomical substrate for interglomerular interactions (Aungst et al., 2003). SAC axons were initially thought to synapse onto PGCs in other glomeruli, while more recent work indicates that they may also target ETCs (see below; Aungst et al., 2003). Mouse SACs were recently shown to contain DA and GABA (Kiyokage et al., 2010; Kosaka and Kosaka, 2011). These DA-GABA SACs exhibit marked heterogeneity with regard to glomerular contacts. Those that receive direct ORN input have processes in ~5 glomeruli, but 50% of the process ramify in one “preferred” glomerulus. SACs lacking direct ORN input fall into two categories associated with ~15 vs. ~39 glomeruli respectively. Some cells in a later group had processes in hundreds of glomeruli, but it is unclear if the process of these and the other subtypes are dendrites, axons or both.

**Figure 8.4** Synchronous activity among ET and PGCs associated with the same glomerulus. (a) Simultaneous current clamp recordings show that ETC spike bursts (blue trace) are associated with PGC EPSP bursts (red trace). Cross-correlogram at left shows that ETC spikes are highly synchronous with PGC EPSPs. (b) Simultaneous current clamp recordings from two ETCs show synchronous membrane potential and spike activity, further evidenced in the membrane potential cross-correlogram at left.

### 8.2.1.2 Excitatory Intraglomerular Processing.

**ORN INPUT** Each glomerulus contains the apical dendritic tufts of about 20 MCs, 50 TCs and 1500–2000 JGCs (Ennis et al., 2007). Glutamate release from ORN terminals, controlled by N- and P/Q-type  $\text{Ca}^{2+}$  channels, excites these populations mainly via AMPA and NMDA receptors that mediate respectively fast and slow synaptic response components (Ennis et al., 1996, 2001; Aroniadou-Anderjaska et al., 1997, 1999a; Chen and Shepherd, 1997; Keller et al., 1998). ET/M/TCs also exhibit smaller, slow synaptic responses to ORN input or prolonged odor responses mediated by the metabotropic glutamate receptor1 (mGluR1) subtype (De Saint Jan and Westbrook, 2005; Ennis et al., 2006; Yuan and Knopfel, 2006; Matsumoto et al., 2009; Dong et al. 2009).

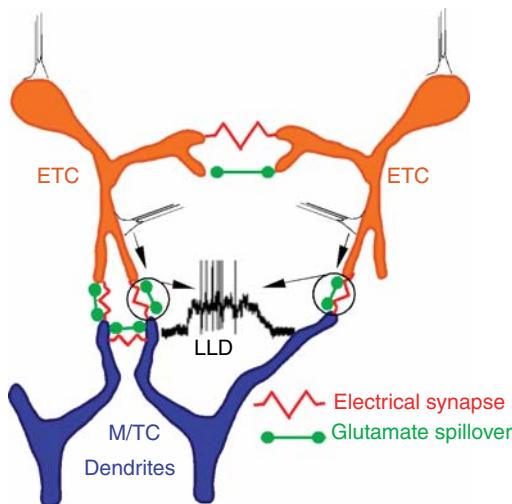

### ORN TO PG/SAC VS. ORN TO ET/M/TC TO PG/SAC CIRCUITS

PG and SACs fall into two populations based on spontaneous and ON-evoked synaptic activity (i.e., EPSPs/EPSCs.) Approximately 30% of PG/SACs exhibit a non-bursting spontaneous EPSC pattern and respond monosynaptically to ON stimulation (Hayar et al., 2004b; Shao et al., 2009; Kiyokage et al., 2010). By contrast, ~70% of PG/SACs exhibit spontaneous EPSC bursts and respond polysynaptically to ON stimulation (Figure 8.3). Since ETC spontaneously burst,

receive monosynaptic ORN input, and form excitatory synapses with PG/SAC dendrites, it is thought that the ETC population largely mediates ON responses in this subset of PG/SACs cells – an ORN-ETC-PG/SAC circuit. Consistent with this, ETCs monosynaptically drive EPSC bursts in PG/SACs (Figure 8.3; Hayar et al., 2004b) with estimates that a given ETC activates ~5 PG/SACs (Murphy et al., 2005). Spontaneous and ON-evoked activity in these ETC-driven PG/SACs is similar when the GL is isolated, consistent with control by ETCs, although this does not exclude a more minor degree of excitation by M/TC apical dendrites. As discussed below, these functionally distinct PG/SAC populations exert differential roles in regulating spontaneous and ON-evoked inhibition. The fact that some PG/SACs are devoid of ORN input is consistent with the bi-compartmental organization of glomeruli into zones rich in vs. devoid of ORN terminals (Kosaka et al., 1997; Kasowski et al., 1999). Cabinda-positive JGCs extend dendrites into compartments devoid of ORN terminals and may correspond to PG/SACs shown electrophysiologically to lack ORN input (Toida et al., 1998, 2000).

### 8.2.1.3 Dendritic Glutamate Spillover Among ET/M//TCs.

Although ET/M//TC dendrites do not form conventional anatomical synapses, dendritic glutamate release (i.e., spillover) can excite  $\alpha$ -amino-3-

**Figure 8.5** Glutamate spillover and electrical synapses mediate intraglomerular synchrony among ET/M/TCs. Glutamate release from, and spillover among, the apical dendrites of ET/M/TCs mediates excitatory interactions among these cells that strengthen intraglomerular synchrony. The apical dendrites of these cells also form bidirectional electrical synapses that facilitate glutamate release and intraglomerular synchrony. Convergent spike bursts from multiple ETCs engage long-lasting depolarizations (LLDs) in M/TCs via glutamate spillover and electrical synapses. (See plate section for color version.)

hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), N-methyl-D-aspartate (NMDA) and metabotropic glutamate receptor 1 (mGluR1) receptors on the parent dendrite (self- or autoexcitation) or neighboring dendrites (lateral or feedforward excitation) (Figure 8.5; Aroniadou-Anderjaska et al., 1999b; Isaacson, 1999; Carlson et al., 2000; Friedman and Strowbridge, 2000; Salin et al., 2001; Schoppa and Westbrook, 2001, 2002; Hayar et al. 2005; Murphy et al., 2005; Christie et al., 2005; Christie and Westbrook, 2006; Pimentel and Margrie, 2008). Spillover excitatory responses typically have a slow time course and chiefly occur among dendrites in the same glomerulus. However, fast monosynaptic-like AMPA receptor-mediated lateral excitation between M/TCs or from ET to M/TCs also occurs (Urban and Sakmann, 2002; Pimentel and Margrie, 2008; De Saint Jan et al., 2009; Najac et al., 2011). Spillover excitation is enhanced by low Mg<sup>2+</sup> or GABA<sub>A</sub> receptor block, which can engage/amplify an NMDA receptor component and trigger autoexcitation of M/TC lateral dendrites. Dendritic glutamate release is facilitated by gap junction electrotonic coupling among ET/M/TC dendrites (Figure 8.5; Schoppa and Westbrook, 2002; Christie et al., 2005; Christie and Westbrook, 2006). Lateral excitation was abolished by genetic deletion of electrical synapses and its strength was correlated with electrotonic coupling strength between MC

pairs (Christie and Westbrook, 2006; but see Pimentel and Margrie, 2008). Lateral excitation is thought to comprise a specialized electrochemical form of communication that synchronizes glomerular activity.

Lateral glutamate spillover is responsible for unusually large and prolonged (1–2 sec) depolarizations (LLDs) in MCs spontaneously, or in response to ON stimulation or antidromic activation of multiple M/TCs, but never by activation of single MCs (Carlson et al., 2000). They are all-or-none in nature, require AMPA receptor activation, originate in the glomeruli and are synchronous among MCs of the same glomerulus (Carlson et al., 2000; Karnup et al., 2006; De Saint Jan et al., 2009). LLDs are generated by network mechanism involving intraglomerular glutamate release from an ensemble of ET/M/TC dendrites and appear to involve gap junctional-coupled amplification of glutamate release (Figure 8.5; Christie and Westbrook, 2006). ETCs appear to play a critical role as their bursts often precede spontaneous MC LLDs and evoked ETC bursts can elicit LLD-like responses in MCs but not vice-versa (De Saint Jan et al., 2009). LLDs clearly amplify ON input onto M/TCs, but there is controversy about their role in driving entirely, in an all-or-none fashion, ON responses in MCs via a disynaptically ORN-ET-MC circuit. In support: (1) ON stimulation produced either no synaptic or spiking response in MCs or an all-or-none disynaptic LLD/spiking response, and (2) monosynaptic ON responses in ETCs preceded LLDs (Gire and Schoppa, 2009; Gire et al., 2012). At odds are observations of (1) graded MC spiking responses to graded intensity ON stimuli or odors (Jiang et al., 1996; Ciombor et al., 1999; Margrie and Schaefer, 2003; Cang and Isaacson, 2003; Davison and Katz, 2007; Cury and Uchida, 2010; Tan et al., 2010), (2) differences in the magnitude or direction of odor-evoked spiking among MCs of the same glomerulus recorded simultaneously (Dhawale et al., 2010), and (3) LLDs producing graded spiking levels or that occur without MC spikes (Karnup et al., 2006). Although ETCs have a lower ON response threshold than MCs, there is clear electrophysiological and anatomical evidence for monosynaptic ORN input to MCs (De Saint Jan et al., 2009; Najac et al., 2011; Shao et al., 2012). Thus, it appears that weak ON input preferentially engaging the more excitable ETCs leads to disynaptic MC LLDs while stronger input engages monosynaptic responses and typically the LLD (Najac et al., 2011; Shao et al., 2012).

### 8.2.1.4 Inhibitory Intraglomerular Processing. PRESYNAPTIC INHIBITION OF ORN TERMINALS

The strength of olfactory input at the first stage of synaptic transfer in the MOB is regulated by presynaptic control of ORN terminal excitability. ORN terminals express GABA<sub>B</sub> and DA D2 receptors (Ennis et al., 2007). GABA and DA

released from PGCs can, despite lack of anatomical PGC to ORN synapses, bind to these presynaptic receptors to inhibit glutamate release. In the case of GABA<sub>B</sub> receptors, presynaptic inhibition is mediated by suppression of Ca<sup>2+</sup> influx into ORN terminals (Wachowiak et al., 2005). GABA<sub>B</sub> or D2 receptor activation reduces spontaneous and ON-evoked activity in all cells tested (PG, ET, MCs), as well as ON- or odor-evoked ORN terminal activity (Keller et al., 1998; Hsia et al., 1999; Aroniadou-Anderjaska et al., 2000; Berkowicz and Trombley, 2000; Ennis et al., 2001; Palouzier-Paulignan et al., 2002; McGann et al., 2005; Wachowiak et al., 2005; Vucinić et al., 2006; Pérez and Wachowiak, 2008; Maher and Westbrook, 2008; Shao et al., 2009). PGCs can, via GABA<sub>B</sub> receptors, presynaptically inhibit their own ORN monosynaptic input (Murphy et al., 2005; Shao et al., 2009). GABA<sub>B</sub> receptor presynaptic inhibition is tonically active *in vitro* and *in vivo* and thus GABA<sub>B</sub> receptor antagonists uniformly increase ON- or odor-evoked responses (Aroniadou-Anderjaska et al., 2000; Pérez and Wachowiak, 2008; Shao et al., 2009); this tonic inhibition appears to mainly be driven by the ETC to PGC circuit. D2 receptor presynaptic inhibition *in vitro* does not appear to have a strong tonic component (Maher and Westbrook, 2008). Presynaptic inhibition increases with repetitive ON stimulation from ~2–10 Hz in slices, suggesting it may provide a sniff frequency dependent negative feedback mechanism (Aroniadou-Anderjaska et al., 2000; Wachowiak et al., 2005; McGann et al., 2005). However, presynaptic inhibition of ORN terminals was constant for odors presented at 1–5 Hz sniffs (Pérez and Wachowiak, 2008), perhaps because robust tonic inhibition *in vivo* masks frequency-dependent effects. Presynaptic inhibition of ORN terminals may provide a negative gain control mechanism for adjusting the scale or dynamic range of odor concentration that can be processed by MOB neurons or to prevent saturation of input. Thus, presynaptic inhibition magnitude may scale with the odor intensity conveyed to PGCs. Alternatively, presynaptic inhibition may increase contrast (i.e., sharpen the spatial pattern) of odorant representations and facilitate detection of strong odors by preferentially suppressing weakly responsive glomeruli. However, GABA<sub>B</sub> presynaptic inhibition does not appear to alter the relative spatial pattern of weakly and strongly activated glomeruli as determined by imaging ORN terminal activity (Pérez and Wachowiak, 2008; see also Vucinić et al., 2006). It remains to be established if this holds for the influence of presynaptic inhibition on postsynaptic odor responses and perception. In this regard, it is noteworthy that D2 blockade increased the number of M/TCs responding to single or multiple odorants and improved odor discrimination (Wilson and Sullivan, 1995; Wei et al., 2006; Escanilla et al., 2009). The later effect seems counter to what one would expect in coding strategies where increases in the overlap of odor

responsive M/TCs would impair discrimination (Linster and Hasselmo, 1997; Linster and Cleland, 2002). Alternatively, a D2 antagonist increase in odor-evoked ORN glutamate release would strengthen perceived odor intensity to enhance discriminability (Wei et al., 2006). D2 receptor agonists by contrast impaired odorant specific glomerular response patterns (2-dexyglucose), reduced odorant detectability, or impaired discrimination of low concentration odorants (Doty and Risser, 1989; Sallaz and Jourdan, 1992; Wei et al., 2006).

**PGC TO ET/M/TC INHIBITION** While it has been known for decades that M/TCs receive inhibitory input spontaneously or in response to ON input, the relative contributions of PGC vs. GCs to such inhibition has only recently come to light. PGCs are driven by rhythmically bursting ETCs and ETC stimulation readily elicits PGC mediated feedback inhibition (Murphy et al., 2005). This circuit is responsible for a significant portion of intraglomerular inhibition. Spontaneous GABA<sub>A</sub> receptor inhibition (i.e., IPSPs/IPSCs) is observed in ET/M/TCs; rhythmic IPSC bursts are prominent in ETCs and are also observed in M/TCs (Hayar et al., 2004b, 2005; Dong et al., 2007). Most MC spontaneous IPSC bursts are eliminated, and overall spontaneous IPSCs are reduced by ~50%, when the GL is excised to remove PGC inhibition. Focal GL GABA<sub>A</sub> receptor block reduces MC spontaneous IPSCs by ~50% (Shao et al., 2012). ON-evoked excitation of ET/M/TCs is sculpted by temporally overlapping inhibition (Carlson et al., 2000; Gire and Schoppa, 2009; Najac et al., 2011). Such inhibition has early and longer duration delayed phases (Shao et al., 2012). The early onset and ~50% of the late inhibition in MCs is abolished by GL GABA<sub>A</sub> receptor block; this also eliminated all spontaneous and ON-evoked IPSCs in ETCs lacking secondary dendrites in the EPL. These and other findings indicate the PGCs mediate most if not all inhibition in ETCs, and the early and half of the late inhibition in M/TCs. Block of PGC mediated intraglomerular inhibition increases the magnitude and duration of ON-evoked LLDs and spiking in ET/M/TCs (Gire and Schoppa, 2009; Shao et al., 2012). Intraglomerular postsynaptic inhibition, along with ORN presynaptic inhibition, are thought to be critical in regulating the gain of glomerular input–output function, and also to curtail prolonged odor responses to allow precise temporal modulation of ET/M/TC activity by the sniff cycle (Wachowiak and Shipley, 2006; Shao et al., 2012). PGC GABA release has also been reported to lead to GABA<sub>A</sub> receptor-mediated self-inhibition or inhibition of adjacent PGCs (Smith and Jahr, 2002; Murphy et al., 2005).

**8.2.1.5 Interglomerular Processing.** As noted earlier, SACs receive input from, and project to, multiple glomeruli, thus forming a circuit for interglomerular

communication. The direct synaptic effect of the SAC interglomerular projection seems to be glutamatergic excitation of ET and PGCs in neighboring glomeruli; MCs by contrast are polysynaptically inhibited (Aungst et al., 2003). Pre-stimulation of one glomerulus suppressed ON-evoked excitation of MCs (i.e., LLDs) in adjacent glomeruli, an effect eliminated by GABA<sub>A</sub> blockade. Based on this, it was proposed that SACs excite PGCs in neighboring glomeruli directly, or disinaptically via ETCs, to increase GABA release and inhibit MCs. This interglomerular circuit may function in a center-on, surround-off manner whereby glomeruli receiving strong odor input inhibit input to weakly responsive surround glomeruli (Aungst et al., 2003). If SACs contain GABA and DA as recently reported (Kiyokage et al., 2010), their excitatory cellular effect would require co-expression of another excitatory transmitter such as glutamate. Also, if SACs excite ETCs, and if ETCs play a critical role in LLDs, one would expect to see excitation in some M/TCs via this interglomerular circuit.

## 8.2.2 External Plexiform Layer (EPL)

**8.2.2.1 Tufted Cells (TCs).** TCs are the most numerous cells of the EPL and three TC subclasses are recognized based on location in the EPL: superficial, middle, and deep TCs. All share several features in common with ET/MCs, including a typical single apical dendrite ending in one glomerulus that receives monosynaptic ORN input and forms dendrodendritic synapses with PG/SACs (Ennis et al., 2007). They also utilize glutamate as their principle transmitter (Christie et al., 2001), although superficial TCs also contain CCK (Liu and Shipley, 1994). Their lateral dendrites are relatively short compared to MCs, but like MCs ramify in the EPL forming dendrodendritic synapses with GCs and other inhibitory EPL interneurons. Indeed, much of the EPL neuropil is devoted by dendrodendritic processing as discussed below. TC axons, together with those of MCs, terminate locally in the IPL/GCL on GCs or exit the MOB to innervate primary olfactory cortical (POC) structures including olfactory or piriform cortex. There are differences in M vs. TC projections to POC, with TCs projecting preferentially to the anterior olfactory nucleus, olfactory tubercle, and rostral olfactory cortex (Ennis et al., 2007; Nagayama et al., 2010). Axons of CCK-containing superficial TCs form the intrabulbar association system (IAS) that connects lateral and medial regions of each MOB (Schoenfeld et al., 1985; Liu and Shipley, 1994). IAS axons travel to the opposite side of the bulb and synapse on GCs apical dendrites. The IAS exhibits a high degree of topographic specificity, such that TCs associated with one glomerulus preferentially target the IPL below the opposite side isofunctional glomerulus and vice-versa

(Belluscio et al., 2002; Lodovichi et al., 2003). Thus, the IAS is configured to modulate M/TCs, via GCs, receiving input from ORNs expressing the same receptor, on opposite sides of the MOB. TCs are excitatory, as is CCK, and therefore the IAS should depolarize GCs to inhibit M/TCs, although this has yet to be tested. TC physiology is discussed below with MCs, but there are some notable differences between the two output classes and among TC subtypes. TCs *in vivo* tend to fire at higher spontaneous rates than MCs (Nagayama et al., 2004). In slices, some TCs exhibit spontaneous and ON-evoked bursting activity somewhat similar to ETCs, although there is significant variability (Hamilton et al., 2005; Ma and Lowe 2010). Different TC classes have differential sensitivity to ORN input, with superficial cells more easily excited by ORN stimulation (Schneider and Scott, 1983; Ezeh et al., 1993; Wellis et al., 1989).

**8.2.2.2 EPL Interneurons.** The EPL contains morphologically and neurochemically heterogeneous interneurons, such as van Gehuchten cells and other subtypes. Many are GABAergic and presumed to be inhibitory, but others express Substance P, enkephalin, neurotensin, somatostatin, neuropeptide Y, and other neuropeptides (Ennis et al., 2007). The role of these transmitters is unknown. EPL interneurons respond to ON input polysynaptically, probably via glutamate release from M/TC lateral dendrites (Hamilton et al., 2005). EPL interneurons are thought to inhibit M/TC, and possibly GC, dendrites. Many EPL interneurons have dendrites spanning several adjacent glomeruli and may provide localized inhibition of M/TCs that are topographically related to overlying glomeruli (Hamilton et al., 2005).

## 8.2.3 Mitral Cell Layer (MCL)

**8.2.3.1 Anatomical Features of MCs.** The thin MCL contains MC somata as well as numerous GCs. Indeed, it is often overlooked that ~90% of the cells in the MCL are GABAergic, corresponding to superficially located GCs (Frazier and Brunjes, 1988; Parrish-Aungst et al., 2007). MC features are similar to those of TCs although MC lateral dendrites are more extensive and may extend up to 1–2 mm. MCs have been subdivided into two classes, Type I and II, based on extension of dendrites into the deep or superficial parts of the EPL, respectively (Orona et al., 1984). Type II MCs are more readily activated by ORN stimulation than Type I cells (Schneider and Scott, 1983; Ezeh et al., 1993; Wellis et al., 1989). M/TC lateral dendrites receive axonal input from certain classes of centrifugal neuromodulatory transmitter systems (see Section 8.9), and dendrodendritic inputs from EPL interneurons and GCs. M/TC axon collaterals synapse with

GCs, or exit the MOB as the lateral olfactory tract (LOT) to innervate POC. In addition to glutamate, some M/TCs contain neuropeptides such as corticotropin-releasing factor.

### **8.2.3.2 Spontaneous Firing and Intrinsic Membrane Properties.**

In anesthetized rodents, M/TCs fire spontaneously over a wide  $\sim$ 1–40 Hz range with mean rates generally 14–18 Hz and faster instantaneous rates during bursts or odors (Chaput and Holley, 1979; Chaput, 1983; Yu et al., 1993; Jiang et al., 1996; Davison and Katz, 2007; Nica et al., 2010). Spontaneous firing in awake rodents is generally similar to that in anesthetized preparations; range, 1–33 Hz, mean range, 12–17 Hz (Kay and Laurent, 1999; Fuentes et al., 2008; Shusterman et al., 2011). However, in one study recordings of M/TCs before and after anesthesia exhibited a large drop in firing from  $\sim$ 27 to 9 Hz (Rinberg et al., 2006). In slices, M/TC discharge is more modest ( $\sim$ 0.5–20 Hz range; 3–6 Hz mean), presumably because tonic sensory input is absent (Ennis et al., 1996; Ciombor et al., 1999; Heyward et al., 2001; Ma and Lowe, 2010). Spontaneous firing in M/TCs is intrinsically generated and persists when their synaptic inputs are inactivated (Ennis et al., 1996; Heyward et al., 2001; Ma and Lowe, 2010). MCs, but not other MOB cell types, exhibit intrinsic membrane bistability characterized by spontaneous alternation between a perithreshold upstate membrane potential and a more hyperpolarized ( $\sim$ -10 mV) downstate potential (Heyward et al., 2001; Heinbockel et al., 2004). Spontaneous or ON-evoked spikes are readily launched from the upstate characterized by high frequency (10–50 Hz) subthreshold membrane potential oscillations (Desmaisons et al., 1999; Heyward et al., 2001; Balu et al., 2004). MC intrinsic membrane properties support temporally precise spiking responses to brief sniff-like phasic inputs (Balu et al., 2004).

A hallmark of spontaneous and odor-evoked activity in M/TCs, and of nearly all MOB subtypes, is phasic rhythmic modulation as a function of the 1–12 Hz theta frequency range of the respiratory cycle (Buonviso et al., 2006; Scott, 2006). Respiratory- or sniff-coupled spiking and membrane potential oscillations occur in the presence and absence of odors and depend upon rhythmic ORN glutamate input in response to airflow across the nasal epithelium (Philpot et al., 1997; Chalansonnet and Chaput, 1998; Kay and Laurent, 1999; Luo and Katz, 2001; Charpak et al., 2001; Margrie and Schaefer, 2003; Debarbieux et al., 2003). Thus, rhythmic activity persists when the MOB is isolated from the brain by olfactory peduncle trans section, but is eliminated when nasal respiration is bypassed by tracheal respiration (Sobel and Tank, 1993; Philpot et al., 1997; Margrie and Schaefer, 2003; Phillips et al., 2012). Peak

depolarization of the MC membrane potential, as well as EPSPs and spikes, occur during or after a short lag from the inhalation/inspiration transition (Charpak et al., 2001; Margrie and Schaefer, 2003; Cang and Isaacson, 2003; Debarbieux et al., 2003). Other aspects of M/TC odor responses are discussed below in Section 8.8.

### **8.2.3.3 Dendritic Spike Propagation.**

Subthreshold ON-evoked EPSPs are decremental and decrease by  $\sim$ 30% over a 300  $\mu$ m distance in the apical dendrite (Djuricic et al., 2004). Suprathreshold input typically elicits spikes that are initiated at the soma, but stronger input can trigger actively propagating apical dendritic  $\text{Na}^+$  spikes originally described *in vivo* as fast prepotentials (Mori, 1987; Chen et al., 1997; Isaacson and Strowbridge, 1998; Debarbieux et al., 2003). Somatic spikes also back-propagate non-decrementally along the apical dendrite and thus could engage M/TC glutamate spillover and dendrodendritic input to PG/SACs. Somatic or lateral dendritic inhibitory input (IPSPs) can block somatic spike initiation providing the cellular basis for modulation of odor responses by GC-mediated inhibition (Chen and Shepherd, 1997; Chen et al., 1997).  $\text{Na}^+$  spikes actively propagate in M/TC lateral dendrites, suggesting that M/TC spikes, via GCs, could inhibit other M/TCs over considerable spatial distances. (Charpak et al., 2001; Xiong and Chen, 2002; Debarbieux et al., 2003). However, other studies report that lateral dendritic spike propagation is attenuating (Margrie et al., 2001; Lowe, 2002; Christie and Westbrook, 2003).

## **8.2.4 Granule Cell Layer (GCL)**

### **8.2.4.1 Granule Cells (GCs).**

GCs are small axon-less cells packed into row-like aggregates in the GCL (Price and Powell, 1970b; Reyher et al., 1991). As noted above, superficially-located GCs are also present in the MCL. GCs have an apical dendrite that ramifies in the EPL and shorter basal dendrites in the GCL. The apical dendrites of superficial GCs arborize in the superficial and deep EPL whereas those of deeper GCs ramify in the deep EPL (Orona et al., 1983; Greer, 1987). GCs contain GABA (Ribak et al., 1977), and some contain enkephalin and other neuropeptides (Bogan et al., 1982; Davis et al., 1982). GC apical dendrites receive synapses from, and make synapses onto, M/TCs. GCs also receive synapses from a variety of centrifugal afferents, including inputs from primary olfactory cortex (POC) (Section 8.6) and neuromodulatory transmitter systems (Section 8.9). Input from POC (e.g., piriform cortex, anterior olfactory nucleus) comprise the bulk of synaptic contacts onto GCs (Price and Powell, 1970a,c). GCs also receive synapses from M/TC axons, as well as inputs from other GCL interneurons. Anatomically, gap junctions have been reported among GCs (Reyher

et al., 1991), although electrophysiological studies found no evidence for electrotonic coupling (Schoppa, 2006). In vivo and in vitro, GCs spontaneous spiking is relatively infrequent, probably due to their hyperpolarized resting potential ( $-65$  to  $-75$  mV), and is driven primarily by glutamatergic input (Wellis and Scott, 1990; Cang and Isaacson, 2003; Zelles et al., 2006; Heinbockel et al., 2007; Pressler et al., 2007). Synaptic input or direct depolarization can elicit  $\text{Na}^+$  and  $\text{Ca}^{2+}$  spikes in GCs (Halabisky et al., 2000; Egger et al., 2005). GC activity is strongly regulated by a transient A-type  $\text{K}^+$  current,  $I_A$ , preferentially expressed in dendrites where it counters brief depolarizing synaptic inputs (Schoppa and Westbrook, 1999). Blockade of  $I_A$  with 4-AP decreases the lag or delay for evoked spikes. GCs in the MOB and AOB are potently activated by mGluR1 agonists while mGluR1 antagonists reduce M/TC-evoked excitation (Castro et al., 2007; Heinbockel et al., 2007). GCs exhibit broader odor tuning (respond to more odorants) than ET/M/TCs (Tan et al., 2010) and seem to lack inhibitory odor responses (Luo and Katz, 2001). In contrast to M/TCs, GC odor responses attenuate rapidly after the first respiratory cycle (Cang and Isaacson, 2003).

**8.2.4.2 Deep SACs.** The IPL and GCL contain a population of SACs, collectively referred to as deep SACs, that form several morphologically distinct subtypes (i.e., Golgi, Cajal, horizontal and Blanes cells) (see Eyre et al., 2008 for review). Most deep SACs have dendrites restricted to the IPL/GCL, while their axons tend to terminate and ramify either in the GL, EPL or GCL. Although long considered interneurons, a subpopulation was found to project to POC. These cells are GABAergic, but may also express neuropeptides such as vasoactive intestinal peptide, neuropeptide-Y, enkephalin, and somatostatin (Eyre et al., 2008). Deep SAC axons seem to exclusively target inhibitory GABA neurons, including PG and GCs. Consistent with this, activation of deep SACs evokes  $\text{GABA}_A$  receptor mediated inhibition of GCs (Eyre et al., 2008; Pressler and Strowbridge, 2006). Thus, deep SACs comprise a major intrabulbar inhibitory circuit and provide the only known local regulatory system from inhibitory neurons below the MCL to the sensory input layer. Since the targets of deep SACs are inhibitory interneurons, functionally deep SAC activation should lead to ET/M/TC disinhibition. One deep SAC type, Blanes cells, appears to exert prolonged modulation of MOB excitability. Brief excitation elicits prolonged (up to 44 min) Blanes cell spiking and in turn, prolonged barrages of IPSCs in GCs (Pressler and Strowbridge, 2006). This would be expected to yield long-lasting excitation (i.e., disinhibition) of M/TCs. Deep SACs cells receive excitatory glutamatergic input from axon terminals, which may include M/TC axons and centrifugal feedback input from POC (Eyre et al., 2008).

## 8.2.5 Dendrodendritic Transmission Between M/T and Gcs

**8.2.5.1 Overview Of M/T - GC Dendrodendritic Interactions.** The majority of synapses of the EPL are between M/TC lateral dendrites and GC apical dendrites. Most of the synapses are: (1) asymmetrical synapses from M/TC dendrites onto GC dendrites, and (2) symmetrical synapses from the spines (“gemmules”) of GC dendrites to M/TC dendrites (Price and Powell, 1970b-d). These synapses are mostly reciprocal and occur in roughly equal proportion (Hirata, 1964; Rall et al., 1966; Price and Powell, 1970d; Jackowski et al., 1978; Woolf et al., 1991). A M/TC can therefore generate self- or feedback inhibition and also lateral inhibition of other M/TCs.

**8.2.5.2 Excitatory M/T to GC Transmission.** M/TC glutamate release requires activation of  $\text{Ca}^{2+}$  influx via high voltage activated (HVA) channels located close to active release sites (Isaacson and Strowbridge, 1998). M/TC stimulation evokes dual component EPSCs in GCs, consisting of a fast AMPA and slow NMDA receptor components (Isaacson and Strowbridge, 1998; Schoppa et al., 1998; Aroniadou-Anderjaska et al., 1999a; Chen et al., 2000; Isaacson, 2001). The AMPA receptor component is less effective than the NMDA receptor component in evoking spikes in GCs, especially in  $\text{Mg}^{2+}$  free conditions (Schoppa et al., 1998). Block of GC  $I_A$  enhances AMPA receptor-dependent spiking (Schoppa and Westbrook, 1999). An mGluR1 component is involved in M/TC to GC transmission in the MOB and AOB (Heinbockel et al., 2007; Castro et al., 2007).

**8.2.5.3 Inhibitory GC to M/TC Transmission.** GC activation evokes  $\text{GABA}_A$  receptor-mediated IPSPs/IPSCs in M/TCs (Chen et al., 2000; Isaacson and Vitten, 2003; Dietz and Murthy, 2005).  $\text{Ca}^{2+}$  influx through P/Q- and N-type channels and through NMDA receptor channels near dendrodendritic synapses, presumably on GC spines, directly couple to GABA release (Isaacson and Strowbridge, 1998; Chen et al., 2000; Halabisky et al., 2000; Isaacson, 2001; Egger et al., 2003, 2005). T-type  $\text{Ca}^{2+}$  currents activated by subthreshold depolarization and store  $\text{Ca}^{2+}$  release also contribute to GABA release (Egger et al., 2003, 2005).

**8.2.5.4 Self and Lateral Dendrodendritic Inhibition.** M/TC depolarization results in a dendrodendritically-mediated feedback IPSP/IPSC; that is, self-inhibition (Isaacson and Strowbridge, 1998; Schoppa et al., 1998; Chen et al., 2000; Halabisky et al., 2000; Dietz and Murthy, 2005). Such inhibition is of long duration (1–2 sec) and consists of a flurry of individual IPSPs/IPSCs suggesting

asynchronous GABA release from multiple GCs (Schoppa et al., 1998). In normal extracellular Mg<sup>2+</sup>, self-inhibition is reduced to similar levels by AMPA or NMDA receptor antagonism, and is abolished when both receptors are blocked (Isaacson and Strowbridge, 1998). Mg<sup>2+</sup>-free conditions enhance self-inhibition and cause it to be dominated by NMDA receptor activation (Isaacson and Strowbridge, 1998; Schoppa et al., 1998; Isaacson, 2001; Chen et al., 2000; Christie et al., 2001; Halabisky and Strowbridge, 2003). Self-inhibition is reduced by mGluR1 blockade (Heinbockel et al., 2007; Castro et al., 2007). Self-inhibition has been reported to be unaffected (Halabisky et al., 2000) or enhanced (Schoppa and Westbrook, 1999; Isaacson, 2001) by blockers of I<sub>A</sub>. Lateral or feedforward inhibition is mediated through the M/TC-GC-M/TC dendrodendritic circuit (Isaacson and Strowbridge, 1998; Urban and Sakmann, 2002). Like self-inhibition, lateral inhibition in Mg<sup>2+</sup>-free conditions is dominated by the NMDA receptor synaptic response (Isaacson and Strowbridge, 1998; Schoppa et al., 1998). I<sub>A</sub> currents, which oppose brief AMPA depolarizations, strongly regulate lateral inhibition. Thus, block of I<sub>A</sub> by 4-AP reduces the duration of lateral inhibition by increasing the ability of AMPA receptors to elicit more rapid and synchronous GABA release (Schoppa and Westbrook, 1999).

**LOCAL VS. GLOBAL MODES OF DENDRODENDRITIC INHIBITION** Current views are that weak stimulation producing small or subthreshold synaptic responses in GCs, and thus Ca<sup>2+</sup> influx into isolated spines, triggers GABA release and inhibition of M/TC that are synaptically-coupled, and in close proximity, to those spines. Such inhibition would tend to be spatially restricted. NMDA receptors, voltage-dependent Ca<sup>2+</sup> channels and store Ca<sup>2+</sup> can trigger GABA release. By contrast, stronger input that elicits Na<sup>+</sup> or Ca<sup>2+</sup> spikes would produce more global or widespread inhibition (Chen et al., 2000; Egger et al., 2003, 2005). This mechanism would tend to dominate long-range lateral inhibition as well as inhibition following excitatory input to GC somata or basal dendrites. The spatial extent of lateral inhibition following TC activation is less than that for MCs, presumably due to the shorter TC lateral dendrites (Christie et al., 2001).

**TEMPORAL MODULATION OF DENDRODENDRITIC INHIBITION** M/TC self-inhibition and GC-M/TC inhibition exhibit paired pulse depression with a slow recovery time constant (Isaacson and Vitten, 2003; Dietz and Murthy, 2005). This may be due to intrinsic GC properties leading to spike adaptation across repetitive sniff frequency input (Pressler et al., 2007). These factors may account for the decrement in GABAergic inhibition of M/TCs across sniffs of an odor (Cang and Isaacson,

2003). Thus, the strength of dendrodendritic inhibition is likely to be temporally modulated by respiration (see also Phillips et al., 2012). Other studies indicate that higher frequency local gamma oscillatory activity generated by M/TC-GC interactions modulates GABAergic inhibition. Gamma frequency stimulation in the GCL or ELP can facilitate M/TC feedback and lateral inhibition by relieving the Mg<sup>2+</sup> block of GC NMDA receptors (Halabisky and Strowbridge, 2003). Lateral inhibition is strengthened in an activity dependent manner among M/TCs that have correlated spike activity (Arevian et al., 2008).

## 8.2.6 Primary Olfactory Cortical Inputs

Extrinsic afferent input to the MOB, also referred to as centrifugal fibers (CFFs), can be subdivided into two classes: (1) inputs arising from non-olfactory, so called neuro-modulatory transmitter systems (see Section 8.9), and (2) feedback inputs arising from olfactory-related structures, in particular those arising from POC. CFF projections from POC arise from glutamatergic pyramidal neurons in layer II and III of piriform cortex, as well as other POC structures (Shipley et al., 1996; Ennis et al., 2007). These projections massively target GCs and terminate mostly heavily on somata/basal dendrites and proximal apical dendrites. CFF activation excites GCs and produces IPSPs in M/TCs, that is, dendrodendritic inhibition (Ennis and Hayar, 2008). CFF-evoked synaptic responses in GC proximal dendrites have AMPA and NMDA receptor components, but have a much faster time course than M/TC synaptic input to GC distal dendrites in the EPL (Balu et al., 2007; Laaris et al., 2007). Activation of proximal synaptic input can reverse the Mg block of NMDA responses at distal EPL inputs, facilitating the expression of M/TC dendrodendritic inhibition (Balu et al., 2007). CFF, but not M/TC synaptic input, exhibits NMDA receptor-dependent LTP that amplifies M/TC inhibition by GCs (Guo and Strowbridge, 2009).

## 8.2.7 Adult-Born Neurons and Sensory/Experience-Dependent Plasticity

In adult animals MOB interneurons (GCs and PGCs) are continually generated from progenitor cells of the rostral migratory stream (see Chapter 9). These new neurons functionally integrate into MOB circuits in a sensory experience-dependent manner and contribute to odor learning and discrimination. This topic is beyond the scope of this chapter and readers are referred to Chapter 9 and other studies on this topic (Gheusi et al., 2000; Rochefort et al., 2002; Carleton et al., 2003; Lledo et al., 2005; Lazarini and Lledo, 2011; Moreno et al.,

2009; Sawada et al., 2011; Sultan et al., 2011; Yokoyama et al., 2011). Similarly, reviewers are referred elsewhere to the effects of odor activity, experience, and learning on ORN input to the glomeruli, MOB circuitry, odor responses, and oscillations and olfactory-guided behaviors (Fletcher and Wilson, 2002, 2003; Gervais et al., 2007; Jones et al., 2008; Mandairon and Linster, 2009; Cummings and Belluscio, 2010; Parrish-Aungst et al., 2011).

## 8.2.8 Odor Responses, Oscillations and Synchrony

**8.2.8.1 Odor Responses.** A comprehensive review of odor coding is beyond the scope of this chapter and we refer the reader to more extensive reviews of this topic (Wachowiak and Shipley, 2006; Mori et al., 2006; Wilson and Mainen, 2006; Johnson and Leon, 2007). ORNs expressing a given odorant receptor are promiscuous or broadly tuned such that odors tend to activate ORN populations expressing different receptors and ORNs expressing the same receptor respond to multiple odorants. ORNs expressing the same receptor are thought to have a receptive field or molecular receptive range (MRR) that encompasses all of the odors they respond to. Optical imaging techniques have revealed that these features are reflected in odor response profiles of ORN terminals in the glomeruli. Thus, glomerular activity mirrors ORN activity and each glomerulus has a unique odor response profile or MRR predicated by the MRR of the ORN population by which it is innervated. An odorant may activate multiple glomeruli and a glomerulus may respond to multiple odorants in a manner that varies with stimulus concentration. ORNs responsive to structurally similar odorants or odorants sharing similar molecular features tend to map onto adjacent glomeruli, and thus similar odorants tend to activate spatially adjacent glomerular clusters. In general, increasing odorant concentration increases the response magnitude of a glomerulus and increases the number of activated glomeruli (Meister and Bonhoeffer, 2001; Wachowiak and Cohen, 2001; Fried et al., 2002; Spors and Grinvald, 2002; Spors et al., 2006). Additionally, glomerular activation patterns have strong temporal components (kinetics, respiratory sniff modulation) that differ across the population of odor responsive glomeruli and vary within a glomerulus in an odorant specific manner (Spors et al., 2006; Carey et al., 2009). Therefore, odor information is conveyed by the pattern of activated glomeruli, their relative activation magnitude, and temporal response dynamics. Each of these response features, at the level of glomerular input and M/TC output, may contribute to the odor code but their relative contribution has yet to be determined.

M/TC odor responses are complex and variable and include inhibitory responses alone or in combination with excitation (Luo and Katz, 2001; Margrie et al., 2001; Cang and Isaacson, 2003; David et al., 2009; Tan et al., 2010). The type (excitation vs. inhibition), magnitude and direction of response can change dramatically with odor concentration. In general, odor-evoked EPSP amplitudes vary proportionately with stimulus strength and spikes are often launched from the rising phase of EPSPs (Margrie and Schaefer, 2003; Cang and Isaacson, 2003). Odor-evoked IPSP strength does not seem to vary with stimulus concentration, although the IPSP amplitude declines across sniffs (Cang and Isaacson, 2003). It has long been known that closely adjacent M/TCs exhibit similar activity profiles and odor responses as one would expect from cells receiving sensory input from the same glomerulus (Buonviso et al., 2006). This has been directly confirmed by the high similarity of odor responses of M/TCs of the same glomerulus; however, odor response dynamics can vary among “sister” M/TCs of the same glomerulus (Dhawale et al., 2010). Nonetheless, it is thought sister M/TCs have a similar molecular receptive range (MRR) to a series of structurally or molecularly similar odorants, with a preferential sensitivity (most vigorous response) to one odorant in the family; more dissimilar members of the family evoke weaker responses with inhibition occurring to even more dissimilar members (Yokoi et al., 1995; Kashiwadani et al., 1999; Fletcher and Wilson, 2003). In addition to a defined MRR, M/TCs may also respond to very different, structurally unrelated odorants. Major differences in the breadth of M/TC receptive fields have been reported, perhaps due to the range or concentration of odorants tested and/or the influences of anesthesia (Kay and Laurent, 1999; Rinberg et al., 2006; Davison and Katz, 2007; Fantana et al., 2008; Tan et al., 2010). There are conflicting reports on the breadth of odor tuning in M vs TCs with some studies reporting similar tuning curves (Tan et al., 2010) and others that TCs exhibit more robust and widely tuned excitatory responses (Nagayama et al., 2004); the later study also reported that TCs exhibit weaker and narrower inhibitory odor response tuning than MCs. Superficial TCs exhibit more prolonged odor responses than MCs (Luo and Katz, 2001).

Inhibitory circuits in the glomerular and deeper layers modulate M/TC odor responses. In some models, inhibitory odor responses are thought to arise from M/TCs in neighboring glomeruli with slightly different, but overlapping MRRs (Yokoi et al., 1995; Nagayama et al., 2004). Thus, neighboring cells that are highly tuned to an odorant suppress activity of M/TC populations that are weakly tuned or unresponsive to an odorant via lateral inhibitory circuits. Observations that M/TCs associated with different but nearby glomeruli interact with a common population

of GCs is consistent with this model (Arevian et al., 2008). Also partially consistent are findings that M/TCs below odor responsive glomeruli are excited, but are inhibited or show no response to odors activating adjacent glomeruli (Luo and Katz, 2001). Inhibitory circuits in the glomerular layer and at the deeper M/TC-GC network are both thought to contribute to inhibitory odor responses. In theory, inhibition is thought to play a key role in population response odor coding strategies via contrast enhancement – sharpening odor representations – by inhibiting weakly responsive M/TCs and/or reducing overlapping populations that respond in common to odors (Yokoi et al., 1995; Linster and Hasselmo, 1997; Linster and Cleland, 2002; Cleland and Sethupathy 2006; Urban and Arevian, 2009). Consistent with this concept, blockade of inhibition or activity at M/TC-GC synapses, enhances excitatory and reduces inhibitory odor responses, and also broadened breadth of tuning (Yokoi et al., 1995; Margrie et al., 2001; Tan et al., 2010). Inhibition is also thought to play a key role in discrimination. Odors that produce overlapping activation of M/TCs will be perceived as more similar (i.e., more difficult to discriminate) than odors that activate non-overlapping populations (Linster and Hasselmo, 1997; Linster and Cleland, 2002); see also Section 8.8.2.

In addition to the magnitude or strength of the odor response (Bathellier et al., 2008), the temporal dynamics of responses are thought to contribute to odor coding. Temporal components of odor responses or phase relative to respiration are also thought to be important to the odor code. The latency of the first spike following stimulus onset is inversely proportional to the number of spikes per sniff, such that shorter latencies occur during bursts (Margrie and Schaefer, 2003; Cang and Isaacson, 2003). This suggests that the initial spike latency provides information about sensory input strength, i.e., odor concentration. It has long been known that M/TC odor responses generally synchronize to the sniff cycle, but also that the number of spikes and their timing evolve over multiple sniffs (Buonviso et al., 2006; Scott, 2006; Schaefer and Margrie, 2007). However, recent studies indicate that the timing of odor responses relative to the sniff phase are relatively invariant but odor specific, suggesting that sub-sniff spike timing contains sufficient information for odor discrimination (Cury and Uchida, 2010; Carey and Wachowiak, 2011; Shusterman et al., 2011). Rodent sniff frequency varies with behavior and this is also thought to modulate odor responses. Imaging studies indicate that the sniff-locked pattern of presynaptic input to the glomeruli attenuates and decouples from respiration as sniff frequency increases (Spors et al., 2006; Verhagen et al. 2007; Wesson et al., 2009; Carey et al., 2009; but see also Oka et al., 2009). How this impacts the magnitude and temporal dynamics of M/TC odor responses is unclear.

Odor response magnitude seems to decrease with increases in sniff rate (Bathellier et al., 2008; Carey and Wachowiak, 2011). Some studies indicate that odor response timing is relatively invariant to sniff frequency, at least up to ~4–5 Hz (Cury and Uchida, 2010; Carey and Wachowiak, 2011; Shusterman et al., 2011). This is at odds with other reports that temporal variability increases or that spike phase locking decouples from the respiratory cycle as sniff frequency increases (Bhalla and Bower, 1997; Kay and Laurent, 1999; Rinberg et al., 2006; Courtiol et al., 2011). Just as inhibition is thought to provide contrast enhancement of odorant representations, it is also thought to regulate gain control of the frequency or amplitude of M/TC odor responses, and to modulate temporal and synchronization dynamics of odor responses. Blockade of GABA inhibition increases the number, rate and temporal pattern of spikes elicited by ON or odor stimuli and this can occur when inhibition is blocked in the glomeruli or in the EPL (Yokoi et al., 1995; Lagier et al., 2004; Gire and Schoppa, 2009; Tan et al., 2010; Najac et al., 2011; Shao et al., 2012).

**8.2.8.2 Oscillations.** Oscillations and synchronous activity are characteristic features of spontaneous and odor-driven activity in the MOB and other olfactory structures. Temporal firing patterns, including rhythmic oscillations and neuronal synchronization are thought to be important in odor processing and coding at intra- and interglomerular levels within the MOB, and also in POC (Wehr and Laurent, 1996; Kauer, 1998; Kay and Laurent, 1999; Friedrich, 2002; Lledo et al., 2005; Gelperin, 2006; Kepcs et al., 2006; Schoppa, 2006; Spors et al., 2006; Beshele et al., 2007; Kay et al., 2009; Wachowiak, 2011). Prominent oscillatory activity is present in MOB field potentials and membrane potential/spike activity of individual MOB neurons. Olfactory sensory input occurs as a result of respiration which imparts slow rhythmic temporal structure to olfactory activity in the theta band (1–12 Hz) (Wachowiak, 2011). Higher frequency oscillations, superimposed on the theta, occur in the beta (15–40 Hz) and gamma (40–80 Hz) bands. Rodent MOB oscillations in the 1–12 Hz range are referred to as “theta” principally by similarity to hippocampal theta oscillations (Kay and Laurent, 1999; Kay, 2003, 2005). Since theta oscillations are generated entirely by respiratory-driven sensory input their prevailing frequency varies with sniff frequency; this includes components related to slow (1–3 Hz) “passive” sniffing as well as a faster components (5–12 Hz) characteristic of “active” investigative sniffing (Adrian, 1950; Welker, 1964; Macrides et al., 1982; Eeckman and Freeman, 1990; Kay and Laurent, 1999; Kay, 2003; Kay et al., 2009). Sniff frequency varies with task demands and increases in response to novel odors or

discriminations tasks, suggesting that rapid sniffing may improve odor processing and perception (Kepecs et al., 2006; Wesson et al., 2008a, b; Wachowiak, 2011).

Beta oscillations do not have a prominent spontaneous component, but are evoked by odorants and are amplified or emerge as animals learn to correctly recognize an odorant (Martin et al., 2004a, 2006; Fletcher et al., 2005; Kay et al., 2009). Sufficiently strong odorants trigger spike bursts occurring within the beta to gamma frequency range (20–60 Hz (Debarbieux et al., 2003)). Although beta oscillations vary with molecular features of odorants, they do not appear to be generated within the MOB but instead involve interactions with the piriform cortex (Neville and Haberly, 2003; Martin et al., 2004b, 2006; David et al., 2009). Gamma oscillations, evoked by odors or ON stimulation, occur on the crest of the slower respiratory driven theta cycle, and are apparent in the EEG, MOB field potentials, and M/TC subthreshold membrane potential and spiking activity (Adrain, 1950; Eeckman and Freeman, 1990; Kay and Freeman, 1998; Kashiwadani et al., 1999; Debarbieux et al., 2003; Friedman and Stowbridge, 2003; Neville and Haberly, 2003; Fletcher et al., 2005; Lagier et al., 2004; Martin et al., 2004b; David et al., 2009; Courtiol et al., 2011). Gamma is generated in the MOB and persists when centrifugal input is disrupted or when the MOB is isolated by peduncle trans section (Gray and Skinner, 1988; Neville and Haberly, 2003; Martin et al., 2004b). Gamma oscillations are generated by reverberatory bidirectional interactions at MT-GC synapses. Manipulations that impair M/TC to GC or GC to M/TC interactions suppress gamma oscillations (Friedman and Stowbridge, 2003; Neville and Haberly, 2003; Lagier et al., 2004, 2007). Gamma oscillations are also strengthened by electrical synapses, and disrupted by gap junction inhibition or in connexin36-knockout mice (Hormuzdi et al., 2001; Friedman and Stowbridge, 2003). Inhibition and gamma oscillations via the M/TC-GC system are thought to regulate spike timing and synchronization to enhance odor discrimination and learning (Linster and Hasselmo, 1997; Desmaisons et al., 1999; Linster and Cleland, 2001; Lagier et al., 2004; Beshel et al. 2007; Kay et al. 2009). Gamma oscillations are enhanced as animals learn to discriminate similar odorants (Kay et al., 2009). Disruption of inhibition through the M/TC-GC system or disruption of gamma oscillations impairs odor discrimination, while strengthening inhibition or gamma oscillations improves discrimination (Nusser et al., 2001; Abraham et al., 2010).

**8.2.8.3 Synchrony.** Temporally correlated or synchronized activity among the elements of the odor responsive neuronal population is thought to be a key element in odor coding (Linster and Cleland, 2001;

Laurent, 2002). Synchronous activity and similar odor response patterns among M/TCs in close proximity have been observed for decades (see Buonviso et al., 2006 for review). Studies over the last decade have revealed that synchronous activity is prominent among MOB neurons associated with the same glomerulus, consistent with the idea that glomeruli comprise fundamental units of olfactory processing. Spontaneous (spikes, subthreshold membrane potential oscillations, EPSPs, IPSPs) and ON-evoked activity is highly synchronous among sister ETCs (Figure 8.4; Hayar et al., 2004b, 2005). Synaptic input can synchronize ETCs, but synchrony persists when glutamate and GABA receptors are blocked; synchronous activity in this condition is mediated by electrical synapses between these cells (Hayar et al., 2004b, 2005). ET and PG/SACs of the same glomerulus exhibit synchronous activity which depends on glutamate synapses from ET to PG/SACs (Figure 8.4; Hayar et al., 2004b). LLDs synchronize sister MCs on a slow (~1 Hz) timescale (Carlson et al., 2000). LLDs seem to be driven by ETCs and consistent with this sister ET and MCs exhibit synchronous activity (Figure 8.5; De Saint Jan et al., 2009). Slow synchronous oscillations (2 Hz) among MCs can be elicited by ON stimulation or NMDA application (Schoppa and Westbrook, 2001, 2002; Christie and Westbrook, 2006). Such oscillations involve AMPA and mGlu receptor mechanisms and are absent in mice lacking electrical synapses. Induced spiking can also elicit faster timescale synchrony among sister MCs that depends on electrical synapses (Schoppa and Westbrook, 2002; Christie et al., 2005; Christie and Westbrook, 2006). These and other electrophysiological studies show that bi-directional electrical synapses exist between ET/M/TCs and also play a role in fast and slow timescale synchrony among sister TCs and among TCs and MCs (Figure 8.5; Pimentel and Margrie, 2008; De Saint Jan et al., 2009; Ma and Lowe, 2010; Gire et al., 2012). GABAergic inhibition is also thought to play an important role in synchronizing M/TC activity, especially over long distances. Such inhibition would coordinate the activity of neurons associated with different glomeruli (Desmaisons et al., 1999; Linster and Cleland, 2001; Lagier et al., 2004; Schoppa, 2006; Arevian et al., 2008).

### 8.2.9 Neuromodulatory Inputs

Context- and behavioral state dependent regulation of neural networks involved in sensory processing are mediated by neuromodulatory transmitter systems, such as the monoamines and acetylcholine (ACh). Context and behavioral state modify network oscillations, neuronal excitability and odor responses in the olfactory system (Kay and Laurent, 1999; Murakami et al., 2005; Tsuno et al., 2008; Linster et al., 2011). MOB receives inputs from cholinergic, noradrenergic, and serotonergic cell

groups in the basal forebrain and brainstem. These systems terminate diffusely in multiple MOB layers and modulate multiple neuronal subtypes. The older literature pertaining to these neuromodulatory inputs is reviewed elsewhere (Ennis et al., 2007; Ennis and Hayar, 2008).

**8.2.9.1 Cholinergic Input.** Cholinergic projections to the MOB and AOB originate mainly in the nucleus of the horizontal limb of the diagonal band (NDB) with a small contribution from the vertical limb (Shipley and Adamek, 1984). About 20% of the NDB neurons that project to the bulb are cholinergic but many NDB-MOB projection neurons are GABAergic (Zaborszky et al., 1986). Cholinergic fibers are present in most layers of the MOB, except the ONL, and are especially dense in the GL and IPL. Indeed, muscarinic and nicotinic receptors are found in most layers of MOB (Ennis et al., 2007). Nicotinic receptor agonists were reported to excite MCs and a bipolar PGC subpopulation (Castillo et al., 1999), while ACh or muscarinic agonists inhibited GL DA cells but had no effect on other PGCs (Pignatelli and Belluzzi, 2008). NBD stimulation was reported to depress (Nickell and Shipley, 1988) or to increase (Kunze et al., 1991, 1992) M/TC activity indirectly via primary actions on GCs. Consistent with the later studies, MOB ACh infusion reduced paired-pulse depression of LOT-evoked GCL field potentials via muscarinic receptor-mediated inhibition of GC GABA release (Elaagouby et al., 1991). Comparable findings indicated that ACh-muscarinic receptor activation reduces GC to M/TC inhibition in a behavioral state dependent manner (Tsuno et al., 2008). Thus, GC to M/TC inhibition is low with higher levels of ACh release during waking or fast wave sleep, and higher during slow wave sleep when ACh release declines. This ACh suppression of GC to M/TC inhibition is at odds with conclusions that muscarinic receptor activation presynaptically enhances GC GABA release (Castillo et al., 1999; Ghatpande et al., 2006), and separately, increases GC excitability in the MOB and AOB by enhancing afterdepolarizations (Pressler et al., 2007; Smith and Araneda, 2010). The later action decreased GC spike adaptation across repetitive sniff-like depolarizations or M/TC synaptic input, and in turn, prevented the reduction of MC GABAergic inhibition during repetitive stimulation. Muscarinic receptor excitation of GCs and enhanced lateral inhibition would be expected to sharpen or reduce overlap of odor responses among M/TCs. Consistent with this, NDB lesions or systemic or MOB injection of muscarinic receptor antagonists impairs odor habituation and discrimination (Linster and Cleland, 2002; Wilson et al., 2004). Other studies show that increasing ACh in the MOB sharpened M/TC odorant receptive fields and enhanced odor discrimination; both effects involved nicotinic and muscarinic receptor components (Mandairon et al., 2006; Chaudhury et al., 2009).

**8.2.9.2 Norepinephrine (NE) Input.** NE input to the bulb arises from the pontine nucleus locus coeruleus (LC) and terminates in nearly all layers but is especially dense in the IPL and GCL (Shipley et al., 1985; McLean et al., 1989). NE receptors occur in multiple layers of the MOB and are expressed by multiple cell types, congruent with the pattern of NE fiber innervation (Ennis et al., 2007). LC neuronal activity varies in a state dependent manner and the activity of these cells increases in conditions when sniff frequency increases; for example, novel odors or environments (see Linster et al., 2011 for review). Odors excite LC neurons and trigger rapid increases in MOB NE levels (Linster et al., 2011). Over the years, a number of often discrepant effects have been reported in the MOB that appear to be due to species or age, mode or site of NE application, or NE concentration (Linster et al., 2011). In particular, NE can elicit concentration dependent effects since NE receptor subtypes have different affinities and some MOB cells express multiple subtypes. LC-evoked NE release in vivo or NE activation of  $\alpha 1$  receptors in slices enhances MC spiking in response to weak or perithreshold intensity ON stimulation, suggesting that NE may function to enhance detection of weak odors (Jiang et al., 1996; Ciombor et al., 1999; Hayar et al. 2001). In slices, NE evokes a moderate direct depolarization of MCs via  $\alpha 1$  receptors due to closure of  $K^+$  channels; this effect, together with increased input resistance, appears to mediate enhanced responses to weak ON stimuli. GC to M/TC inhibition is regulated in a non-linear or bidirectional manner by NE concentration. Low NE levels engaging  $\alpha 2$  receptors suppress GC excitability and decrease MC inhibition (i.e., disinhibition), while higher levels acting at  $\alpha 1$  receptors excite GCs and inhibit MCs (Nai et al., 2009; 2010); similar  $\alpha 1$  effects occur in the AOB (Araneda and Firestein 2006; Smith et al., 2009). These studies indicate that the differential affinities of NE receptor subtypes allow for differential modulation of GABA release and olfactory processing as a function of the level of NE release, which in turn, is regulated by behavioral state (Linster et al., 2011). In preweaning rodents, the disinhibitory  $\alpha 2$  actions are predominant (Pandipati et al., 2010).

NE modulation of odor responses has been less well studied. Repetitive LC stimulation-odor pairings induced prolonged (4 hr) suppression of M/TC responses to the paired odor that was prevented by blockade of  $\alpha$  and  $\beta$  receptors (Shea et al., 2008). Behaviorally, such pairing decreased investigation of the paired odor, suggesting that NE release facilitates a habituation-like memory (i.e., decreased interest), consistent with other odor habituation memory results (Veyrac et al., 2007; Guerin et al., 2008). NE release appears to be important in excitatory-rewarded odor and inhibitory-non rewarded odor responses in pairs of synchronous M/TCs (Doucette et al., 2011). In spontaneous

habituation-dishabituation tests, discrimination between chemically related odorants was impaired when MOB NE receptors, and in particular  $\alpha 1$  receptors, were blocked (Mandairon et al., 2008). A similar testing paradigm showed that MOB NE infusion improved odor detection and discrimination in a non-linear manner that varied as a function of NE and odor concentration (Escanilla et al., 2010). Computational modeling studies suggested that NE excitation of MCs and GCs via the  $\alpha 1$  receptor improved odor signal-to-noise ratios, gamma oscillatory dynamics, and M/TC spike synchronization to improve odor detection and discrimination (Escanilla et al., 2010). By contrast, odorant discrimination in reward-motivated tasks was impaired only when all NE receptors in MOB were blocked (Doucette et al., 2007; Mandairon et al., 2008). The well documented role of LC projections to the MOB and AOB in neonatal conditioned odor preference learning, chemosensory regulation of pregnancy, and in post-partum maternal behavior has been reviewed elsewhere (Ennis and Hayar, 2008).

### **8.2.9.3 Serotonergic (5-HT) Input to MOB.**

Serotonergic inputs to the MOB and AOB arise from midbrain dorsal and median raphe neurons (McLean and Shipley, 1987). Serotonergic fibers are present in most layers of MOB, but are especially dense in the GL where they target GABAergic PGC and perhaps ET/M/TC dendrites (Gracia-Llanes et al., 2010). 5-HT receptors are localized in most layers of the MOB (Ennis et al., 2007). 5-HT depolarized 34% of JGCs in vitro via of 5HT<sub>2C</sub> receptor activation of a nonselective cation current (Hardy et al., 2005); the heterogeneous properties of 5-HT-responsive cells suggested that several JGC types are targeted by 5-HT fibers. More recent work showed that 5-HT depolarized and increased the bursting frequency of ETCs via engaging a transient receptor potential channel-mediated cation current linked to 5HT<sub>2A</sub> receptor activation (Liu et al., 2012). Some MCs are depolarized via 5-HT<sub>2A</sub> receptors, while others are hyperpolarized by an indirect action mediated by GCs (Hardy et al., 2005); the inhibition was mediated by 5-HT<sub>2A</sub> receptors. Subsequently, stimulation of dorsal raphe 5-HT neurons or topical 5-HT<sub>2A</sub> agonists reduced odor-evoked input to the glomeruli as visualized by imaging activity in ORN terminals (Petzold et al., 2009). This was due to GABA<sub>B</sub> receptor presynaptic inhibition of ON terminals subsequent to 5-HT excitation of GABAergic PGCs via the 5-HT<sub>2C</sub> receptor. Behavioral studies indicate that lesion of serotonergic fibers reversed or impaired conditioned olfactory learning, while 5-HT release or 5-HT<sub>2</sub> receptor agonists promoted odor conditioning (Morizumi et al., 1994; McLean et al., 1996; Yuan et al., 2003; McLean and Harley, 2004).

## **8.3 ACCESSORY OLFACTORY BULB (AOB)**

The AOB is a distinct region of the olfactory bulb. In mice, it is located at the posterior face, separated from forebrain by the rhinal fissure. Unlike the MOB, the AOB does not receive input from the nasal epithelium: its sensory information comes from the vomeronasal organ (VNO). The VNO detects non-volatile (liquid-phase) stimuli which are delivered by a pumping mechanism (Meredith and O'Connell, 1979), so that operationally the accessory olfactory system is reminiscent of the taste system.

### **8.3.1 Glomerular Layer (GL)**

**8.3.1.1 Major Divisions of the GL.** Like the MOB, the AOB is a laminar structure, and sensory input from the nose arrives in the glomerular layer. Anatomically, one of the most striking features of the rodent AOB is its regional organization, which is closely linked to the molecular organization of the VNO. Vomeronasal sensory neurons (VSNs) express G protein-coupled receptors from different gene families: the *VIRs* (Dulac and Axel, 1995), the *V2Rs* (Herrada and Dulac, 1997; Matsunami and Buck, 1997; Ryba and Tirindelli, 1997), and the *FPRs* (Liberles et al., 2009; Rivière et al., 2009; Roberts and Matsunami, personal communication). The *V2R*-expressing cells can be subdivided further by whether they express members of a family of non-classical class I major histocompatibility genes denoted *H2-Mv* (Loconto et al., 2003; Ishii et al., 2003; Ishii and Mombaerts, 2008).

The anterior portion of the AOB glomerular layer receives input from VSNs expressing members of the *VIR* family (Halpern et al., 1995; Jia and Halpern, 1996). The posterior AOB receives inputs from *V2R*-expressing neurons, with the *H2-Mv*-positive VSNs projecting to the most posterior AOB, and the *H2-Mv*-negative VSNs projecting to a “middle” (anterior part of the posterior) region (Ishii and Mombaerts, 2008). The division between anterior and posterior, called the *linea alba* (Larriva-Sahd, 2008), is often readily visible in sections and three-dimensional reconstructions. It is worth noting that many mammals, including ruminants and carnivores, do not express *V2R* receptors. Consequently, their AOBs consist of just the anterior compartment (Takigami et al., 2000; Tirindelli et al., 2009).

Anatomically, AOB glomeruli are much less distinct than their counterparts in the MOB (Ramón y Cajal, 1901; Yokosuka, 2012), largely because they are not as clearly delineated by JGCs (Section 8.10.3). Glomeruli are quite variable in size, many as small as 10  $\mu\text{m}$  with a few reaching approximately 100  $\mu\text{m}$  in diameter. While MOB glomeruli form a (mostly) two-dimensional sheet, in the AOB the glomeruli are stacked one atop the other

(Ramón y Cajal, 1901). This physical arrangement necessitates the use of physical or optical sectioning to visualize the three-dimensional structure of the glomerular layer.

**8.3.1.2 Spatial Organization of Glomeruli.** As in the MOB, the VSNs expressing the same receptor type send their axons to common targets. However, while the typical main olfactory receptor type targets two glomeruli per bulb (the usual range being 1–4, Zou et al., 2004), in the AOB they typically target more. While only a few receptor types have been examined, the anterior (V1R) receptor types have targeted an average of 4–30 glomeruli, depending on the receptor (Belluscio et al., 1999; Rodriguez et al., 1999; Wagner et al., 2006), and posterior types have targeted three to ten glomeruli (Del Punta et al., 2002; Haga et al., 2010). These studies also revealed that the “coarse” features – but often not the details – of the projection pattern were reproducible across animals.

Physiological mapping via calcium imaging has shown that neurons responding to sulfated steroids target both the anterior (*V1R*) AOB and the “middle” region innervated by the *H2-Mv*-negative *V2R*-expressing neurons (Hammen et al., 2014). The latter projections appear to be largely restricted to cells responding to a particular subfamily of sulfated steroids, the pregnanolones, known as metabolites of progesterone and as potent neurosteroids (Shu et al., 2004). Many individual glomeruli have seemingly-identical stimulus responses, in accord with the finding that single receptor types target multiple glomeruli. A battery of 11 sulfated steroids allowed at least 10 distinct patterns to be identified in individual animals, each pattern encompassing an average of 12 glomerular regions of interest. Collectively, these steroid-responsive glomeruli account for approximately 25% of the volume of the anterior AOB, and thus sample more comprehensively than molecular labeling.

There are indications that individual glomeruli in the AOB may receive input from more than one receptor type (Belluscio et al., 1999); however, not all glomeruli show evidence for this phenomenon (Del Punta et al., 2002). When tested physiologically using sulfated steroids, virtually all glomeruli showed similar patterns of responsiveness as observed in the VNO (Hammen et al., 2014), suggesting a high degree of functional “purity.”

While the sensory map varies significantly from animal to animal, reproducible features of the projections have been identified by examining multiple receptor types simultaneously. Using mice expressing three different reporter genes in cells expressing three different receptor types, it was shown that two receptor types within the same V1R subfamily targeted neighboring glomeruli, even when the precise position of these targets varied among animals (Wagner et al., 2006). Physiologically, the most striking

form of chemotopic organization is “heterophytic”: reproducible clumps of glomeruli that respond to very disparate stimuli, or glomeruli responding to similar stimuli that tend to be systematically far apart. It seems possible that these two apparently-opposing forms of organization may coexist at different levels, one operating within receptor subfamilies and the other operating between receptor subfamilies. Individual ligands can activate multiple VSN types, and individual VSNs can respond to multiple ligands (Meeks et al., 2010; Turaga and Holy, 2012). Consequently, just as with the main olfactory system, sensory coding in the accessory system is “combinatorial” (Revial et al., 1982; Friedrich and Korschning, 1997). It is possible that the physical arrangement of glomeruli plays a role in processing these combinatorial responses, through the actions of local interneurons.

**8.3.1.3 GL Neurons.** By comparison with the MOB, the neurons of AOB glomerular layer are more sparse (Larriva-Sahd, 2008; Yokosuka, 2012). The most abundant neurons are GAD67-positive, and their density seems approximately commensurate with the MOB. In contrast, there are far fewer TH-positive neurons, and their cell bodies tend to reside at the edge of the external cellular layer (see below). There are some indications that the morphology of AOB JGCs is quite diverse (Yokosuka, 2012). Superficial SACs have also been identified, with somewhat larger somata than is typical in the MOB (Larriva-Sahd, 2008).

TCs are not universally recognized in the AOB, but studies have identified a class of neurons, sometimes called “superficial MCs,” that may correspond to the ETCs of the MOB (Larriva-Sahd, 2008; Yonekura and Yokoi, 2008). These neurons are protocadherin-21 positive, reside near the boundary of the glomerular and external cellular layers, possess a single dendritic tuft, and do not project outside the bulb. They are much less numerous than their MOB counterparts: by Golgi and protocadherin-21 staining, these cells are seen only 10–15% as frequently as the AOB MCs (discussed below). At present, we are not aware of any studies of the physiology and/or function of AOB glomerular layer neurons. Some AOB MCs are powerfully inhibited by particular stimuli (Hendrickson et al., 2008), but the cellular origin of this inhibition has not been studied in detail.

### 8.3.2 External Cellular Layer (ECL)

While the AOB is often divided into the same layers as the MOB, there is no dramatic separation between “EPL” and “MCL.” For this reason, here we adopt a suggestion (Larriva-Sahd, 2008) to use the term “external cellular layer” (ECL) for the combined region.

**8.3.2.1 Mitral Cells (MCs).** The most numerous class of cells in the ECL are the so-called MCs, the main projection neurons of the AOB. These differ in several important respects from their counterparts in the MOB. First, their appearance is quite different, and not at all mitral, leading some authors to prefer the term large principal cells (Larriba-Sahd, 2008). Second, they are not organized in a thin layer as in the MOB, but are found throughout the ECL. Third, AOB MCs possess multiple dendrites that innervate glomeruli in tufts, with a reported range of 1–9 and a median of three tufts per cell (Takami and Graziadei, 1991; Larriba-Sahd, 2008; Yonekura and Yokoi, 2008). All of the innervated glomeruli reside on one side of the *linea alba*, indicating that these neurons receive primary sensory input from only one of the two major families of VRs. While the somata of the MCs are typically found on the same side of the *linea alba* as their glomerular tufts (Jia et al., 1997; Larriba-Sahd, 2008), this is not guaranteed (Yonekura and Yokoi, 2008). Moreover, their secondary dendrites are frequently observed to span the gap between anterior and posterior bulb (Larriba-Sahd, 2008).

Because AOB MCs have multiple dendritic tufts, in principle they may be able to integrate, in a direct excitatory sense, the outputs of multiple receptor types (Takami and Graziadei, 1991). Current evidence suggests some heterogeneity in the degree to which this actually happens in practice. A study of two genetically-labeled receptor types, V1rb2 and V2r1b (Del Punta et al., 2002), showed that the MCs receiving input from these receptor types formed tufts exclusively in glomeruli innervated by these receptor types – consequently, these neurons did not integrate directly from multiple receptor types. However, another study of three different receptor types, V1ra1, V1ra3, and V1rb1, did identify MCs receiving input from both labeled and unlabeled glomeruli (Wagner et al., 2006). Determining the “typical” rule by genetic labeling appears to be a difficult challenge, since it requires a specific mouse for each receptor.

More broadly, several lines of evidence suggest that direct integration happens, but perhaps in only a minority of MCs. In the anterior AOB, approximately two-thirds of the MCs have tufts that span a relatively narrow range of the depth of the glomerular layer (Yonekura and Yokoi, 2008). As the different subfamilies of V1Rs form glomeruli in layers in the anterior AOB (Wagner et al., 2006), this is consistent with the notion that these neurons sample from a restricted set of inputs. Moreover, a physiological study of responses of AOB neurons to dilute urine and sulfated steroids showed that approximately three-quarters had excitatory responses consistent with the profile of known single VSNs (Meeks et al., 2010). However, both studies also suggest that integration may happen in a subset of cells: approximately one third of MCs had tufts at multiple

depths within the anterior AOB (Yonekura and Yokoi, 2008), and approximately one quarter of MCs had physiological responses which appeared to directly integrate multiple sensory streams (Meeks et al., 2010).

When stimulated with either complex mixtures or pure compounds, AOB MCs show both excitatory and inhibitory responses (Luo et al., 2003; Hendrickson et al., 2008; Meeks et al., 2010; Ben-Shaul et al., 2010). Even in some neurons lacking obvious inhibitory responses, the prevalence of such input was indicated by the observation of strong mixture suppression (Hendrickson et al., 2008). Consequently, inhibitory processing may substantially alter MCs’ output.

**8.3.2.2 Other Neurons of the ECL.** Several other cell types in the ECL have been identified (Larriba-Sahd, 2008). The “round projecting cell” lacks a glomerular tuft, and its dendrites are confined to the ECL, but (as suggested by its name) it projects outside of the AOB. Some TCs are displaced from the glomerular/ECL boundary, and hence may be a distinct type. External GCs are relatively abundant spiny neurons that tend to reside deeper within the ECL. The dwarf cells and polygonal neurons are two additional, rarer, classes of interneurons within this layer.

### 8.3.3 Internal Cellular Layer (ICL)

The internal cellular layer (ICL) is deep in the lateral olfactory tract. The most abundant neurons of the internal cellular are the internal GCs, spiny neurons whose morphology is similar to their counterparts of the MOB. More rarely, one finds cells which appear to be the analog of Cajal cells (Larriba-Sahd, 2008). These cells have elaborate dendrites, some of which are entangled with the lateral olfactory tract, and it has been speculated that they might integrate information between the main and accessory olfactory bulbs (Larriba-Sahd, 2008). Finally, the “interstitial neurons of the bulbi” lie at the junction between main and accessory olfactory bulbs, and consist of recognizably-distinct subtypes.

## 8.4 EXTRINSIC INPUTS

Several distinct sources of afferents are known, of which the most extensively investigated is the noradrenergic input from locus coeruleus (Broadwell and Jacobowitz, 1976). This neuromodulatory input has attracted attention as a trigger for the Bruce effect, a form of olfactory learning that occurs when a recently-mated female mouse is exposed to the scent of a male (Brennan and Keverne, 1997; Brennan, 2009).

Briefly (see Brennan (2009) for an excellent in-depth review), a wide range of behavioral and pharmacological

evidence suggests that mating increases NE levels in the AOB, and this has been hypothesized to disinhibit AOB MCs and thus lead to potentiation of their outputs onto GCs. While this model received support from *in vivo* neuronal recordings employing vagino-cervical stimulation presumably triggering NE release in the AOB (Otsuka et al., 2001), *in vitro* studies indicated that NE decreases output of MCs (Kaba and Huang, 2005) and increases GC inhibition (Araneda and Firestein, 2006; Smith et al., 2009). The differences among these findings, and delicate balance between excitation and inhibition mediated by NE in the MOB (see Section 8.9.2), suggest the need for additional study.

AOB neuronal excitability is also modulated by ACh, using both nicotinic and muscarinic receptors (Smith and Araneda, 2010). ACh increased the excitability of both MCs and GCs, through very different mechanisms. A direct behavioral role for cholinergic modulation of the AOB does not yet seem to have been documented, but afferent projections from the NDB have recently been identified (Mohedano-Moriano et al., 2012).

In addition, the AOB receives projections from regions that are not known to be directly neuromodulatory. Two of the AOB's principal output targets, the bed nucleus of the stria terminalis (BST) and the vomeronasal amygdala, provide feedback projections (Raisman, 1972; Broadwell and Jacobowitz, 1976; Davis et al., 1978; Kevetter and Winans, 1981) with laminar specificity (Barber, 1982; Fan and Luo, 2009). The ECL is targeted exclusively by the BST, and these projections are GABAergic (Fan and Luo, 2009). Conversely, the ICL receives efferent input from the medial amygdala posteroventral nucleus and the posterior medial cortical amygdala. This projection is probably glutamatergic, and likely involves considerably more neurons than the one from the BST (Fan and Luo, 2009). Interestingly, more than half of the neurons providing this feedback, in both the BST and the vomeronasal amygdala, express estrogen receptor  $\alpha$ , and hence are candidates for incorporating aspects of the animal's hormonal status (Fan and Luo, 2009). Another major projection from the bed nucleus of the accessory olfactory tract, another target of the AOB, has also been identified (Mohedano-Moriano et al., 2012).

Two studies (Cenquizca and Swanson, 2007; de la Rosa-Prieto et al., 2009) have identified feedback projections to the AOB ICL from the CA1 region of the hippocampus and ventral subiculum. These regions also project to the MOB, but the projection to the AOB is more substantial. Consequently, all areas that receive projections from the AOB, and even some that do not, provide feedback to the AOB.

Clues as to the circuit role of the feedback connections from the medial amygdala to the AOB were found by combining retrograde tracing with *c-fos* labeling after exposure

to odors (Martel and Baum, 2009). A significant increase in *c-fos*-positive retrogradely-labeled neurons was seen in those mice (all female) which were exposed to male mouse urine volatiles; using other odors produced little or no increase. This result may help explain the increase in *c-fos* seen in the AOB when the mouse is exposed only to volatiles (Martel and Baum, 2007), which presumably do not gain access to the VNO. Since the medial amygdala receives projections from both major olfactory systems (Kang et al., 2009), this feedback connection may incorporate signals from the main olfactory system to modulate the function of the accessory olfactory system.

## Adult Neurogenesis in the Subventricular Zone and Migration to the Olfactory Bulb

JOHN W. CAVE and HARRIET BAKER

### 9.1 INTRODUCTION

The past two decades have witnessed an explosive growth of research investigating neurogenesis in adult vertebrate brains. Prior to this intense exploration, prevailing opinion was that adult brains did not generate new neurons beyond peri-natal development, despite pioneering studies showing evidence of proliferation and the generation of new neurons in the adult rat brain (Altman, 1962; Kaplan and Hinds, 1977). Consensus began to change, however, with the conclusive demonstration of neurogenesis in adult brains of birds (Alvarez-Buylla and Nottebohm, 1988; Goldman and Nottebohm, 1983; Paton and Nottebohm, 1984). Within a decade of these findings in avians, several studies in adult rodents confirmed that both the subventricular zone (SVZ) of the lateral ventricles and dentate gyrus produce progenitors that migrate and become neurons in the olfactory bulb (OB) and hippocampus, respectively (Altman and Bayer, 1990; Cameron et al., 1993; Lois and Alvarez-Buylla, 1993, 1994; Luskin, 1993). The current consensus is that adult neurogenesis occurs in several brain regions of non-mammalian vertebrates (Chapouton et al., 2007; Kaslin et al., 2008), but in mammals it is limited to the SVZ/OB and hippocampus (Bonfanti and Peretto, 2011; Lledo et al., 2006; Ming and Song, 2011). Neurogenesis in other regions of the adult mammalian brain has been reported, but these findings are either species-specific or controversial (Bonfanti and Peretto, 2011; Gould, 2007).

This chapter will focus on both neurogenesis in the SVZ and the migration of neuroblasts through the rostral

migratory stream (RMS) in the adult mammalian brain. Much of the research in this field has been conducted with rodents, specifically with mice. A growing number of studies with animals other than rodents, however, indicate that some significant differences exist between mammalian species (Bonfanti and Peretto, 2011). Although the discussion in this chapter is based largely on studies performed with rodents, documented differences in humans are noted.

### 9.2 SUBVENTRICULAR ZONE AND ROSTRAL MIGRATORY STREAM AS A NEUROGENIC NICHE

#### 9.2.1 Cytoarchitecture of SVZ

The SVZ of the adult lateral ventricles is derived from several regions of the embryonic neuroepithelium, including the lateral and medial ganglionic eminences as well as cortex and septum (Merkle et al., 2007; Stenman et al., 2003; Willaime-Morawek et al., 2006; Young et al., 2007). In rodents, OB interneuron progenitors are generated from neural stem cells that span the entire rostro-caudal length of the ventricle (Merkle et al., 2007). By contrast, generation of human progenitors is limited to only the ventral region of the anterior horn in the lateral ventricle (Curtis et al., 2007; Quinones-Hinojosa et al., 2006; Sanai et al., 2011; Sanai et al., 2004; Wang et al., 2011a). Neuronal and glial progenitors also can be generated *in vitro* from multi-potent stem cells isolated from RMS and OB core in both rodents and humans (Gritti et al., 2002; Liu and

Martin, 2003; Pagano et al., 2000). Only in rodents, however, have multi-potent neural stem cells outside the SVZ been demonstrated to generate OB interneurons *in vivo* (Alonso et al., 2008; Hack et al., 2005; Mendoza-Torreblanca et al., 2008; Merkle et al., 2007).

The rodent SVZ lies adjacent to ependymal cells lining the ventricular wall (Figure 9.1) (Doetsch et al., 1997). Most ependymal cells are multi-ciliated (type E1), but there is a small subset with two partially invaginated cilia (type E2) (Mirzadeh et al., 2008). The cilia of E1 cells have been suggested to direct cerebrospinal fluid (CSF) flow in the ventricle and establish gradients of various signaling molecules (Sawamoto et al., 2006). Alternatively, these cilia may serve as mechanical or chemical sensors of the CSF (Götz and Stricker, 2006), which is analogous to the proposed function of the E2 cells (Mirzadeh et al., 2008).

Adjacent to the ependymal cells are astrocytes (B1 cells), which have an apical process that contacts the CSF and a basal process that terminates on blood vessels (Mirzadeh et al., 2008; Shen et al., 2008). Together, the B1 and ependymal cells have a pinwheel-like organization on the ventricular wall with the apical processes of several B1 cells at the center and the ependymal cells forming a rosette around this center (Mirzadeh et al., 2008). Vascular cell adhesion molecule 1 (VCAM1) is critical for maintaining this organization (Kokovay et al., 2012). The B1 cells are derived from embryonic radial glia and function as slowly dividing neural stem cells in the SVZ (Doetsch et al., 1999; Laywell et al., 2000; Merkle et al., 2004; Ventura and Goldman, 2007). These cells are typically identified by the expression of glial fibrillary acidic protein (GFAP), epidermal growth factor receptor (EGFR), and the filament protein Nestin.

Slowly dividing B1 cells generate rapidly proliferating transit amplifying cells (type C cells), which can be identified by the expression of EGFR and Nestin as well as the transcription factors Distal-less homeobox 2 (Dlx2) and Achaete-Scute Complex-like 1 (ASCL1). Transit amplifying cells produce neuroblasts (type A cells), which are the progenitor cells that migrate to the OB and become interneurons (Doetsch et al., 1999). Neuroblasts characteristically express neuron-specific class III beta-tubulin ( $\beta$ TubIII/Tuj1), Doublecortin (Dcx) and polysialylated-neuronal cell adhesion molecule (PSA-NCAM). The collection of A, B1, and C cells are separated from the neighboring striatum by a second set of GFAP-containing astrocytes that have a more stellate morphology (B2 cells) (Doetsch et al., 1997). Mitotically active cells in the SVZ and RMS typically express markers such as the transcription factor SRY related HMG box 2 (Sox2), proliferating cell nuclear antigen (PCNA), nuclear protein Ki-67, and phospho-histone H3.

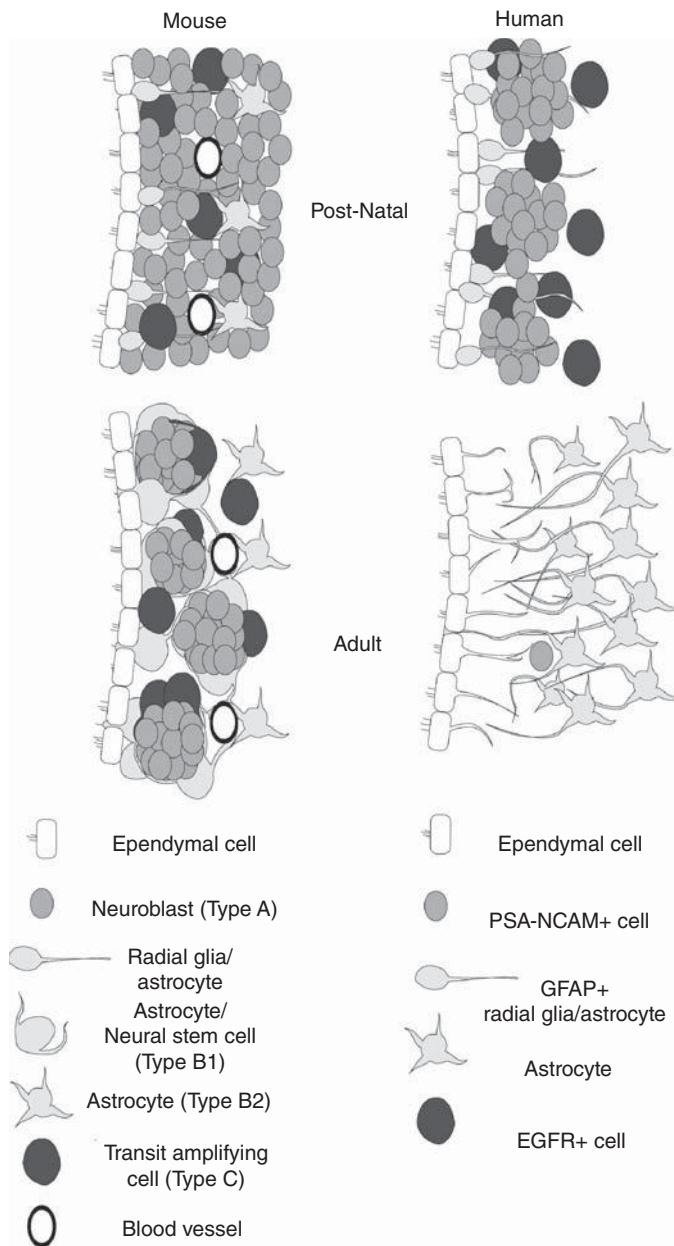

The cytoarchitecture of adult human SVZ is significantly different from rodents (Figure 9.1) (Quinones-

Hinojosa et al., 2006; Sanai et al., 2004). The border with the ventricular space is formed by a single row of multi-ciliated ependymal cells, but unlike rodents, the layer adjacent to these ependymal cells is a region with few cell bodies and has an extensive network of astrocytic processes. Many ependymal cells have basal processes that also project into this region. On the other side of this hypocellular gap is a dense ribbon of GFAP-expressing astrocytic cell bodies. Within this ribbon, some astrocytes express markers of mitotic activity. These proliferative cells may be the multi-potent progenitors observed with *in vitro* cultured explants, but a rigorous determination as to whether they act as neural stem cells *in vivo* remains to be established. Furthest from the ventricle is a transitional region that starts to resemble the neighboring striatal region and contains the first neuronal cell bodies.

Also unlike rodents, the adult human SVZ has noticeably very few cells that express markers of migrating neuroblasts, such as PSA-NCAM or Dcx (Quinones-Hinojosa et al., 2006; Sanai et al., 2011; Sanai et al., 2004; Wang et al., 2011a). The few cells that are present typically are found as individuals or pairs of cells in either the hypocellular layer or astrocytic ribbon on the ventral surface of the anterior horn. There is no dense network of migrating neuroblasts, as in adult rodents. The SVZ in both the human fetus (22–24 weeks post-conception) and infant (less than 18 months), however, has large numbers of PSA-NCAM expressing cells (presumably neuroblasts) adjacent to the ependymal layer that resemble the migrating chains of neuroblasts observed in rodents (Figure 9.1) (Guerrero-Cazares et al., 2011; Sanai et al., 2011; Wang et al., 2011a; Weickert et al., 2000). There are also several EGFR-expressing cells in the infant human SVZ that are either transit amplifying cells or neural stem cells. Unlike rodents, however, neither these EGFR-expressing cells nor the GFAP-expressing cells form tubes around the putative neuroblasts. Rather, the GFAP-expressing cells that line the ventricle wall have radial glia-like processes. Approximately eighteen months after birth, however, the population of PSA-NCAM expressing cells is depleted and the apparent migratory route adjacent to the ependymal cells transforms into the hypocellular space observed in adults. Although blood vessels have a major role in the organization of the rodent SVZ and RMS, their role, if any, in humans has not been described.

### 9.2.2 Neuroblast Migration Through the SVZ and RMS

In the adult rodent SVZ, migrating neuroblasts form chains that are ensheathed by astrocytes and transit-amplifying cells and tangentially migrate along the rostro-caudal axis of the ventricle (Doetsch and Alvarez-Buylla, 1996;

**Figure 9.1** Cytoarchitecture of the post-natal and adult SVZ in mice and humans. These cartoons represent coronal views of either the anterior SVZ of the murine lateral ventricle or the ventral SVZ in the anterior horn of the human lateral ventricle. In the post-natal mouse, neuroblasts (Type A cells) migrate in a mass tangentially along the rostro-caudal axis of the ventricle. Transit amplifying cells (Type C cells) are interspersed among the neuroblasts and GFAP-expressing glia have radial glia-like projection. In adult mice, the astrocytes (Type B1 cells), including the neural stem cells, have organized their processes into a mesh that form tubes surrounding the tangentially migrating chains of neuroblasts. Transit amplifying cells (Type C cells) are also part of these glial tubes. This cellular network is separated from the adjacent brain parenchyma by astrocytes (Type B2 cells). By contrast, the human post-natal SVZ contains chains of tangentially oriented PSA-NCAM expressing cells that are adjacent to the ependymal cells. Interspersed among these presumptive neuroblasts are EGFR-expressing cells (likely either transit amplifying cells or neural stem cells) and GFAP-expressing glia with radial processes. In the adult, the populations of PSA-NCAM and EGFR expressing cells are drastically depleted, leaving a hypocellular gap between ependymal cells and a thick ribbon of astrocyte cell bodies. This gap region is filled largely with processes from the neighboring astrocytes and ependymal cells. Although blood vessels have a major role in the organization of the murine SVZ, a similar role in humans has not been documented.

Doetsch et al., 1997; Lois et al., 1996). This progenitor migration parallels CSF flow in the lateral ventricle, which is suggested to contain gradients of guidance molecules that provide direction for migrating neuroblasts (Sawamoto et al., 2006). The SVZ also has a rich plexus of blood vessels that are closely associated with astrocytes in the SVZ and serve as a scaffold for migrating neuroblast chains (Shen et al., 2008; Snappy et al., 2009; Tavazoie et al., 2008).

Migrating neuroblasts in adults reach the OB by traversing the RMS, which is a rostral extension of the SVZ formed by closing of the olfactory ventricle

that extends from main lateral ventricle during embryonic development. The RMS in adult rodents contains a network of interconnected glial tubes through which neuroblasts migrate and blood vessels serve as important scaffolds for these glial tubes (Whitman et al., 2009). This cytoarchitecture of the adult RMS, however, does not develop until about the third postnatal week of life (Alves et al., 2002; Pencea and Luskin, 2003; Peretto et al., 2005). At birth, astrocytes in the SVZ and RMS still have radial glial-like fibers and neuroblasts migrate as a mass with little organization. During the first several weeks of postnatal development, the astrocytic processes

start to form a mesh that becomes glial tubes and the migrating neuroblasts organize into chains ensheathed by this meshing. The organization of the astrocytic processes in the glial tubes is actively modulated by neuroblasts in order to form and maintain their migration routes (Kaneko et al., 2010).

Astrocytes have a prominent role in RMS and SVZ cytoarchitecture, but they are not required for migrating neuroblasts to form chains (Peretto et al., 2005; Wichterle et al., 1997). Rather, glia may have other critical organizational functions. Since astrocytes express several molecules that regulate both neural precursor proliferation and neuroblast migration (discussed further in Section 9.2.3), the mature glial cytoarchitecture of the SVZ and RMS may be necessary to effectively regulate neurogenesis in adults. Alternatively or in addition, the mature glial cytoarchitecture may ensure that neuroblasts are shunted towards the OB. In early postnatal rodent brains, SVZ-derived progenitors also migrate to cortical and sub-cortical regions in addition to the OB (De Marchis et al., 2004a; Inta et al., 2008). In human infants, SVZ-derived progenitors migrate along a medial migratory stream to the ventromedial pre-frontal cortex in addition to the OB via the RMS (Sanai et al., 2011). In both adult rodents and humans, however, these alternative post-natal migratory pathways are absent.

Neuroblasts migrate through the SVZ and RMS in a saltatory manner with rapid changes in their morphology (Kakita and Goldman, 1999). Although neuroblasts appear organized in chains, their individual movements are complex and include turning motions between 30 to 90 degrees as well as direction reversals (Martinez-Molina et al., 2011; Nam et al., 2007; Suzuki and Goldman, 2003). This non-linear migration makes it difficult to estimate the speed at which individual progenitors migrate, but studies using confocal microscopy of slice cultures have estimated average migration speeds between 50–105  $\mu\text{m}/\text{hr}$  (De Marchis et al., 2001; Nam et al., 2007; Plate et al., 2008b). Neuroblast migration rates are inherently variable, however, and they are regulated by several mechanisms (discussed further in Section 9.2.3).

Once neuroblasts reach the OB, they switch from tangential to radial migration. The cellular motion remains saltatory, but radial migration rates tend to be slower than chain migration and range between 5 to 65  $\mu\text{m}/\text{hr}$  (Bovetti et al., 2007b; De Marchis et al., 2001). Similar to the SVZ and RMS, blood vessel networks guide radially migrating neuroblasts towards their final positions in the OB (Bovetti et al., 2007b). Adult olfactory radial glia also assist in this migration (Emsley et al., 2012). These glia are distinct from those in either the SVZ or RMS and have cell bodies in the OB granule cell layer that send non-arborized radial

processes into the mitral cell layer. Olfactory radial glia are born in either the RMS or OB of both embryos and adults, but how these cells direct radial migrating neuroblasts remains to be established.

The nature of the RMS in adult humans has been a source of controversy. The human RMS descends ventrally and caudally from the ventral surface of the anterior horn in the lateral ventricle before turning in a rostral direction through the olfactory tract towards the OB (Curtis et al., 2007; Sanai et al., 2011; Wang et al., 2011a). A similar laminar organization and shared expression of Neogenin (Netrin and RGMa receptor) indicates that the human RMS is a rostral extension of SVZ as it is in rodents (Bradford et al., 2010; Kam et al., 2009). Some studies have reported that the adult human RMS contains either an open or partially closed ventricle that extends the length of RMS (Curtis et al., 2007; Kam et al., 2009), but others have failed to observe this ventricular space (Sanai et al., 2011; Wang et al., 2011a). The human SVZ and RMS have been consistently reported to lack an intricate network of glial tubes containing migrating chains of neuroblasts found in rodents, but the number of progenitors present in the SVZ and RMS has been debated. Some investigators have suggested that both the SVZ in the ventral surface of anterior horn and descending limb of the RMS contain many proliferating cells and neuroblasts expressing PSA-NCAM (Curtis et al., 2007; Kam et al., 2009). By contrast, others have reported that the entire SVZ/RMS axis is only sparsely populated with proliferating cells and PSA-NCAM expressing neuroblasts (Sanai et al., 2011; Sanai et al., 2004; Wang et al., 2011a). Differences in both the experimental methodology and patient populations used for the human studies may account for some discrepancies between these two sets of studies, but further investigation is necessary to resolve these fundamental issues regarding the cytoarchitecture of the adult human SVZ and RMS.

### 9.2.3 Factors that Control Proliferation and Migration

The cytoarchitecture of the SVZ and RMS places neural stem cells, transit amplifying cells and neuroblasts in close proximity to blood vessels, CSF and axon terminals originating from other brain regions. The micro-environmental niche of the SVZ and RMS integrates many different developmental and physiological signals to control neurogenesis (Ihrie and Alvarez-Buylla, 2011; Riquelme et al., 2008). Some of the factors that modulate proliferation and migration in the adult SVZ and RMS are listed in Table 9.1. The list is extensive, but not exhaustive, and is intended to

**Table 9.1** Factors that regulate neural progenitor proliferation and migration in the adult SVZ and RMS

Factor	Reported Function in either Proliferation or Migration	Reference
<b>Cell Cycle</b>		
Cyclin dependent kinase 2 (Cdk2)	Promotes proliferation of transit amplifying cells	Jablonska et al., 2007

Factor	Reported Function in either Proliferation or Migration	Reference
Neogenin/ Deleted in Colorectal Cancer (DCC)/Netrin	Chemoattractant that guides migrating neuroblasts towards OB	Hakanen et al., 2011; Murase and Horwitz, 2002
Neural cell adhesion molecule (NCAM)	Facilitates chain formation of migrating neuroblasts	Battista and Rutishauser, 2010; Chazal et al., 2000; Cremer et al., 1994; Hu, 2000; Hu et al., 1996; Ono et al., 1994
Prokinectin 2 (PK2)	Chemoattractant for migrating neuroblasts and facilitates switch from tangential to radial migration in OB	Ng et al., 2005; Prosser et al., 2007; Puverel et al., 2009
Reelin	Facilitates switch from tangential to radial migration in OB	Courtes et al., 2011; Hack et al., 2002; Simo et al., 2007
Robo/Slit	Chemorepellant guiding neuroblasts towards OB and maintain organization of glial surrounding migrating neuroblasts	Chen et al., 2001; Hu, 1999; Kaneko et al., 2010; Nguyen-Ba-Charvet et al., 2004; Wu et al., 1999
Stromal derived factor 1 (SDF1/CXCL12)/ Chemokine receptor 4(CXCR4)	Maintains progenitor cells in quiescent state in absence of activated EGFR; stimulates migration to blood vessels with EGFR is activated	Kokovay et al., 2010
Tenascin-R	Facilitates switch from tangential to radial migration in OB	Saghatelyan et al., 2004
Vascular Cell Adhesion Molecule 1(VCAM1)	Maintains neural stem cell and ependymal cell pinwheel structure in SVZ	Kokovay et al., 2012
<b>Transcription Factors and miRNA</b>		
Aristaless related homeobox (Arx)	Promotes proliferation and migration of progenitors	Yoshihara et al., 2005
Arsenate-resistance protein 2 (Ars2)	Promotes neural stem cell self-renewal	Andreu-Agullo et al., 2012
Bmi1	Promotes neural stem cell self-renewal	Fasano et al., 2009; Molofsky et al., 2003; Zencak et al., 2005
Cyclic AMP response element binding protein (CREB)	Promotes proliferation of neural precursor cells	Iguchi et al., 2011
Distal-less related homeobox (Dlx) family	Promotes proliferation of transit amplifying cells as well as their transition from neural stem cells	Suh et al., 2009
Empty spiracles homeobox 2 (Emx2)	Negative regulator of neural precursor proliferation	Galli et al., 2002
Forkhead box protein O3 (FoxO3)	Promotes maintenance of precursor cells in a mitotically quiescence and undifferentiated state	Renault et al., 2009
Genome screened homodomain 2 (Gsx2)	Promotes maintenance of precursor cells in a mitotically quiescence and undifferentiated state	Mendez-Gomez and Vicario-Abejon, 2012
High mobility group A protein 2 (Hmg2a)	Promotes neural stem cell self-renewal	Nishino et al., 2008
Let-7b	Promotes neural stem cell proliferation and self-renewal	Nishino et al., 2008; Zhao et al., 2010

**Table 9.1 (Continued)**

Factor	Reported Function in either Proliferation or Migration	Reference
miR-124	Promotes differentiation of progenitors	Akerblom et al., 2012; Cheng et al., 2009
miR-9	Promotes neural stem cell proliferation and self-renewal	Zhao et al., 2009
Querkopf (Qkf/Myst4)	Promotes neural stem cell self-renewal	Merson et al., 2006; Sheikh et al., 2012
SRY related HMG box 2 (Sox2)	Promotes proliferation of neural precursor cells	Ferri et al., 2004
SRY related HMG box 9 (Sox9)	Inhibits transition of transit amplifying cells to neuroblasts	Cheng et al., 2009
Serum Response Factor (SRF)	Promotes neuroblasts migration by modulating regulating structure and dynamics of actin microfilaments	Alberti et al., 2005
Smad interacting protein 1 (Sip1)	Regulates production of astrocytes associated with glial tubes	Nityanandam et al., 2012
Specificity protein (Sp8)	Promotes survival in a subset of neuroblasts	Waclaw et al., 2006
Tailless (Tlx)	Promotes proliferation and self-renewal of neural stem cells	Liu et al., 2010; Qu et al., 2010
Ventral anterior homeobox 1 (Vax1)	Negative regulator of neural precursor proliferation	Soria et al., 2004
<b>Growth Factors</b>		
Brain derived neurotrophic factor (BDNF)	Increases neuroblast migration rate; its role in regulating proliferation of either neural stem cell or transit amplifying cell is controversial	Bath et al., 2012
Ciliary neurotrophic factor (CNTF)	Increases proliferation of neural stem cells and transit amplifying cells	Emsley and Hagg, 2003b; Shimazaki et al., 2001
Epidermal growth factor (EGF)	Increases proliferation in a subpopulation of neural stem cells and transit amplifying cells	Doetsch et al., 2002a; Gonzalez-Perez and Alvarez-Buylla, 2011
Fibroblast growth factor (FGF)	Increases proliferation of neural stem cells and transit amplifying cells	Mudo et al., 2009
Glial derived neurotrophic factor (GDNF)	Chemoattractant for RMS-derived neuroblasts	Paratcha et al., 2006
Hepatocyte growth factor (HGF)	Increases transit amplifying cell proliferation and acts as a chemoattractant for neuroblast migration to OB	Garzotto et al., 2008; Nicoleau et al., 2009; Wang et al., 2011b
Insulin growth factor (IGF)	Promotes neuroblast migration transition from SVZ to RMS	Hurtado-Chong et al., 2009
Leukemia inducible factor (LIF)	Promotes self-renewal of neural stem cells	Shimazaki et al., 2001
Oncostatin M	Decreases proliferation of neural stem cells and transit amplifying cells	Beatus et al., 2011
Platelet-derived growth factor (PDGF)	Promotes proliferation of a subset of neural stem cells	Jackson et al., 2006
Transforming growth factor-alpha (TGF- $\alpha$ )	Promotes proliferation of transit amplifying cells	Tropepe et al., 1997

(continued)

**Table 9.1 (Continued)**

Factor	Reported Function in either Proliferation or Migration	Reference
Vascular endothelial growth factor (VEGF)	Increases production of migrating neuroblasts and facilitates development of vascular scaffold surrounding RMS; its role as a chemoattractant for migrating neuroblasts is controversial	Bozoyan et al., 2012; Jin et al., 2002; Licht et al., 2010; Wittko et al., 2009; Zhang et al., 2003
<b>Signaling Pathways</b>		
Eph tyrosine kinase receptor family /Ephrin ligands	Reduce proliferation of neural stem cells and, in some cases, facilitates migration of neuroblasts	Conover et al., 2000; Holmberg et al., 2005; Katakowski et al., 2005; Ricard et al., 2006
Hedgehog pathways	Promote proliferation of neural stem and transit amplifying cells and promotes migration of neuroblasts; Sonic hedgehog (Shh) ligand is also a chemoattractant for migrating neuroblasts	Ahn and Joyner, 2005; Angot et al., 2008; Balordi and Fishell, 2007a; Machold et al., 2003; Palma et al., 2005
Notch pathway	Maintains pool size of proliferating neural stem and transit amplifying cells by promoting self-renewal	Ables et al., 2011; Alexson et al., 2006; Basak et al., 2012; Hitoshi et al., 2002
Nucleotide	Increases proliferation of transit amplifying cells	Mishra et al., 2006; Suyama et al., 2012
Wingless/Integration 1 (Wnt) pathway	Promotes proliferation of neural stem and transit amplifying cells, but co-expression of homeodomain interacting protein kinase (Hipk1) in some neural stem cells may induce Wnt signaling to promote cell cycle arrest	Adachi et al., 2007; Marinaro et al., 2012
<b>Neurotransmitters</b>		
Dopamine	Promotes proliferation of transit amplifying cells	Borta and Hoglinger, 2007; O'Keeffe et al., 2009a
GABA	Decreases proliferation of both neural stem cells and neuroblasts, also reduces neuroblast migration rates	Bolteus and Bordey, 2004; Gascon et al., 2006; Liu et al., 2005; Nguyen et al., 2003
Glutamate	Promotes neuroblast proliferation and survival, but decreases migration rates	Brazel et al., 2005; Di Giorgi Gerevini et al., 2004; Platel et al., 2008b
Serotonin	Increases markers of proliferation	Banasr et al., 2004; Hitoshi et al., 2007; Soumier et al., 2010

provide a sense for the wide range of mechanisms that regulate neurogenesis and migration in the adult SVZ and RMS.

**9.2.3.1 Cell Cycle Regulators.** The finding that cell cycle gene disruption affects neural precursor proliferation is not surprising, but the cell type specificity for some of these genes during adult neurogenesis is unexpected

(Beukelaers et al., 2012). For example, loss of p21<sup>Cip1</sup> preferentially increases proliferation in neural stem cells in the SVZ (Kippin et al., 2005). When compared to wild-type controls, loss of p21<sup>Cip1</sup> increases the number of mitotically active neural stem cells in adult mice. This increase is not sustained throughout adult life, however, since the number of mitotically active neural stem cells

in aged adults is significantly reduced. These findings suggest that SVZ neural stem cells have a limited capacity for self-renewal and p21<sup>Cip1</sup> is required to maintain these stem cells in a quiescent state so that only a limited number of neural stem cells are mitotically active at any one time.

In contrast to p21<sup>Cip1</sup>, loss of p27<sup>Kip1</sup> selectively increases proliferation of transit amplifying cells in the SVZ without noticeably affecting either the stem cells or neuroblasts (Doetsch et al., 2002b). Although the proliferation rate of mitotically active neuroblasts is not disturbed, there is a significant reduction in the number of neuroblasts present in the SVZ and RMS that is likely due to transit amplifying cells undergoing rounds of self-renewal instead of generating neuroblasts.

**9.2.3.2 Cytoskeletal Proteins.** Neuroblast migration through the SVZ and RMS is initiated by the extension of a leading process that is followed by movement of the centrosomes and translocation of the nucleus in the same direction (Kakita and Goldman, 1999). The cell soma moves forward when the trailing process detaches and repositions itself. Thus, migration requires the movement of centrosomes coordinated with the rearrangement of cytoskeletal structures necessary for the extension and repositioning of processes. Consistent with a pivotal role for this coordination, neuroblast migration is impaired by disruptions in either microtubule-associated proteins, like Dcx and Microtubule affinity-regulating kinase 2 (Mark2), or centrosome-interacting proteins, like Pericentrin (Pent) (Endoh-Yamagami et al., 2010; Koizumi et al., 2006; Mejia-Gervacio et al., 2012). The human-specific GFAP- $\delta$  splice variant promotes collapse of cytoskeletal intermediate filaments near the nucleus and its expression in the SVZ astrocytic ribbon suggests that these astrocytes have motility requirements distinct from other regions (Roelofs et al., 2005).

**9.2.3.3 Extra-Cellular Matrix and Guidance Molecules.** The extra-cellular matrix environment in the SVZ and RMS contains chondroitin sulfate, heparin sulfate, proteoglycans, Tenascin-C, and laminin (Cayre et al., 2009; Leong and Turnley, 2011; Sun et al., 2010b). These extra-cellular matrix molecules regulate neuroblast migration by serving as ligands for integrin receptors, which are heterodimeric cell surface receptors composed of one  $\alpha$  and  $\beta$  subunit. Inhibition of  $\alpha 6 \beta 1$  integrin disrupts both the association of neuroblasts with blood vessels and tangential chain migration of neuroblasts (Belvindrah et al., 2007; Emsley and Hagg, 2003a; Kokovay et al., 2010; Shen et al., 2008). Similar disruptions are also observed with inhibition of the  $\beta 8$  subunit (Mobley and McCarty, 2011;

Mobley et al., 2009). Interactions between  $\alpha 6 \beta 1$  integrin and laminin are also critical for guiding the neuroblasts towards the OB and infusion of exogenous laminin can misroute progenitor towards sites of infusion (Emsley and Hagg, 2003a).

Before chain migration and glial tubes are established in the postnatal SVZ and RMS, neuroblast migration is dependent on matrix metalloproteases (Bovetti et al., 2007a). Once the mature glial cytoarchitecture is established, however, metalloprotease enzymes are not required for tangential chain migration. Rather, both integrin and ErbB4 receptors as well as PSA-NCAM are necessary for neuroblast chain organization (Anton et al., 2004; Belvindrah et al., 2007; Hu et al., 1996; Mobley and McCarty, 2011; Ono et al., 1994). In the case of PSA-NCAM, genetic deletion of NCAM disrupts chain migration, in part, by disrupting glial tube formation (Chazal et al., 2000). Since NCAM is only expressed by neuroblasts, this perturbation of glial tube formation indicates that interactions between neuroblasts and the surrounding astrocytes are critical for maintenance of the glial cytoarchitecture.

Further evidence that neuroblasts are necessary for the maintenance of the adult glial cytoarchitecture in the SVZ and RMS comes from studies with Slit ligands and their cognate Robo receptors. The canonical roles for Slit 1/2 ligands are as chemorepellants secreted by the choroid plexus and septum that guide migrating neuroblasts towards the OB (Hu, 1999; Nguyen-Ba-Charvet et al., 2004; Wu et al., 1999). Recent studies, however, show that migrating neuroblasts also secrete Slit1 and activate Robo receptors on astrocytic processes (Kaneko et al., 2010). This signaling alters the distribution and extension of astrocytic processes forming the glial tube. The expression of Slit1 in the RMS and SVZ may be regulated by Sonic hedgehog (Shh), which can partially account for neuroblast migration defects observed when Hedgehog signaling is disrupted (Balordi and Fishell, 2007a).

Some of the factors required for tangential migration, such as ErbB4 receptors and Dcx, are also necessary for radial migration (Anton et al., 2004; Koizumi et al., 2006), whereas others, like PSA-NCAM, are dispensable (Hu et al., 1996; Ono et al., 1994). The transition to radial migration also requires Reelin (Courtes et al., 2011; Hack et al., 2002; Simo et al., 2007), Tenascin-R (Saghatelyan et al., 2004) and Prokinectin 2 (Ng et al., 2005; Prosser et al., 2007; Puverel et al., 2009).

The extra-cellular signals and guidance cues that determine the final location of radially migrating neuroblasts are not established. Since OB interneurons in different OB lamina have distinct sets of characteristic synaptic connectivities (Shepherd, 1972), elucidating the cues that terminate radial migration is critical for understanding how OB circuits are established during development and maintained by adult neurogenesis.

#### **9.2.3.4 Transcription Factors and miRNA.**

Each successive stage of neurogenesis requires a specific set of transcription factors to establish the proper gene expression profile of the cell. MicroRNAs (miRNA) are important modifiers of transcription factor gene expression during both embryonic and adult neurogenesis. These non-coding RNAs target complementary regions in transcription factor mRNA transcripts, which promotes transcript degradation and suppresses protein production. Thus, regulation of both transcription factor and miRNA expression is critical for controlling both the timing and progression of neurogenesis.

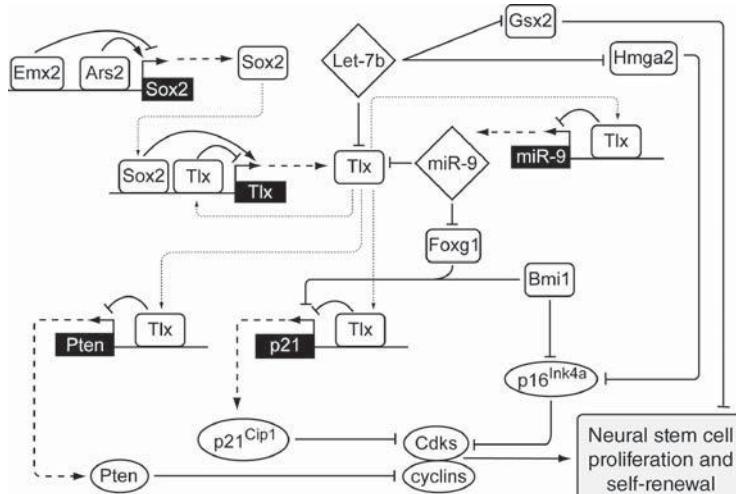

Proliferation and self-renewal of neural stem cells in the adult SVZ is tightly controlled by several of transcription factors and miRNA. Several of these factors, including a pivotal role by the transcription factor Tail-less homeobox (Tlx), are shown in Figure 9.2. Tlx is a transcription repressor protein and its expression is directly activated by Sox2 (Shimozaki et al., 2012), a common marker of proliferation in the SVZ. Tlx expression is antagonized by negative auto-feedback and both miR-9 and Let-7b miRNAs, which also target other transcription factors that regulate neural stem cell proliferation and self-renewal (Nishino et al., 2008; Shibata et al., 2011; Zhao et al., 2010; Zhao et al., 2009). Expression of miR-9, however, is directly repressed by Tlx (Zhao et al., 2009). Thus, Tlx participates in multiple feedback loops to regulate its own expression levels. Tlx promotes neural stem cell proliferation and self-renewal by directly repressing the transcription of cell cycle inhibitors, such as Pten and p21<sup>Cip1</sup> (Sun et al., 2007).

The differentiation of transit amplifying cells into neuroblasts is controlled, in part, by Dlx2 and Sox9 transcription factors and miR-124. Dlx2 cooperates with EGFR signaling to promote self-renewal of cells at the

transition between transit amplifying cells and migrating neuroblasts (Suh et al., 2009). This function of Dlx2 may be mediated by its activation of Arista-less homeobox (Arx) expression (Cobos et al., 2005; Colasante et al., 2008), which is critical for the proliferation and migration of progenitors (Yoshihara et al., 2005). Sox9 impedes the transition from transit amplifying cells to neuroblasts, but its target genes are not identified (Cheng et al., 2009). In contrast to both Dlx2 and Sox9, miR-124 promotes the differentiation of neuronal progenitors. This miRNA is expressed at low levels in neuroblasts, but progressively increases as they differentiate into mature neurons (Akerblom et al., 2012; Cheng et al., 2009). miR-124 advances differentiation of transit amplifying cells to mitotically quiescent neuroblasts by down regulating both Dlx2 and Sox9. Since miR-124 expression is maintained in post-mitotic mature OB interneurons, it likely has many additional and stage-specific targets that are essential for promoting neuronal differentiation.

**9.2.3.5 Growth Factors.** Most growth factors stimulate proliferation and/or facilitate migration, but their actions are not always uniform throughout the SVZ. Transforming growth factor- $\alpha$  (TGF- $\alpha$ ), for example, is required for the proliferation of transit amplifying cells in a specific region of SVZ (Tropepe et al., 1997). Genetic loss of TGF- $\alpha$  diminishes neural precursor proliferation in only the dorsolateral corner, but intraventricular infusion of TGF- $\alpha$  can stimulate proliferation throughout the entire SVZ, suggesting that other growth factors are functionally redundant to TGF- $\alpha$  outside of the dorsolateral corner.

This partial functional redundancy within the SVZ indicates that there is heterogeneity in the expression of different growth factor receptors. Such heterogeneity in

**Figure 9.2** A network of select transcription factors and miRNAs that regulate neural stem cell proliferation and self-renewal. The Tlx transcription factor has a pivotal role in maintaining the neural stem cell pool size. Tlx promotes proliferation and self-renewal by directly repressing transcription of cyclin and cyclin dependent kinase (Cdk) inhibitor genes, such as Pten and p21<sup>Cip1</sup>. The expression of Tlx itself in neural stem cells is tightly controlled by several transcription factors and miRNA, including feedback loops that are either positive (repressing miR-9 expression) or negative (binding its own promoter).

growth factor sensitivity suggests that different factors can target specific subsets of neural stem cells, transit amplifying cells and neuroblasts. As discussed further in Section 9.4, the SVZ is organized in spatially distinct regions that preferentially generate specific OB interneuron phenotypes. Heterogeneity of growth factor receptors in neural stem cells and transit amplifying cells may be integral for regulating the production of specific interneurons phenotypes. This heterogeneity may also be an important determinant of neuronal vs. glial cell-fate production in the SVZ. For example, EGF and Platelet-derived growth factor (PDGF) promote proliferation of specific subsets of neural stem cells and transit amplifying cells that preferentially generate oligodendrocytes (Doetsch et al., 2002a; Gonzalez-Perez and Alvarez-Buylla, 2011; Jackson et al., 2006; Menn et al., 2006).

Although many growth factors promote proliferation and migration in the SVZ, Oncostatin M is an exception. The receptor protein for this member of the gp130-dependent family of cytokines is expressed in a subset of neural stem cells and transit amplifying cells (Beatus et al., 2011). Both *in vitro* studies with neurospheres and intraventricular infusion with Oncostatin M *in vivo* demonstrate that it is a potent inhibitor of neural precursor proliferation. This inhibitory role contrasts with other members of the gp130-dependent family of cytokines, including ciliary neurotrophic factor (CNTF) and leukemia inducible factor (LIF), which promote progenitor proliferation and contribute to the long-term maintenance of proliferating neural precursors pools (Emsley and Hagg, 2003b; Shimazaki et al., 2001). The differential mitogenic responses to these factors may be mediated by the precise subunit composition of the receptor complexes receiving either the Oncostatin M, CNTF, or LIF signals (Beatus et al., 2011).

### **9.2.3.6 Intercellular Signaling Pathways.**

Several inter-cellular signaling pathways are necessary for maintaining the pool size of proliferating neural precursor cells. As discussed with the role of cell cycle components (Section 9.2.3.1), the transition from mitotic quiescence to active proliferation in neural stem cells as well as self-renewal rate of both neural stem cells and transit amplifying cells needs to be tightly controlled so that a reservoir of proliferating precursor cells can be maintained through life. Disruption of either Notch or Hedgehog signaling pathways, results in the precocious differentiation of precursors cells and readily depletes the number of neural stem cells and transit amplifying cells in the SVZ (Alexson et al., 2006; Balordi and Fishell, 2007b; Basak et al., 2012; Hitoshi et al., 2002). Consistent with these roles in regulating proliferation, both Notch and Hedgehog pathways have been shown in other cellular systems to

directly target genes encoding cell cycle regulatory proteins. The Notch pathway regulates the transcription of Cyclin D1, Cyclin dependent kinase 2 (Cdk2) and p21<sup>Cip1</sup> (Castella et al., 2000; Ronchini and Capobianco, 2001), whereas the Hedgehog pathway directly targets Cdk6 and p16Ink4a (Bishop et al., 2010; Lopez-Rios et al., 2012).

Also consistent with the role that growth factors have in stimulating proliferation in the SVZ, there are extensive interactive networks between growth factors and intercellular signaling pathways. Activated EGFR signaling in neural stem cells, for example, promotes Numb-mediated ubiquitination of the Notch-1 receptor (Aguirre et al., 2010). This degradation of Notch-1 suppresses Notch pathway activity and reduces the number, proliferation, and self-renewal of neural stem cells. Several other interactions between growth factor and intercellular signaling pathways are reported in the adult SVZ, including: Notch and CNTF (Chojnacki et al., 2003), Notch and pigment epithelium-derived factor (PEDF) (Andreu-Agullo et al., 2009), Notch and soluble factors, including VEGF, released by endothelial cells (Shen et al., 2004; Sun et al., 2010a), Hedgehog and FGF (Goncalves et al., 2009), as well as purinergic signaling pathways and EGF (Grimm et al., 2009).

### **9.2.3.7 Neurotransmitters.**

Neurotransmitters are essential regulators of cell proliferation and migration during adult neurogenesis. The role of GABA is the most extensively studied. In the SVZ, GABA is synthesized and released by neuroblasts (De Marchis et al., 2004b; Plachez and Puche, 2012; Wang et al., 2003). Functional GABA<sub>A</sub> receptors are on both neuroblasts and neural stem cells, but not transit amplifying cells (Gascon et al., 2006; Nguyen et al., 2003; Stewart et al., 2002; Wang et al., 2003). For neuroblasts, GABA functions as an autocrine signal that reduces both their migration speed and proliferation rate (Bolteus and Bordey, 2004; Gascon et al., 2006; Nguyen et al., 2003). GABA depolarizes neuroblasts and increases intracellular Ca<sup>2+</sup> concentrations, in part, by activating L-type calcium channels (Darcy and Isaacson, 2009; Nguyen et al., 2003; Wang et al., 2003). GABA depolarizes neuroblasts because of their high intracellular chloride concentrations generated by the expression of sodium-potassium-chloride co-transporter 1 (NKCC1), and pharmacological disruption of NKCC1 reverses the effect of GABA on neuroblasts (Gascon et al., 2006; Mejia-Gervacio et al., 2011; Sun et al., 2012). In neural stem cells, GABA is a paracrine signal that reduces proliferation (Liu et al., 2005). GABA stimulates opening of L- and T-type calcium channels in neural stem cells (Young et al., 2010) and this calcium influx may be communicated throughout the SVZ by an extensive network

of connexin-43 gap junctions between astrocytes (Lacar et al., 2011).

Glutamate synthesized and released by astrocytes can also regulate proliferation and migration in the SVZ (Platel et al., 2010; Platel et al., 2007). Functional glutamate receptors have not been identified on either neural stem cells or transit amplifying cells in the SVZ, but neuroblasts express metabotropic mGluR5 (GRM5) and kainate GluK5-7 (GRIK 1-3) receptors (Platel et al., 2008b). Stimulation of mGluR5 increases neuroblast proliferation, but activation of the GluK5 receptors reduces neuroblast migration rates (Di Giorgi Gerevini et al., 2004; Platel et al., 2008b). As neuroblasts migrate towards the OB, they also progressively increase in their responsiveness to NMDA (Platel et al., 2010). The specific sub-unit composition of the NMDA receptors is not established, but stimulation of these receptors blocks apoptosis and promotes survival of neuroblasts. Studies with SVZ-derived neurospheres indicate that metabotropic receptors can also block apoptosis as well as increase proliferation (Brazel et al., 2005; Castiglione et al., 2008), but whether these receptors serve this function *in vivo* remains to be established.

In addition to locally generated GABA and glutamate, the SVZ receives serotonergic input from axon terminals originating in the raphe nuclei (Azmitia and Segal, 1978). Studies using either lesions to the raphe nuclei or treatment with serotonin receptor agonists indicate the activation of serotonin receptors in the SVZ stimulates proliferation (Banasr et al., 2004; Brezun and Daszuta, 1999; Soumier et al., 2010). The precise cell-types that express these receptors, however, are not established. Analysis of transgenic mice show that neuroblasts express the 5-HT3 receptors (Inta et al., 2008), and both pharmacological studies and reverse-transcription/polymerase chain reaction analyses indicate that 5-HT1 and 5-HT2 classes of serotonin receptors are also expressed (Banasr et al., 2004; Councill et al., 2006; Hitoshi et al., 2007; Soumier et al., 2010). Some 5-HT1 receptors, however, may have species-specific functions (Arnold and Hagg, 2012).

Dopaminergic terminals originating in the substantia nigra also modulate neurogenesis in the SVZ (Freundlieb et al., 2006). D2-like dopamine receptors are expressed by transit amplifying cells and both D2-like and D1-like receptors are expressed by neuroblasts (Hoglinger et al., 2004). Loss of midbrain dopaminergic input either by deafferentation or chemical lesions indicate that dopamine stimulates proliferation in the SVZ (Borta and Hoglinger, 2007). The mechanism of action for dopamine may be integrated with the role of growth factors, such as CNTF and EGF (O'Keeffe et al., 2009b; Yang et al., 2008). *In vitro* studies, however, have produced some conflicting results regarding the action of dopamine on SVZ neurogenesis, but technical experimental differences, such as the specific

antagonists or agonists used, may underlie some of these discrepancies (O'Keeffe et al., 2009a).

The regulation of neurogenesis by the locally generated GABA and glutamate make a convenient reciprocal feedback pathway between neuroblasts and neural stem cells to modulate progenitor production (Platel et al., 2008a). The input from either the raphe nuclei or substantia nigra, however, appears to be one-way since there is no evidence that the SVZ sends any direct signal back to these regions. The physiological significance of regulating adult SVZ neurogenesis by either of these distant regions is uncertain, but suggests that olfaction in adults can be modified by the control of either alertness/mood by the raphe nuclei or movement by the midbrain.

### 9.3 INTEGRATION OF ADULT-GENERATED NEURONS IN THE OB

The integration of adult-born interneurons into the pre-existing OB circuitry begins when progenitors reach their final position in either the periglomerular or granule cell layer. The temporal dynamics of morphological maturation and functional integration, however, are different for progenitors in each of these layers. Adult-generated periglomerular interneurons take up to 6 weeks from progenitor formation in the SVZ to develop mature dendritic arbors and spine densities (Whitman and Greer, 2007a). They develop voltage-dependent sodium currents and the capacity to fire action potentials before the formation of synaptic connections (Belluzzi et al., 2003). The first synapses made on maturing periglomerular interneurons are GABAergic, whereas glutamatergic synaptic input from olfactory receptor neurons and/or mitral/tufted cells requires an additional two weeks. As these interneurons mature, their glutamatergic synaptic inputs evolve as both the AMPA/NMDA ratio increases and the contribution of the NR2B (GRIN2B) subunit to the NMDA response decreases (Grubb et al., 2008). Thus, the functional character of the excitatory input received by periglomerular interneurons changes during the course of maturation.

In contrast to the periglomerular interneurons, granule cells receive synaptic input before they generate action potentials (Carleton et al., 2003; Whitman and Greer, 2007b). Almost as soon as granule cell progenitors stop radial migration and begin to extend dendritic processes, both GABAergic and glutamatergic synaptic inputs form on the basal and apical dendrites as well as the soma (Katagiri et al., 2011; Kelsch et al., 2008; Panzanelli et al., 2009; Whitman and Greer, 2007b). The glutamatergic input is from either centrifugal or mitral/tufted cell axon collaterals (Kelsch et al., 2008; Whitman and Greer, 2007b). The initial density of GABAergic and glutamatergic synapses

are about the same, but the glutamatergic synaptic density substantially increases as maturation proceeds (Kelsch et al., 2008; Panzanelli et al., 2009; Whitman and Greer, 2007b). During this maturation, there is a transient increase in both the number of functional glutamatergic input sites and the NMDA/AMPA ratio at these sites (Katagiri et al., 2011). Dendritic arbors and spine densities mature within 4 weeks of progenitor formation in the SVZ (Whitman and Greer, 2007b). Maturation of dendritic branching and spine density as well as glutamatergic synapses requires GABAergic input mediated by the GABA<sub>A</sub> receptor  $\alpha 2$  subunit (Pallotto et al., 2012). The ability to generate action potentials develops between 1–2 weeks after granule cell progenitors are generated in the SVZ, but the large majority of output synapses are not formed until a month after the cell is able to generate action potentials (Bardy et al., 2010). Thus, granule cells “silently integrate” and “listen” to the pre-existing circuitry before they “speak” (Kelsch et al., 2008).

Approximately 10,000 to 30,000 neuroblasts per day migrate into the OB from the SVZ and RMS in adult rodents (Lois and Alvarez-Buylla, 1994), but many of these new neurons do not stably integrate into the OB and are eliminated. In the murine periglomerular layer, approximately 50% of the new interneurons are gone within 1–2 months of their formation in the SVZ (Bovetti et al., 2009; Kato et al., 2000; Whitman and Greer, 2007a). The surviving neurons are stable and remain in the periglomerular layer for up to another 19 months (Winner et al., 2002). The turnover rate in this layer is estimated to be about 3% per month, which would require almost 35 months, essentially the maximum life span of mice, to completely replace all interneurons (Lagace et al., 2007; Mizrahi et al., 2006; Ninkovic et al., 2007). In the granule cell layer, approximately 50% of new interneurons are also lost within 1–2 months of their generation and the surviving neurons are stable for up to another 19 months (Lemasson et al., 2005; Petreanu and Alvarez-Buylla, 2002; Winner et al., 2002). The turnover rate for granule cells, however, is controversial. Some have suggested that adult born interneurons constitute only a minor population of the granule cell interneuron population (Ninkovic et al., 2007). Several other studies, however, have reported substantially higher turnover rates and that adult-born granule cell progenitors predominantly target the deep granule cell region (Imayoshi et al., 2008; Lagace et al., 2007; Lemasson et al., 2005; Mandairon et al., 2006). In one study, almost the entire deep granule cell layer was reported to turn over within a year, and only about 50% of the superficial granule cells were replaced during the same time (Imayoshi et al., 2008).

In both periglomerular and granule cell layers, the window between 15–45 days after progenitor formation in the SVZ is a critical period for establishing which adult-born

neurons survive (Kelsch et al., 2009; Mandairon et al., 2006; Petreanu and Alvarez-Buylla, 2002; Yamaguchi and Mori, 2005). During this critical period, odorant-induced synaptic activity is an important determinant of survival (Bovetti et al., 2009; Mandairon et al., 2006; Petreanu and Alvarez-Buylla, 2002; Rochefort and Lledo, 2005; Saghatelian et al., 2005; Yamaguchi and Mori, 2005). Modulation of odorant-induced synaptic activity before this critical period does not affect progenitor maturation, likely because effective synaptic connections on the progenitors have not developed. Sensory input is critical for modifying the distribution and density of dendritic spine densities as well as the complexity of dendritic branching (Dahlen et al., 2011; Kelsch et al., 2009; Livneh et al., 2009; Saghatelian et al., 2005). In addition to glutamatergic input from mitral/tufted cells (and olfactory receptor neurons in the glomerular layer), centrifugal input from other brain regions is suspected to be an essential component of the activity-dependent maturation and survival of adult-born OB interneurons (Katagiri et al., 2011; Whitman and Greer, 2007b). Furthermore, both feeding and sleeping behaviors strongly influence the temporal dynamics of survival (Yokoyama et al., 2011). The molecular mechanisms that integrate behavioral and sensory input to promote survival of adult-born interneurons has not been elucidated, but the transcription factor cAMP Response Element-Binding (CREB) protein has an established and pivotal role for the maturation and survival of newborn adult OB neurons (Giachino et al., 2005; Herold et al., 2011).

For interneurons that achieve long-term survival, their dendritic morphology and spine density retain some plasticity. Spine densities on mature periglomerular interneurons are dynamic in response to changes to sensory input (Livneh et al., 2009; Mizrahi, 2007). The age of the animal at which time neurons are born also affects the mature dendritic structure. Periglomerular interneurons born in older adults have a reduced total dendritic length and increased spine density relative to those generated in younger animals (Livneh and Mizrahi, 2011). By contrast, mature granule cell interneurons born in older animals have lower spine densities relative to those generated in younger adults. The spine densities in adult granule cell interneurons, however, are more stable when compared to those born during neo-natal development (Kelsch et al., 2012). The regulation of dendritic maturation and plasticity in adult OB interneurons is regulated by several molecular factors, including 5T4 (Yoshihara et al., 2012), VEGF (Licht et al., 2010), Agrin signaling (Burk et al., 2012), Wnt signaling (Pino et al., 2011) and miR-132 (Pathania et al., 2012).

## 9.4 PHENOTYPE SPECIFICATION AND MAINTENANCE

OB interneurons contain a wide range of mature interneuron phenotypes. In the periglomerular layer, there are numerous phenotypic subsets based on distinct combinatorial expression patterns of neurotransmitters, neuroactive peptides, transmembrane receptors, and calcium binding proteins (Brill et al., 2009; Panzanelli et al., 2007; Parrish-Aungst et al., 2007). Most interneurons in this layer are GABAergic, but there is also a small subset of excitatory glutamatergic cells (Brill et al., 2009). Different subsets of periglomerular layer interneurons also make distinct synaptic connections within the OB circuitry (Kosaka and Kosaka, 2005). In the granule cell layer, all interneurons are GABAergic, but the superficial and deep granule cell layers preferentially co-express 5T4 and calcium/calmodulin-dependent protein kinase type IV (CamKIV), respectively (Saino-Saito et al., 2007; Yoshihara et al., 2012). Superficial and deep granule cells also preferentially synapse with tufted and mitral cells, respectively (Mori et al., 1983; Orona et al., 1983). Although there is greater phenotypic diversity in the periglomerular layer, adult neurogenesis produces more granule cells relative to periglomerular interneurons at approximately a 3:1 ratio (Luskin, 1993; Zigova et al., 1996).

Nearly all OB interneuron phenotypes in both periglomerular and granule cell layers are regenerated by adult neurogenesis, but they turn over at different rates. Deep granule cells turn over and are regenerated at a faster rate than the superficial granule cells (Imayoshi et al., 2008; Lagace et al., 2007; Lemasson et al., 2005; Mandairon et al., 2006). In the periglomerular layer, interneurons co-expressing both GABA and dopamine turn over faster than those that co-express GABA with either Calbindin or Calretinin (Kohwi et al., 2007; Whitman and Greer, 2007a). The turnover rate for mature OB dopaminergic neurons is not constant, however, and is inversely proportional to the levels of odorant-induced synaptic activity (Bastien-Dionne et al., 2010; Bovetti et al., 2009; Sawada et al., 2011).

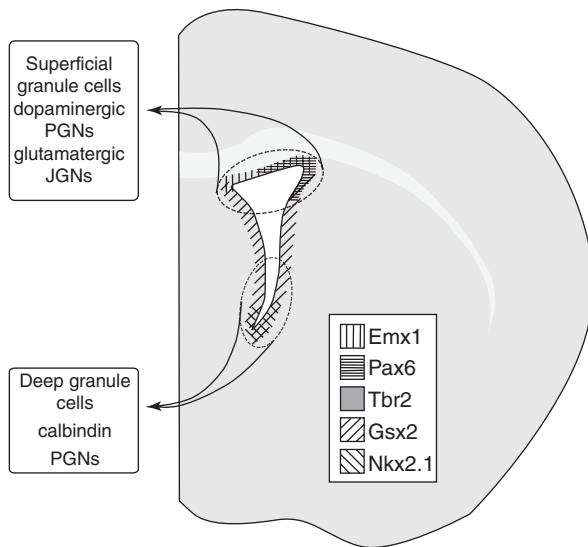

In addition to differential turnover rates, production rates for specific phenotypes are age-dependent. For example, the production of superficial granule cells peaks during the first postnatal week of development (Lemasson et al., 2005), but the 5T4-expressing subset of superficial granule cells are generated at a constant rate through postnatal and adult life (Batista-Brito et al., 2008). By contrast, production of Calbindin-expressing periglomerular interneurons peak during a late embryonic and neo-natal time window before dropping to a lower rate in adults (Batista-Brito et al., 2008; De Marchis et al.,

2007). Periglomerular layer calretinin-expressing interneurons display the opposite temporal relationship, where their production is lowest during embryonic and neo-natal development and greatest in adults (Batista-Brito et al., 2008; De Marchis et al., 2007).

The molecular mechanisms that regulate which phenotype is adopted by SVZ-derived progenitors is not well understood, but combinatorial transcription factor codes are proposed to direct progenitors towards distinct differentiation pathways (Allen et al., 2007; Brill et al., 2008). For example, the co-expression of Dlx2, Pax6, Er81, and Meis2 direct OB neuronal progenitors towards the combined GABAergic and dopaminergic neurotransmitter phenotype. By contrast, co-expression of Sp8 with either Er81 or Meis2 is associated with periglomerular neurons expressing Calretinin.

The diversity of transcription factor codes specifying OB interneuron phenotypes reflects the intrinsic heterogeneity of neural stem cells in the SVZ. As noted in Section 9.2.1, the SVZ in the adult lateral ventricles is derived from several regions of the embryonic neuroepithelium, including the lateral and medial ganglionic eminences as well as cortex (Merkle et al., 2007; Stenman et al., 2003; Willaime-Morawek et al., 2006; Young et al., 2007). During embryonic development, each of these regions express distinct sets of transcription factors that specify different neuronal phenotypes (Wonders and Anderson, 2006). In the adult SVZ, these regions generate distinct domains that can be visualized by lineage-tracing studies (Allen et al., 2007; Kohwi et al., 2007; Young et al., 2007). Coupled with spatially restricted expression patterns of signaling molecules, such as Shh (Ihrie et al., 2011), these distinct lineage domains establish unique dorso-ventral and rostro-caudal origins within the adult SVZ for different interneuron phenotypes (Figure 9.3) (Brill et al., 2009; Kelsch et al., 2007; Merkle et al., 2007; Young et al., 2007). For example, cells derived from Emx1 and Pax6 lineages are limited to dorso-lateral edges of the SVZ and preferentially generate dopaminergic periglomerular layer interneurons and superficial granule cells (Merkle et al., 2007; Young et al., 2007). Within this region, a subdomain Tbr2-expressing cells produce glutamatergic juxtaglomerular neurons (Brill et al., 2009). By contrast, Gsx2 and Nkx2.1 lineages populate the lateral and ventral portions of the SVZ, respectively. Both Calbindin-expressing periglomerular layer interneurons and deep granule cells are preferentially generated in the ventral region of the adult SVZ (Merkle et al., 2007; Young et al., 2007). Thus, neural stem cells are temporally and spatially heterogeneous in their potential to produce progenitors of specific OB interneuron phenotypes (Bovetti et al., 2007c; Lledo et al., 2008; Weinandy et al., 2011).

Adult neural stem cells in the SVZ also produce glial progenitors that migrate separately from neuroblasts and

**Figure 9.3** Heterogeneity in the origin of specific OB interneuron phenotypes derived from the adult SVZ. A cartoon of a coronal section through an adult mouse brain showing the partial overlap in the lineage of regions comprising the SVZ. During embryonic development, transcription factors (such as Emx1, Pax6, Tbr2, Gsx2 and Nkx2.1) are expressed in distinct regions of the neuroepithelium. These regions eventually fuse and form the adult SVZ. The neural stem cells derived from these different lineages generate specific OB interneuron phenotypes in the adult SVZ. Superficial granule cells, dopaminergic periglomerular layer neurons (PGNs) and glutamatergic juxtaglomerular neurons (JGNs) are preferentially generated in the dorsal SVZ regions. By contrast, deep granule cells and Calbindin-expressing PGNs are produced in the ventral regions of the SVZ.

populate several regions, including the corpus callosum and striatum (Menn et al., 2006; Suzuki and Goldman, 2003). Peak production of glial progenitors occurs in early post-natal development before tapering off to low levels in adults, but either demyelination in the corpus callosum or seizures increases production of adult-generated glia (Marshall et al., 2003; Menn et al., 2006; Nait-Oumesmar et al., 1999; Parent et al., 2006). Oligodendrocyte lineage transcription factor 2 (Olig2) is a key regulator of the neuronal vs. glial cell fate decision. The Olig2 transcription factor is an early marker of the glial fate that is expressed in a subset of neural stem cells and transit-amplifying cells and is both necessary and sufficient for preventing neuronal differentiation (Hack et al., 2005; Marshall et al., 2005; Menn et al., 2006). Glial cell fates are also promoted by stimulation of EGF and PDGF receptors, which preferentially enhance oligodendritic progenitor production (Aguirre et al., 2007; Gonzalez-Perez and Alvarez-Buylla, 2011; Gonzalez-Perez and Quinones-Hinojosa, 2010; Jackson et al., 2006). In addition to EGFR and PDGFR, activation of bone morphogenic protein (BMP) receptors by BMP ligands also promotes glial differentiation of

SVZ-derived progenitors (Lim et al., 2000). BMP receptors are expressed by neural stem cells, transit amplifying cells, and neuroblasts, whereas BMP ligands are highly expressed in only the neural stem cells and transit amplifying cells. Ependymal cells lining the lateral ventricle, however, do not express either BMP ligands or receptors; rather they strongly express the BMP antagonist, Noggin. The blockade of BMP signaling by Noggin released from ependymal cells represses gliogenesis and enables the formation of neurogenic microenvironments in the SVZ. Continued elucidation of the molecular mechanisms controlling the neuronal vs. glial cell fate in SVZ-derived progenitors may foster the development of novel therapeutic strategies to treat demyelination disorders and brain tumors (Jackson and Alvarez-Buylla, 2008; Nait-Oumesmar et al., 2008).

## 9.5 ADULT NEUROGENESIS IN THE SVZ/RMS OF THE AGING AND PATHOLOGICAL BRAIN

As discussed above in Section 9.2, neuroblast production in the human SVZ precipitously declines after the first 18 months after birth (Sanai et al., 2011). The precise size of the proliferative neural progenitor population present in the adult SVZ is controversial (Curtis et al., 2007; Kam et al., 2009; Quinones-Hinojosa et al., 2006; Sanai et al., 2004), but the comparative size of the adult proliferative population consistently has been found smaller than in the infant SVZ (Sanai et al., 2011; Wang et al., 2011a; Weickert et al., 2000). Despite the presence of some multi-potent neural stem cells in the adult SVZ, post-mortem C<sup>14</sup> analysis of human OBs confirms that most, if not all, OB interneurons are generated at the time of birth and not during adolescence or adulthood (Bergmann et al., 2012).

Adult rodents maintain neurogenesis in the SVZ, but neurogenic output does progressively decline during aging (Conover and Shook, 2011). There is an approximately 50–70% decrease in the number of both proliferative cells in the SVZ and progenitors migrating into the OB of aged mice (22–26 months old) when compared to younger mice (2–5 months) (Ahlenius et al., 2009; Tropepe et al., 1997). This reduction in neurogenic capacity is caused, at least in part, by an increase in the number of neural stem cells becoming mitotically quiescent (Luo et al., 2006). Several cell cycle regulators are critical for regulating the pool size of proliferating neural stem cells in the SVZ (discussed in Section 9.3.1), and the expression levels of Cdk inhibitors, such as p27<sup>Kip1</sup> and p16<sup>INK4a</sup>, in the SVZ progressively increase with age (Ahlenius et al., 2009; Molofsky et al., 2006). Cell cycle inhibitor expression levels are also likely critical for regulating neural stem cell pool size in the human SVZ, but the mechanistic differences responsible for the rapid reduction in the number of proliferative

human progenitors during postnatal development remains to be established.

Aging-related pathological conditions in the brain also modulate SVZ neurogenesis. Parkinson's disease, for example, is associated with a decrease in the rate of SVZ neurogenesis (Marxreiter et al., 2013; Winner et al., 2011). Several rodent lesion models report decreases in both proliferation in the SVZ and survival of new neurons in the OB. Transgenic mice over-expressing variants of alpha-synuclein have produced mixed results regarding progenitor proliferation, but they have consistently displayed a diminished survival of new neurons in the OB. Some studies of human Parkinson's disease patients have also indicated that there is a disease-related reduction in markers of SVZ progenitor proliferation (Hoglinger et al., 2004; O'Keeffe et al., 2009b), but others have challenged these findings (van den Berge et al., 2011). Analysis of the SVZ in Parkinson's patients is difficult, however, because proliferation levels in the SVZ may vary significantly due to confounding factors that are unique to each patient, such as the presence of other neurological conditions and differences in medication histories.

In contrast to the diminution of adult SVZ neurogenesis associated with Parkinson's disease, human patients with Huntington's disease show an increase in markers of proliferation in the SVZ (Curtis et al., 2003; Curtis et al., 2005a; Curtis et al., 2005b). The SVZ in Huntington's disease patients is thicker and contains substantially more neural stem cells, as well as additional transit amplifying cells and neuroblasts. Consistent with these findings, rodent models of Huntington's disease show that progenitor proliferation in the adult SVZ does not decrease, rather it remains unchanged or is increased (Batista et al., 2006; Kohl et al., 2010; Phillips et al., 2005; Tattersfield et al., 2004). Rodent studies also show that neuroblasts migrate into the damaged striatal regions, which comes at the expense of new neurons migrating into the OB (Kohl et al., 2010).

In addition to neurodegenerative disease, ischemia also alters adult neurogenesis in the SVZ (Cayre et al., 2009; Conover and Shook, 2011; Kernie and Parent, 2010). Studies with rodent models have consistently reported that focal ischemia stimulates adult SVZ neurogenesis (Arvidsson et al., 2002; Jin et al., 2001; Parent et al., 2006; Zhang et al., 2001). Although the neurogenesis rates peak one or two weeks post-stroke before declining, significantly elevated levels can persist for up to 4 months (Thored et al., 2006). Consistent with the rodent models, human stroke victims also show evidence for increased cell proliferation in the SVZ (Jin et al., 2006; Macas et al., 2006; Martí-Fabregas et al., 2010). Analyses of rodent stroke models reveal that the increase in SVZ neurogenesis is accompanied by a redirection of migrating neuroblasts towards the infarct area. This redirection of neuroblasts

can be detected for up to a year after the stroke and comes at the expense of progenitors normally destined for the OB (Kernie and Parent, 2010; Thored et al., 2007). Despite this influx of neural progenitors, few progenitors reaching the damaged regions survive and differentiate into mature functioning neurons (Arvidsson et al., 2002; Parent et al., 2002). The reasons for this failure to survive and integrate are not clear. Also, the functional significance, if any, for stroke-induced neurogenesis in either rodents or humans remains to be determined.

## 9.6 FUNCTIONAL ROLES OF ADULT-GENERATED NEURONS

The functional role of adult neurogenesis in the SVZ, RMS, and OB has been challenging to assess. In rodents, conflicting conclusions have been reported. Typical rodent studies have disrupted adult neurogenesis (e.g., through irradiation (Lazarini et al., 2009) or by genetically driven toxin expression (Imayoshi et al., 2008)) then compared olfactory-based functional behavior between the experimental and control groups. Differences in the experimental methods used to disrupt neurogenesis may account for some discrepancies in the reported findings, but the specific behavioral testing methods used are a critical factor in the outcome of functional testing (Lazarini and Lledo, 2011). Studies using operant learning paradigms show that adult neurogenesis is required for long-term odor associative memory (Lazarini et al., 2009; Sultan et al., 2010). By contrast, those using non-operant learning indicate that adult neurogenesis is not necessary (Breton-Provencher et al., 2009; Imayoshi et al., 2008). The dependence of newborn adult OB neuron survival on operant, but not non-operant, learning is consistent with the importance of selecting appropriate testing methods to assess the functional analysis of adult neurogenesis (Mandairon et al., 2011). Even within operant learning paradigms, however, the difficulty of an odor discrimination task is a critical parameter. For easy discrimination challenges (i.e., presentation of dissimilar odors), adult neurogenesis is dispensable. Difficult discrimination tasks (presentation of similar odors), however, require input specifically from adult-born and not early post-natal born neurons (Alonso et al., 2012).

The importance of olfaction in rodents underlies the significance that adult neurogenesis has in shaping odor discrimination and associative learning and memory, as well as odor-based fear discrimination (Valley et al., 2009), mate preference (Mak et al., 2007), and maternal behavior (Shingo et al., 2003). In humans, olfaction is integral for many behaviors, but it does not have the same prominent role as in rodents. Furthermore, the precipitous decline in neuroblast production by the SVZ in infants suggests

that humans do not rely on adult neurogenesis for odor discrimination and associative learning. Human olfactory function does decline with senescence (Doty et al., 1984), but age-related decreases in the number of glomeruli and mitral cells (Meisami et al., 1998), as well as an increased prevalence of neurodegenerative disease or injury (as discussed in Section 9.5), make it difficult to assess whether the negligible addition of adult-born OB interneurons underlies this diminution of olfactory function. Thus, the functional role of neural proliferation in the adult human SVZ is unknown and elucidating this role is a critical challenge for future studies to address.

## Cortical Olfactory Anatomy and Physiology

DONALD A. WILSON, JULIE CHAPUIS, and REGINA M. SULLIVAN

### 10.1 INTRODUCTION

The olfactory cortex is defined as those regions receiving direct monosynaptic input from the olfactory bulb and includes areas such as the olfactory tubercle, piriform cortex, and lateral entorhinal cortex, among others. Over the past 5–10 years (since the previous edition of this handbook), there has been an exponential growth in research on the anatomy, physiology, and function of olfactory cortex. This work has substantially enhanced understanding of what the cortex contributes to odor perception, and how disruption of olfactory cortical function in disease and aging may contribute to olfactory perceptual deficits. In this chapter we review the current knowledge of olfactory cortical anatomy and physiology, and describe current ideas about how this functional anatomy shapes odor perception. In addition, we touch on the contributions of other cortical regions, for example the orbitofrontal cortex, to odor perception.

There is a long history of neuroanatomical and electrophysiological interest in the olfactory cortex which created a rich groundwork for ideas about how olfactory cortex functions and what it contributes to odor perception. Comparative anatomical studies noted the evolutionary conservation of piriform cortex throughout vertebrates relative to other cortical areas (Herrick, 1933). Herrick argued that given that olfactory cortex is the most evolutionarily primitive cortex, it has unique associative impact on other regions, both providing subtle modulation of those other regions and receiving multi-sensory feedback from them (Herrick, 1933). “At all stages of cortical elaboration an important function of the olfactory cortex, in addition to participation in its own specific way in cortical

associations, is to serve as a non-specific activator for all cortical activities” (1933: 14). Electrophysiological analyses of odor-evoked piriform cortical activity was also explored very early on, first with the pioneering use of local field potentials (Adrian, 1942), and subsequently with single-unit recordings (Haberly, 1969). The piriform cortex was the first cortical region successfully used for *in vitro* slice electrophysiology, pre-dating development of hippocampal slices (Yamamoto and McIlwain, 1966). This has led to a wealth of information on synaptic physiology and connectivity within olfactory cortex that rivals that of any other brain region (e.g., Suzuki and Bekkers, 2010; Poo and Isaacson, 2011a; Suzuki and Bekkers, 2011). As experimental data mounted, hypotheses of olfactory cortical function and the role of piriform cortex in odor perception matured, especially in the mid-1980s (Haberly, 1985; Lynch, 1986; Wilson and Bower, 1988; Hopfield, 1991). These early models included basic concepts still held today, though current models are now more strongly supported by experimental data.

Currently, the olfactory cortex is hypothesized to function as both the primary olfactory sensory cortex and as association cortex (Haberly, 2001; Gottfried, 2010; Wilson and Sullivan, 2011). Activity in the olfactory cortex merges odorant feature information extracted at the sensory epithelium and refined in the olfactory bulb into odor objects which form the basis of perception. However, these odor object representations include not only odorant information, but also information conveying hedonics, context, and expectation (Gottfried, 2009). For example, odor evoked activity in the olfactory cortex can be shaped

by a visual image associated with the smell (Gottfried and Dolan, 2003), just as the color of the source of an odorant can influence the perception of its odor (Zellner and Kautz, 1990; Zellner et al., 1991). The olfactory cortex is the target of descending, multimodal, and modulatory inputs that may contribute to these rich perceptual outcomes. Furthermore, based on anatomical and physiological differences, the olfactory cortex can be divided into many sub-regions. Anatomically, these sub-regions differ in both local circuitry and afferent and efferent connectivity. While still under examined, there is increasing evidence for specialization of function among these sub-regions, perhaps forming a parallel processing stream of information leading to different aspects of the overall perception. It is increasingly apparent that experience and cortical plasticity play an important role in olfactory cortical function and odor perception.

## 10.2 OLFACTORY CORTEX: STRUCTURE AND FUNCTION

The olfactory cortex (Figure 10.1) is unique among mammalian sensory cortices in that: 1) it is primarily a 3-layered paleocortical structure in contrast to the 6-layered neocortex of other systems; 2) despite remarkable spatial patterning of odor-evoked activity in the olfactory bulb, the olfactory cortex shows no detectable topography, in contrast to neocortical sensory regions; and 3) in contrast to thalamocortical sensory systems, there is no thalamic nucleus between the peripheral receptors and olfactory cortex, though functions similar to those of the thalamus may occur in the olfactory bulb (Kay and Sherman, 2007) or cortex itself (Shepherd, 2005).

The olfactory cortex, that is, the termination zone of olfactory bulb mitral and tufted cells (Figure 10.2), includes the anterior olfactory nucleus (AON), tenia tecta, olfactory tubercle (OT), anterior and posterior piriform cortices (aPCX and pPCX respectively), the cortical nucleus of the amygdala, and the lateral entorhinal cortex. In rodents, these structures lie within the olfactory peduncle and along the ventral lateral edge of the forebrain, extending the full length of the forebrain with the lateral entorhinal cortex at the caudal end. In primates, the majority of these structures have moved medially with the expansion of the neocortex, with AON and piriform cortex lying anterior medial and the base of the olfactory peduncle in the same anterior-posterior plane as the amygdala. All regions of the olfactory cortex send efferents back to the olfactory bulb, as well as to a number of ipsilateral and contralateral targets.

Many of the sub-regions of olfactory cortex have received relatively little experimental attention, and will be

only briefly described here. The majority of the review will focus on piriform cortex. Although evidence is beginning to emerge for specialization of function among cortical sub-regions (e.g., (Sosulski et al., 2011; Wesson and Wilson, 2011)), perhaps suggestive of parallel processing of olfactory bulb output, the data are currently sparse.

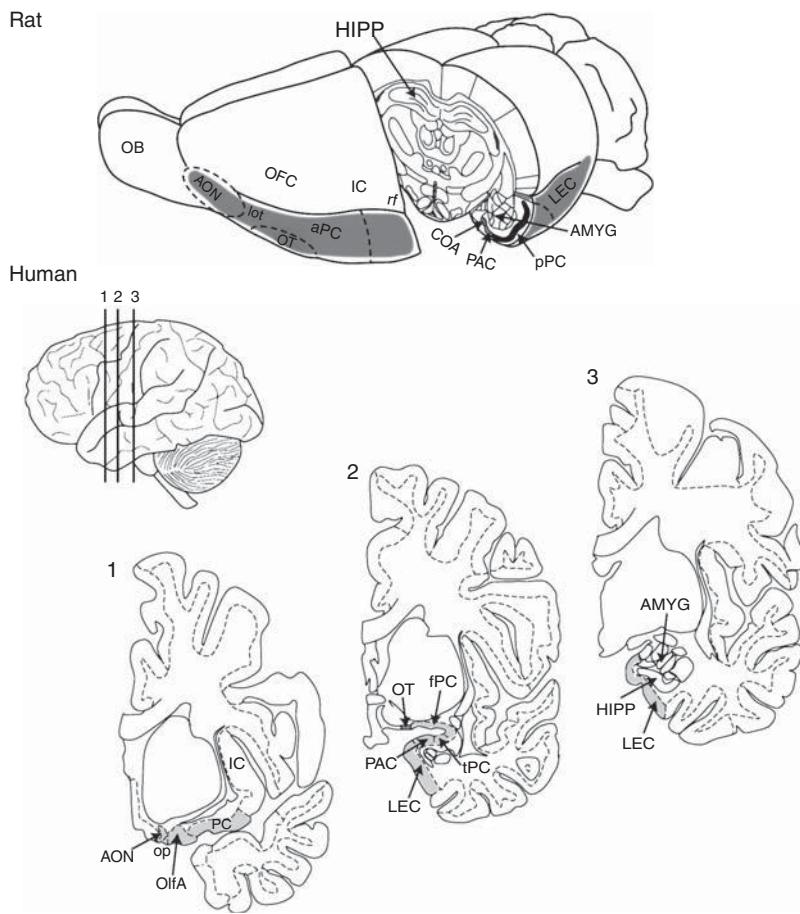

### 10.2.1 Anterior Olfactory Nucleus

The anterior olfactory nucleus lies in the olfactory peduncle and is the most anterior region of the olfactory cortex. It is a laminated structure, with clear molecular and cell body layers (Brunjes et al., 2005), and the argument has been made that it should more properly be named anterior olfactory cortex (Haberly, 2001). The AON can be divided into at least two major sub-regions, the pars externalis and the pars principalis. AON neurons receive direct input from mitral and tufted cell axons as they leave the olfactory bulb along the lateral surface of the olfactory peduncle forming the lateral olfactory tract. A definitive review of AON structure and cell types is published elsewhere (Brunjes et al., 2005).

The pars externa appears to receive a topographic input from the olfactory bulb, and in turn projects in a highly precise topographic manner to the contralateral olfactory bulb (Yan et al., 2008). In accord with this topographical anatomy, odor-evoked activity within the AON pars externa displays odor-specific spatial patterning, similar to that observed in the olfactory bulb (Kay et al., 2011). Odor-evoked activity in pars externa is also bilaterally asymmetrical, with ipsilateral inputs driving primarily excitatory activity and contralateral inputs primarily inducing activity suppression (Kikuta et al., 2008; Kikuta et al., 2010). This odor-specific, bilateral convergence suggests that the AON pars externa could play a role in odor localization (Rajan et al., 2006; Porter et al., 2007).

Similar to the pars externa, the AON pars principalis is a major source of commissural fibers to the contralateral olfactory bulb, AON, and piriform cortex (Brunjes et al., 2005; Illig and Eudy, 2009). However, in contrast to the AON pars externa, the pars principalis does not show spatial patterning in odor-evoked activity, but instead shows highly distributed odor-evoked activity (Meyer et al., 2006) similar to that observed in the piriform cortex (Illig and Haberly, 2003; Rennaker et al., 2007; Stettler and Axel, 2009).

In addition to serving as an important point of bilateral convergence and comparison, the AON may also begin the process of synthesizing molecular features extracted at the periphery and olfactory bulb into odor objects (Haberly, 2001). In fact, AON single-units are driven most effectively by odor mixtures, with subthreshold presentation of components in a mixture adding non-linearly to evoke a robust mixture response (Lei et al., 2006).

**Figure 10.1** General anatomy of the olfactory system in rodent (top) and human (bottom). The olfactory cortex is labeled in gray. Abbreviations: AMYG: amygdaloid complex; AON: anterior olfactory nucleus; COA: cortical amygdala; HIPP: hippocampus; LEC: lateral entorhinal cortex; IC: insular cortex; lot: lateral olfactory tract; OB: olfactory bulb; OFC: orbitofrontal cortex; OlfA: olfactory area; OT: olfactory tubercle; op: olfactory peduncle; PAC: periamygdaloid cortex; aPC: piriform cortex, anterior part; pPC: piriform cortex, posterior part; fPC: piriform cortex, frontal area; tPC: piriform cortex, temporal area; rf: rhinal fissure.

## 10.2.2 Olfactory Tubercl

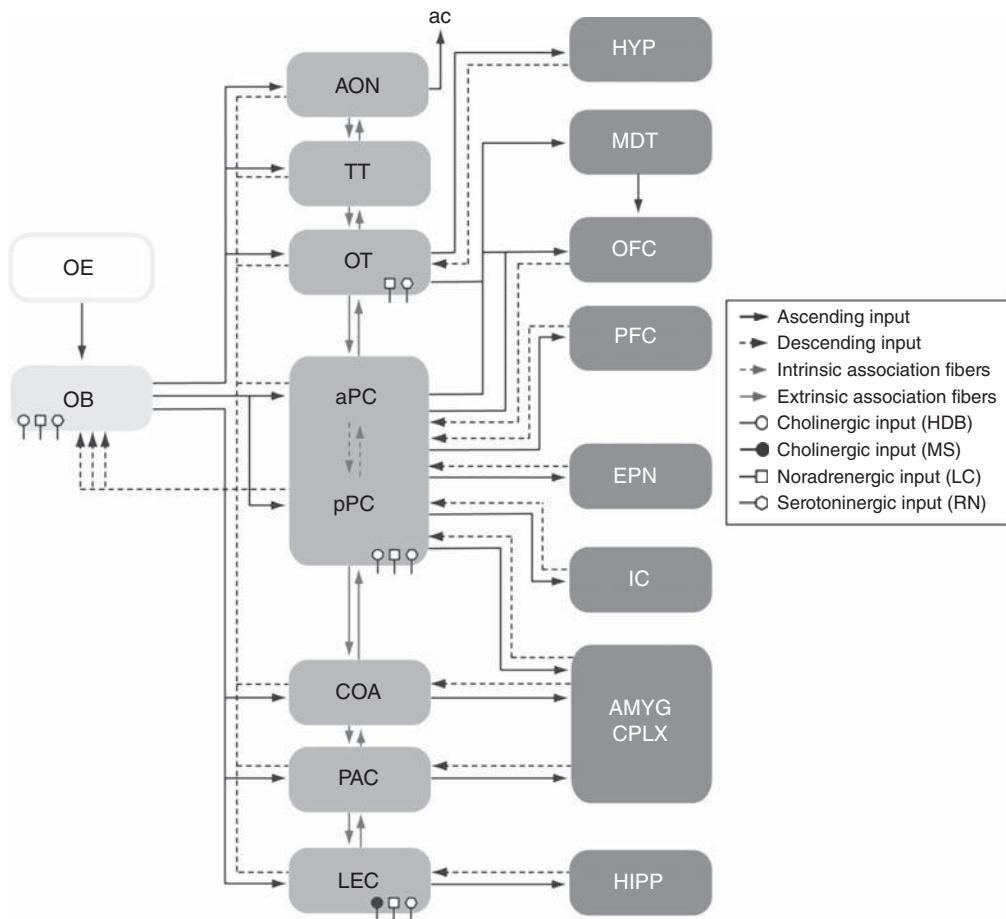

The olfactory tubercle is a relatively large region of the rodent olfactory cortex, lying along the ventral surface of the brain, medial to the piriform cortex. The human OT is located in a similar location, though appears to be much smaller compared to other olfactory cortical areas. Developmentally, the OT is ventral striatal in origin, and maintains strong reciprocal connections with the nucleus accumbens, ventral tegmentum and ventral pallidum. In fact, as might be expected from this connectivity, the largest body of research on the OT relates to its role in reward and motivation (Heimer, 2003; Ikemoto, 2007).

The OT receives its strongest input from the ventrolateral olfactory bulb (Imamura et al., 2011), with tufted cells more dominant than mitral cells (Nagayama et al., 2010; Igarashi et al., 2012). The ventrolateral olfactory bulb is robustly responsive to conspecific urine odor in rodents (Schaefer et al., 2001), and thus may be important in certain social odor-motivated social behaviors. Single-units in OT respond to a variety of odors including biologically meaningful ones (e.g., estrus odors, urine, food odors) (Payton

et al., 2012; Rampin et al., 2012), as well as monomolecular odorants (Wesson and Wilson, 2010). Simple odor coding in OT single-units appears relatively similar to that in anterior piriform cortex (Payton et al., 2012), though such comparative studies have only just begun. Given the differences in both inputs and outputs between the OT and other olfactory cortical areas, it has been suggested that olfactory bulb output may display characteristics consistent with a parallel processing system (Wesson and Wilson, 2011; Payton et al., 2012). Regions of the bulb, or specific output cell types from individual glomeruli, may target specific cortical regions for localized information processing and transmittal to specialized downstream circuits.

In addition to odor responses, the rodent OT displays multimodal convergence. OT single-units respond to both odor and sound (Wesson and Wilson, 2010). The behavioral significance of such convergence is unclear, though coincident sound and odor may contribute to localization of moving objects in nocturnal rodents.

Finally, data from both rodents and humans suggests a potential role for the OT in odor-evoked attention or arousal. Lesions of the OT in rats impair the normal

**Figure 10.2** Schematized organization of the vertebrate olfactory system. Light gray structures (primary olfactory cortex) receive direct input from the main olfactory bulb. Most areas receiving direct input from the main olfactory bulb project back to the bulb. The intrinsic association fibers interconnect the anterior and posterior region of the piriform cortex. The extrinsic association fibers bind the different structures composing the primary olfactory cortex. Dark gray structures receive direct inputs from the primary olfactory cortex. Modulatory inputs project broadly to all primary olfactory structures Abbreviations: ac: anterior commissure; AMYG CPLX: amygdaloid complex; AON: anterior olfactory nucleus; COA: cortical amygdala; EPN: endopiriform nucleus; HDB: horizontal limb of the diagonal band of Broca; HIPP: hippocampus; HYP: hypothalamus; IC: insular cortex; LEC: lateral entorhinal cortex; LC: locus coeruleus ; MDT: mediodorsal thalamus; MS: medial septum; OB:olfactory bulb; OE: olfactory epithelium; OFC: orbitofrontal cortex; OT: olfactory tubercle; PAC: periamygdaloid cortex; aPC: piriform cortex, anterior part; pPC: piriform cortex, posterior part; PFC: prefrontal cortex; RN: raphe nucleus; TT: tenia tecta.

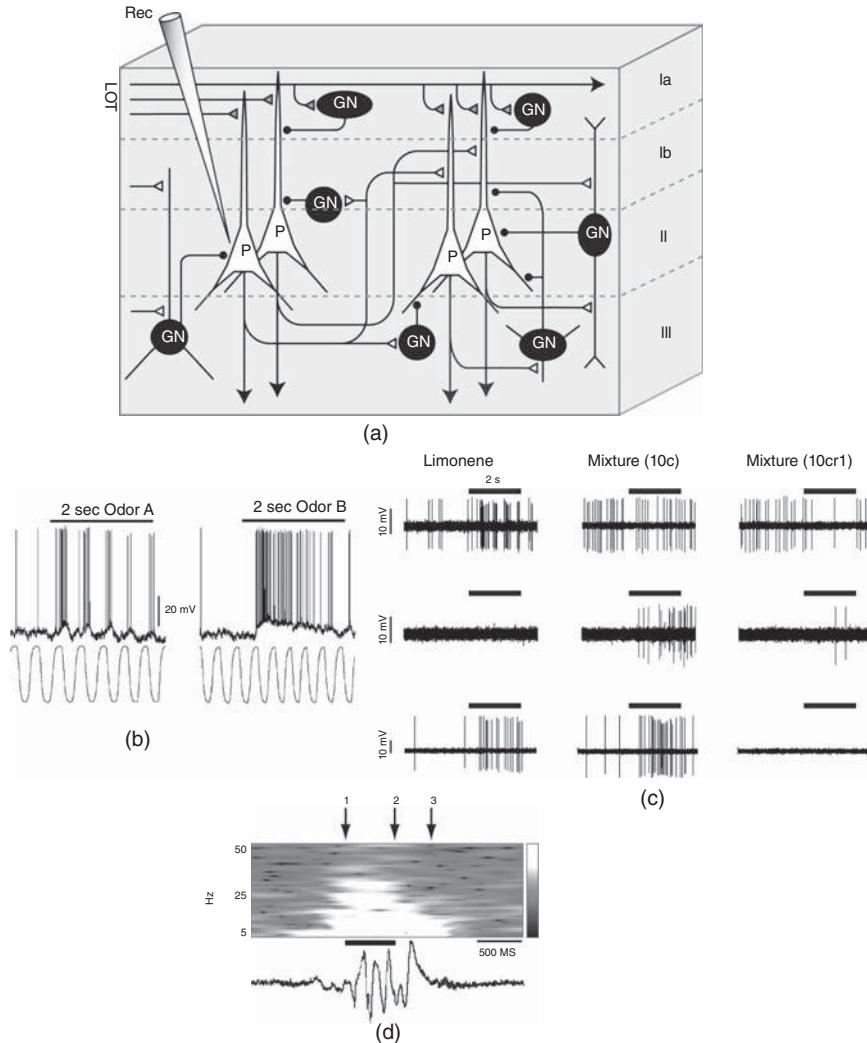

sleep-wake cycle modulation of odor-evoked arousal in cortical EEG (Gervais, 1979). In humans, active sniffing of clean air in an attempt to detect an odor evokes more activity in the anterior piriform/OT than sniffing clean air when no odor is expected (Zelano et al., 2005). This elevated activity in the OT/anterior piriform has been interpreted to reflect attention to sniff and sampled air. No such attention effects were observed in the more posterior temporal piriform cortex.

### 10.2.3 Piriform Cortex

The piriform cortex is unlike other mammalian sensory cortices in several respects (Figure 10.3). First, its primary

sensory input does not originate in the thalamus, but rather from second order sensory neurons in the olfactory bulb, mitral, and tufted cells. Second, it is not neocortical in architecture, but rather is a ‘simpler’ 3-layered cortex, with afferents directed at superficial layer I and primary cell bodies located in layers II and III. Finally, rather than being organized topographically relative to its primary afferent structure and the sensory world, the piriform cortex is highly non-topographic and instead highly associative.

The primary input to the piriform cortex is from the ipsilateral olfactory bulb’s mitral and tufted cells. Mitral cells project throughout both the anterior and posterior piriform cortices, while tufted cells appear to terminate rostrally, primarily in the anterior olfactory nucleus and

**Figure 10.3** (a) Cellular organization of the piriform cortex. Layers II and III contain the cell bodies of pyramidal (P) neurons; the bulbar afferents contact their apical dendrites in superficial layer Ia (gray synapses). Layer Ib contains the intrinsic and extrinsic association fibers (white synapses). The different classes of GABAergic neurons (GN) described by Suzuki & Bekkers (2010, *Cereb. Cortex*, 20:2971–2984) are also represented. Example of cortical intracellular (b), extracellular (c) and population (d) recordings are illustrated below. (a) Intracellular activity and respiration over the course of 2 s odor stimulation in urethane-anesthetized rat (b) Odor-evoked response of three piriform cortical neurons to a monomolecular odorant (limonene) and to two different complex mixtures, each containing 10 components and differing by just one. (c) Representative piriform local field potentials (bottom: raw signal; top: time-frequency representation) obtained from a rat performing an olfactory discrimination task (1: nose poke in the odor port; 2: end of odor sampling; 3: access to the water port). The odor sampling induced the emergence of a powerful oscillation in the beta (15–40 Hz) frequency band.

olfactory tubercle, and much less so in the piriform cortex (Nagayama et al., 2004; Igarashi et al., 2012). Given the differences in mitral and tufted cell odor-evoked activity (Nagayama et al., 2004; Igarashi et al., 2012), these different projection patterns may underlie a parallel processing structure in olfaction (Igarashi et al., 2012; Payton et al., 2012), analogous to that observed in vision (Nassi and Callaway, 2009). Despite the remarkable spatial patterning of olfactory sensory neurons to the olfactory bulb glomerular layer and thus, spatial patterns of odor-evoked activity

in the glomeruli (Rubin and Katz, 2001; Johnson and Leon, 2007) and output neurons (Imamura et al., 1992; Luo and Katz, 2001; Fletcher, 2012), the projection to the piriform cortex loses all detectable topography. Output neurons from individual glomeruli project widely throughout piriform cortex, with no detectable spatial patterning (Ghosh et al., 2011; Mitsui et al., 2011; Sosulski et al., 2011). Furthermore, individual cortical neurons receive input from broadly distributed glomeruli, producing a classic divergent-convergent pattern (Miyamichi et al., 2011).

This input pattern creates an anatomical substrate for synthesis of co-occurring odorant features. In fact, piriform cortical neurons appear to require co-activation of multiple glomeruli to drive spiking activity. Individual piriform cortical pyramidal cells are responsive to specific spatial patterns of glomerular activation, however single glomerulus activation is ineffective at driving cortical neurons (Davison and Ehlers, 2011). Although afferent fiber glutamatergic synapses onto piriform cortical pyramidal cells are relatively strong, layer II pyramidal cells require co-activation of multiple afferent fibers to reach spike threshold (Franks and Isaacson, 2006; Suzuki and Bekkers, 2006, 2011). However, subclasses of pyramidal cells show differential sensitivity to afferent input. Semi-lunar cells, which have apical dendrites with large spines located selectively within Layer Ia and thus anatomically appear highly sensitive to afferent input, are in fact more strongly depolarized by afferent input rather than superficial pyramidal cells in Layer II (Suzuki and Bekkers, 2011). In addition, semi-lunar cells have no basal dendrites (Neville and Haberly, 2004), and thus appear to be primarily tuned to afferent input and only minimally responsive to association fiber input (Suzuki and Bekkers, 2011). Thus, these cells may have unique contributions to the intra-cortical association fiber system described below. For example, semilunar cells form a major component of the association fiber input to superficial pyramidal cells, forming in essence a second layer of processing in piriform cortex (Suzuki and Bekkers, 2011).

The divergent/convergent projections from olfactory bulb to piriform cortex mean that there are no obvious odor-specific spatial patterns of odor-evoked activity within the piriform cortex (Cattarelli et al., 1988; Rennaker et al., 2007; Stettler and Axel, 2009). Neighboring neurons are as likely to respond to different odors as they are to respond to the same odors (Rennaker et al., 2007; Stettler and Axel, 2009). Although intracortical association fiber activity contributes to this odor-evoked pyramidal cell activity (Franks et al., 2011; Poo and Isaacson, 2011b), the results strongly suggest convergence of multiple glomerular input onto individual pyramidal cells. This allows individual, distributed piriform cortical neurons to synthesize odorant features extracted by the periphery and refined in the olfactory bulb, beginning the process of odor object formation.

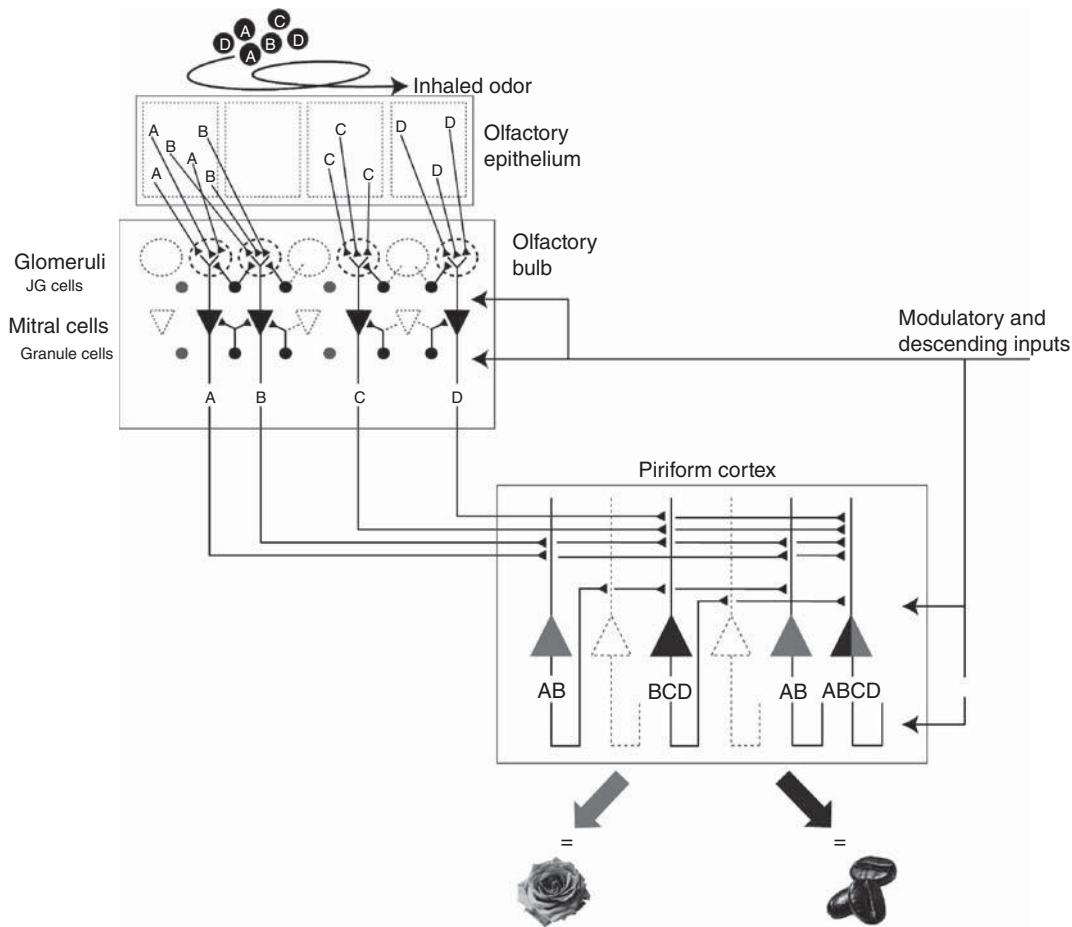

As noted, however, a critical component of the synthesis of odorant features is the extensive intracortical association fiber system (Haberly, 2001). This intrinsic network helps bind distributed co-active neurons into an ensemble unique to a given input (Figure 10.4). These association fiber connections are an important component in driving odor-evoked activity. In some cases, pyramidal cells that do not respond directly to stimulation of individual glomeruli, do respond when specific combinations of glomeruli are

activated, suggesting a role for intrinsic excitatory connections in driving this activity (Davison and Ehlers, 2011). In fact, selective blockade of association fibers reduces pyramidal cell odor responses and narrows receptive field width (range of effective odor stimuli) (Poo and Isaacson, 2011b).

It has previously been demonstrated that rodents can detect, discriminate, and learn about different spatial patterns of olfactory bulb activation (Roman et al., 1987; Mouly et al., 2001). Recent work using optogenetic stimulation techniques has demonstrated similar behavioral outcomes with stimulation of a relatively small set of distributed piriform cortical pyramidal cells (Choi et al., 2011). Associating activation of the distributed pyramidal cells with aversive (foot shock) or appetitive (food) rewards can produce conditioned learned approaches or avoidance behaviors, similar to natural odor conditioning. Activation of around 500 cells was sufficient to mediate this behavior (Choi et al., 2011). Such a small ensemble of neurons (0.5% of the piriform cortical population) capable of driving behavior allows for high capacity storage of many odor objects and is consistent with Marr's model of archicortex (Marr, 1971).

In addition to allowing convergence of multiple odorant features, the association fibers also play an important role in odor memory (Haberly, 2001). Association fiber synapses exhibit robust NMDA-dependent long-term potentiation (Kanter and Haberly, 1990; Poo and Isaacson, 2007). Associative learning with odors can increase synaptic currents evoked by association fiber stimulation (Saar et al., 2002), as well as dendritic spine density in regions of the apical dendritic where association fibers terminate (Knafo et al., 2001).

This plasticity of association fiber synapses is believed to help bind members of a co-active cortical ensemble. With this binding of spatially distributed neurons, discrimination and odor acuity improve. A second hypothesized consequence of this network effect is pattern completion. Computational models of piriform cortex have demonstrated that optimal associative plasticity in association fiber synapses helps store a template of familiar odor patterns which allow "filling-in" features of degraded inputs and full response to an odor object (Hasselmo et al., 1992; Barkai et al., 1994). Either too much or too little plasticity can result in excessive or impaired pattern completion and thus, impaired recognition and discrimination (Hasselmo and McGaughy, 2004). Recent work has directly tested the pattern completion ability of piriform cortical circuits (Barnes et al., 2008; Wilson, 2009). Complex mixtures of monomolecular odorants were "morphed" by either removing individual components (10 component mix, 10 component mix with 1 missing, 10 component mix with 2 missing, etc.) or by replacing individual components with a novel contaminant. Ensembles of mitral/tufted cells de-correlated (responded significantly differently between)

**Figure 10.4** Neurobiological steps leading to the synthetic perception of odors. Individual receptors localized in the olfactory epithelium express one of 1000 different receptor proteins and are randomly scattered within one of four zones. Receptors expressing the same receptor protein converge on to a small number of exclusive glomeruli (four receptor types are labeled A, B, C and D in this example). The receptors are hypothesized to be responsive to individual odorant features, rather than odorant molecules as a whole. Mitral cells receive receptor input from a single glomerulus (and thus convergent receptor input; e.g., A or B), and project to the piriform cortex. Within the olfactory bulb, inter-glomerular and inter-output neuron lateral inhibition is mediated by juxtaglomerular and granule cells, respectively, heightening contrast between similar odorant features. Neurons in the piriform cortex form a combinatorial array, allowing convergence of multiple odorant features and/or behavioral state/non-olfactory inputs to occur on single neurons. Thus, distributed ensembles of pyramidal cells can synthesize the bulbar messages into unified percepts like the smell of “rose” (here synthesis of A and B) or “coffee” (synthesis of B, C and D) and store these representations in memory. Both the olfactory bulb and piriform cortex receive extensive input from neuromodulatory and non-olfactory inputs.

all the various mixture morphs from the standard 10 component mixture. This is consistent with a pattern separation role for the olfactory bulb, similar to that of the hippocampal dentate gyrus (Sahay et al., 2011). In contrast, piriform cortical single-unit ensembles failed to de-correlate the 10 component mixture from that missing a single component, despite the fact that sufficient information was available in the olfactory bulb. This suggests that the piriform cortical ensembles completed the slightly degraded input, and responded as if the entire odor object was present. As more components are removed, or novel contaminants added, piriform cortical ensembles de-correlate the mixtures even more strongly than the olfactory bulb (Barnes

et al., 2008). Behavioral discrimination performance in a two-alternative choice task mirrored the cortical ensemble de-correlation—mixtures not de-correlated by the cortex are difficult for the animals to discriminate (Barnes et al., 2008). These results suggest that, as originally hypothesized (Haberly, 2001), the piriform cortex can perform pattern completion which contributes to perceptual stability. Interestingly, new data suggest that the boundary between cortical pattern completion and separation is experience dependent. Cortical pattern completion can be enhanced in tasks requiring odor generalization and pattern separation can be enhanced in tasks requiring fine odor acuity (Chapuis and Wilson, 2011). These changes in

olfactory cortical processing lead to changes in perceptual acuity in both rodents (Fletcher and Wilson, 2002; Chapuis and Wilson, 2011; Chen et al., 2011) and humans (Li et al., 2006; Li et al., 2008).

Piriform cortical based pattern completion may contribute to perceptual stability in the face of changing odor intensity or mixture content, which will affect feature input to the cortex. If such changes are minimal, the cortex can “ignore” them by filling in the missing components through the activation of previously strengthened synapses, thus allowing perceptual stability. More significant changes, or previous odor training, can enhance a shift toward pattern separation and odor discrimination.

A second form of synaptic plasticity within the piriform cortex contributes to odor background segmentation. The piriform cortex rapidly adapts to stable odor input (Wilson, 1998a), and this cortical adaptation to odor is associated with afferent (mitral/tufted cell) synaptic depression recorded intracellularly, *in vivo* (Wilson, 1998b). The recovery of odor responses occurs within about 2 min, as does the synaptic depression (Best and Wilson, 2004). This cortical adaptation is mediated by pre-synaptic metabotropic receptors (group III) which reduce glutamate release from mitral/tufted cell axons during repetitive stimulation (Best and Wilson, 2004). Blockade of mGluRIII receptors within the piriform cortex prevents the synaptic depression, cortical odor adaptation, and short-term behavioral habituation (Best et al., 2005; Yadon and Wilson, 2005; Bell et al., 2008).

The synaptic depression is homo-synaptic, leaving afferent inputs conveying information from other non-active mitral/tufted cells (and glomeruli) intact (Best and Wilson, 2004). Thus, homosynaptic depression may contribute to the fact that short-term cortical adaptation (Wilson, 2000) and short-term behavioral habituation are highly odor specific (Fletcher and Wilson, 2002; McNamara et al., 2008). However, homosynaptic depression is not sufficient to account for habituation specificity between highly overlapping input patterns (Linster et al., 2009). Potentiation of association fiber synapses also plays a major role in this odor-specificity. In a computational model of the olfactory system which includes olfactory sensory neurons, olfactory bulb neurons, and piriform cortex (Linster et al., 2007), cortical odor adaptation was induced if afferent homosynaptic depression was included in the model, although this cortical adaptation was only minimally odor specific. In contrast, if long-term potentiation was included in association fiber synapses, and odor exposure was sufficiently long enough to induce familiarization, then cortical adaptation was highly odor specific (Linster et al., 2009). The same constraints hold true *in vivo*. The specificity of cortical odor adaptation and of behavioral odor habituation is dependent on how familiar the odors are (e.g., duration of exposure (Fletcher

and Wilson, 2002; Wilson, 2003), and this specificity can be disrupted by disruption of normal synaptic plasticity in association fiber synapses, for example with modulation of piriform cortical acetylcholine muscarinic receptors (Wilson, 2001; Fletcher and Wilson, 2002).

Having a central mechanism of short-term odor adaptation (rather than at the olfactory sensory neuron) allows the system to adjust to contingency changes. For example, using odors to guide performance in a discrimination task would be severely impacted if the cortex stopped responding to repeated cues across trials. Importantly, noradrenergic inputs to the piriform cortex can modulate synaptic depression within the piriform cortex (Best and Wilson, 2004), potentially via pre-synaptic beta receptors on mitral cell axons. Activation of noradrenergic beta receptors can inhibit mGluRIII receptor function via a protein kinase A dependent phosphorylation (Cai et al., 2001). Loud sounds which elevate norepinephrine within the piriform cortex (Smith et al., 2009) can induce dishabituation of odor-evoked behavioral responses (Smith et al., 2009). The behavioral dishabituation is blocked by intra-cortical infusion of the noradrenergic beta receptor antagonist propranolol (Smith et al., 2009). A similar reduction in cortical adaptation may occur under conditions of arousal or attention, allowing sustained cortical odor responses.

Together these results suggest that while the olfactory epithelium and olfactory bulb are obviously required for normal olfaction, the piriform cortex moves the system from an odorant feature oriented process towards an odor object oriented system, capable of synthetic or configural processing, and capable of treating odors as distinct from background. Both of these processes—odor object formation and odor-background segmentation—require synaptic plasticity and experience (Wilson and Stevenson, 2006; Gottfried, 2010; Wilson and Sullivan, 2011).

Experience also shapes hedonic responses to odors (Davis, 2004; Moriceau and Sullivan, 2006; Li et al., 2008; Hegoburu et al., 2009; Fletcher, 2012). Simple associative learning through pairing of an odor with either an aversive or appetitive stimulus modifies both the behavioral response to the odor and odor-evoked activity within the olfactory cortex (Sevelinges et al., 2004; Barkai, 2005; Martin et al., 2006; Chapuis and Wilson, 2011; Chen et al., 2011). These changes appear to contribute to both learned changes in acuity as described above, and to the memory of the hedonic association. For example, odor-fear conditioning can result in either generalized fear to many odors or relatively odor-specific to the conditioned stimulus (Chen et al., 2011). Although the basolateral amygdala is required for the fear conditioning itself (Johansen et al., 2011), the stimulus control over the learned fear (generalized or specific) appears to be related to changes in receptive fields of piriform cortical single-units. In animals trained to show generalized odor fear, chronically recorded

piriform cortex single-units were more broadly tuned than those in pseudo-conditioned animals. In contrast, animals trained to show highly odor-specific fear had piriform single-units that were more narrowly tuned than those in pseudo-conditioned animals. Similar changes in ‘tuning’ of piriform cortical odor-evoked activity have been observed in humans undergoing odor-aversion conditioning (Li et al., 2008).

However, in addition to these learned changes in cortical acuity, learned pleasant and aversive odors may differentially activate the piriform cortex (Gottfried et al., 2002a). For example, in young rats, the anterior piriform cortex appears more robustly activated by learned appetitive/preferring odors while the posterior piriform cortex is more strongly activated by learned aversive odors (Moriceau et al., 2006). Importantly however, it should be noted that how an odor is experienced may shape the circuit activated in response to odors with learned hedonic significance. Food odors, which may be experienced either orthonasally before they enter the mouth or retronasally during chewing can activate piriform cortex (Chabaud et al., 2000; Small et al., 2005; Yoshida and Mori, 2007) Ortho- and retronasal routes of stimulation can activate different neural circuits during recall of a learned aversion odor (Chapuis et al., 2009).

The piriform cortex is also a major source of top-down control of the olfactory bulb (Restrepo et al., 2009; Manabe et al., 2011). This top-down control provides another source of either immediate or long-lasting fine-tuning of odor processing, potentially similar to that produced by neocortical feedback to thalamic nuclei in other sensory systems. Piriform cortical input to the olfactory bulb primarily targets inhibitory granule cells (Price and Powell, 1970), and thus could help shape contrast or gain of bulb output via modulation of this inhibitory circuit (Lledo et al., 2004; Strowbridge, 2009). Descending input to olfactory bulb granule cells shows long-term potentiation (Gao and Strowbridge, 2009) [perhaps most robustly on newborn granule cells (Nissant et al., 2009)], and thus experience-dependent changes in olfactory bulb activity mediated by this pathway could be long lasting (Manabe et al., 2011).

While plasticity is necessary for the piriform cortex to process odors, create odor objects, and adapt to background odors, this reliance on plasticity may contribute to the vulnerability of the olfactory system across a wide range of pathologies (Mesholam et al., 1998), including Alzheimer’s disease (Doty et al., 1987; Nordin and Murphy, 1998; Morgan and Murphy, 2002; Olichney et al., 2005), Parkinson’s disease (Sobel et al., 2001; Siderowf et al., 2005; Wattendorf et al., 2009; Doty, 2012), and schizophrenia (Hudry et al., 2002; Rupp, 2010; Malaspina et al., 2012). For example, in both animal models (Wesson et al., 2010; Cramer et al., 2012) and human functional

imaging studies (Li et al., 2010), olfactory deficits are strongly correlated with piriform cortex dysfunction, though damage (e.g., amyloid-beta deposition or tauopathy) can be expressed throughout the olfactory pathway from the olfactory sensory neurons to the entorhinal cortex (Macknin et al., 2004; Braak et al., 2011; Rawson et al., 2011). It should be noted that functional disruption of a single region within a pathway may reflect damage localized to that region, damage to other areas targeting that region, or abnormal connectivity between regions. In fact, normal functional connectivity within the primary olfactory pathway is impaired by amyloid deposition in mouse models of Alzheimer’s disease (Wesson et al., 2011)

#### 10.2.4 Entorhinal Cortex

The lateral entorhinal cortex is located caudal to the piriform cortex in rodents and anteromedially along the temporal lobe in humans (Brodmann areas 28 and 34). The rodent entorhinal cortex is divided into medial and lateral subdivisions, which together form the primary cortical input to the hippocampal formation. The entorhinal cortex is highly multisensory, with cortical inputs from other perirhinal and parahippocampal cortices and return projections to these structures (Kerr et al., 2007; Agster and Burwell, 2009). Its primary thalamic input is primarily from the dorsal midline thalamic nuclei (Kerr et al., 2007). However, relevant to the current discussion, in both rodents (Schwob and Price, 1978; Sosulski et al., 2011; Igarashi et al., 2012) and primates (Carmichael et al., 1994) the lateral entorhinal cortex receives direct input from olfactory bulb mitral cells and thus fits the definition of olfactory cortex. The lateral entorhinal also receives input from the piriform cortex. Given these inputs, it is not surprising that neurons in the lateral entorhinal cortex respond to odors (Deshmukh and Knierim, 2011; Xu and Wilson, 2012). Although very few sensory physiology studies have examined the lateral entorhinal, single units there appear to show more selectivity in their responses than cells in piriform cortex (Xu and Wilson, 2012).

In addition to receiving input from the olfactory bulb and piriform cortex for transmission to the hippocampal formation, the lateral entorhinal is also a major source of top-down feedback to more peripheral parts of the olfactory system. This pathway has not been explored in much detail, though both the piriform cortex and olfactory bulb are targets (Wyss, 1981; Insanedi et al., 1997). Aspiration lesions of the entorhinal cortex enhance odor-evoked c-fos in piriform cortex (Bernabeu et al., 2006), suggesting entorhinal cortex-mediated a top-down suppression of olfactory cortical activity. In fact, electrical stimulation of the lateral entorhinal cortex can inhibit piriform cortical response to olfactory bulb stimulation, though the use of

electrical stimulation for these studies and the resulting antidromic activation of the circuits complicates interpretation. Nonetheless, these studies suggest a powerful role of the lateral entorhinal cortex in modulating olfactory function. Given the nature of other inputs to the entorhinal noted above, including the amygdala, hippocampus, and perirhinal cortices, this feedback could be rich in memory, hedonic, and multimodal information.

Interestingly, aspiration lesions of the entorhinal cortex disrupt some forms of odor memory but enhance others. Odor-based tasks that require the hippocampus are disrupted by entorhinal lesions, as might be expected (Staubli et al., 1984). However, hippocampal independent odor-based memory tasks, such as conditioned odor aversion are enhanced by entorhinal lesions (Ferry et al., 1996; Wirth et al., 1998). This enhancement could reflect a release from inhibition that the lateral entorhinal cortex imposes on the olfactory cortex (Bernabeu et al., 2006; Mouly and Di Scala, 2006).

Finally, it should be mentioned that the entorhinal cortex is heavily impacted by Alzheimer's disease and associated deposition of amyloid beta and phosphorylated tau pathologies. The trans-entorhinal area appears to be the earliest forebrain region impacted by Alzheimer's disease (Braak and Braak, 1992). The role of entorhinal pathology in the early emergence of olfactory deficits in mild cognitive impairment and early Alzheimer's disease (Doty et al., 1987; Murphy, 1999; Murphy et al., 1999) is not clear. Declines in odor identification test scores in mild cognitive impairment do not correlate with entorhinal cortex volume (Devanand et al., 2010). However, entorhinal dysfunction could affect both the transmission of olfactory information towards memory circuits in the hippocampus, and also impact descending modulation of the olfactory bulb and cortex. In both humans (Li et al., 2010) and rodents (Wesson et al., 2010; Wesson et al., 2011), pathology and dysfunction in the piriform cortex are highly correlated with olfactory perceptual and memory breakdown. The contribution of disrupted top-down modulation of piriform cortical function in this disorder deserves further examination.

### 10.2.5 Orbitofrontal Cortex

Although orbitofrontal cortex does not fit the classic definition of olfactory cortex since it does not receive direct input from the olfactory bulb, it has an important role in olfaction and chemosensation. The orbitofrontal cortex is located dorsal to the piriform cortex in rodents and at the anterior base of the frontal lobes in humans (Brodmann areas 10, 11, and 47). The orbitofrontal cortex is the target of the dorsomedial nucleus of the thalamus, and also receives inputs from sensory cortices

of all modalities. Both the ventral tegmentum and the nucleus accumbens project to the orbitofrontal cortex, which may provide important information regarding relative reward value and its relationship to sensory objects. There are reciprocal connections between the orbitofrontal cortex and the insular and parahippocampal cortices, amygdala nuclei, the hippocampus and hypothalamus. The orbitofrontal cortex even extends projections to the brainstem including the locus coeruleus. Directly relevant to the present discussion, the orbitofrontal cortex also has a strong, reciprocal connection with the piriform cortex, with the strongest projections to and from the anterior piriform cortex, and less to the posterior piriform cortex (Johnson et al., 2000; Ekstrand et al., 2001; Illig, 2005). The piriform cortex also projects indirectly to the orbitofrontal cortex via the dorsomedial thalamus.

The orbitofrontal cortex is broadly involved in reward or outcome value, decision making, memory, and emotion (Schoenbaum et al., 2011). Similar to the entorhinal cortex, the orbitofrontal cortex can be divided into anatomically and functionally based sub-regions along both the medial-lateral and anterior-posterior axes (Carmichael and Price, 1994; Rudebeck and Murray, 2011).

Single units in the orbitofrontal cortex can be highly multimodal (Schoenbaum and Eichenbaum, 1995; Rolls et al., 2003; Kadohisa et al., 2004), including strong responses to chemosensory stimuli (Tanabe et al., 1975; Schoenbaum and Eichenbaum, 1995; Critchley and Rolls, 1996b; Rolls et al., 1996). For example, orbitofrontal single units can respond to the smell, taste, and sight or mouth feel of food items. Similar odor-evoked activity can be observed in human functional imaging analyses of the orbitofrontal cortex (Jones-Gotman and Zatorre, 1993; Royet et al., 2001; Gottfried et al., 2002b; Small et al., 2005), often displaying a lateralization (Zatorre et al., 1992; Royet and Plailly, 2004).

The orbitofrontal cortex, particularly ventrolateral regions, appear to play several roles in odor perception. This area may play an important role in flavor perception (Schul et al., 1996), though separation of pure sensory information from hedonic or reward value is difficult. For example, responses to food odors are reduced by feeding to satiety or previous negative/aversive associative learning (Critchley and Rolls, 1996a; O'Doherty et al., 2000; Gottfried et al., 2002a). In fact, odor pleasantness is a strong modulator of orbitofrontal cortical odor responses in humans (Royet et al., 2000; Rolls et al., 2008). The orbitofrontal cortex may also be involved in attention to odors. For example, attention to odors selectively enhances the functional connectivity between the dorsomedial nucleus of the thalamus and the orbitofrontal cortex compared to the direct piriform-orbitofrontal cortex

pathway (Plailly et al., 2008). These findings suggest a potential thalamocortical contribution to sensory attention in olfaction, similar to that seen in other sensory systems (McAlonan et al., 2008).

Finally, as with the entorhinal cortex, the orbitofrontal cortex provides top-down input to the piriform cortex. This top-down feedback presumably provides information about stimulus value or motivational significance (Schoenbaum and Eichenbaum, 1995; Schoenbaum et al., 1999; Schoenbaum et al., 2011). Given the nature of associative odor coding in piriform cortex, this feedback could become directly incorporated into the cortical representation of the odor itself. Furthermore, this top-down input is plastic, showing robust enhancement induced by olfactory learning (Cohen et al., 2008).

### 10.3 SUMMARY

The olfactory cortex is a structurally and functionally heterogeneous cortical region targeted by olfactory bulb output neurons. Olfactory cortical neuroarchitecture includes ventral striatal (olfactory tubercle), paleocortical (piriform cortex), and neocortical (lateral entorhinal cortex) components. There is no classic thalamic relay between the peripheral receptors and olfactory cortex, though the dorsomedial nucleus of the thalamus receives input from the piriform cortex and projects on the orbitofrontal neocortex—an important higher order olfactory and chemosensory structure.

Data currently support a role for the piriform cortex in pattern recognition of olfactory bulb odor-specific spatial-temporal output, with an experience-dependent synthesis of those feature-driven patterns into perceptual odor objects. The anterior piriform cortex may be specialized for encoding odor identity while posterior regions more specialized for encoding odor categories and adding hedonic content. The piriform cortex is also importantly involved in short-term odor habituation, which contributes to odor-background segmentation.

Less is known about the other olfactory cortex components. The olfactory tubercle displays multi-sensory sensory characteristics, and based on its anatomical circuitry could be an important mediator between odors and motivated behavior. Initial investigations of the entorhinal cortex suggest it may play a role not only as a gateway for olfactory input to the hippocampal formation, but also as an important top-down modulator of olfactory cortical and olfactory bulb function. The orbitofrontal cortex appears important in odor hedonics and reward/decision-making consequences of odor stimulation. The orbitofrontal cortex is also an important multisensory site for convergence of taste, olfaction, mouth feel, and vision that together contribute to flavor.

Finally, olfaction is increasingly recognized to express vulnerability to early stages of several neuropathologies including Parkinson's and Alzheimer's disease. Dysfunction within the piriform cortex has been strongly associated with olfactory dysfunction in both humans suffering from Alzheimer's disease and in rodent models of the disease. Understanding how the primary olfactory system functions, and how it fits within larger cortical and subcortical networks will help elucidate why this seemingly simple system is so susceptible to such a wide variety of disorders.

## Psychophysical Measurement of Human Olfactory Function

RICHARD L. DOTY and DAVID G. LAING

### 11.1 INTRODUCTION

During the last two centuries, numerous tests have been devised to assess the function of the human sense of smell. Many of these tests have been modeled on procedural and mathematical concepts developed in the mid-nineteenth century by Weber (1834) and Fechner (1860), and by Thurstone, Stevens, and others in the twentieth century (e.g., Anderson, 1970; Thurstone, 1927a,b; Stevens, 1961). Tests derived from these traditions include absolute detection thresholds (the lowest odorant concentration that can be perceived), differential thresholds (the smallest difference in concentration of a given chemical that can be perceived), and various indices of suprathreshold sensation magnitude. Most of these tests were developed within the theoretical framework of establishing mathematical rules or laws that govern the build-up of suprathreshold sensation relative to stimulus intensity. To achieve all of these ends, well-defined stimuli (e.g., single chemicals of known chemical purity) were usually employed, allowing for straightforward stimulus specification.

In addition to these developments, other trends resulted in the development or application of tests more useful in applied settings. For example, eighteenth and nineteenth-century physicians simply presented familiar odorants to patients to see if they could be identified, usually without insight into prior psychophysical developments. In the twentieth century relatively sophisticated procedures were developed within the food industry (e.g., the forced-choice triangle test; Helm and Trolle, 1946; Peryman and Swartz, 1950), where the need exists to quantify the acceptability of various product formulations in

relation to perceived qualitative attributes. Unlike the academic psychophysical traditions, and akin to the clinical traditions, the stimuli were generally chemically complex, that is, not made up of single chemicals. Although quantitative, the metrics employed in these paradigms were more operational and rarely linked to physicochemical properties such as odorant concentration.

More recently, techniques have been developed to study odor perception arising from stimuli within the oral cavity, i.e., so-called retronasal odor perception (Burdach and Doty, 1987; Bender et al., 2009; Chen and Halpern, 2000; Croy et al., 2014; Heilmann et al., 2002). The measurement of such perception has practical consequences for both clinicians and food manufacturers, given the critical role of olfaction in determining the flavor of foods and beverages.

The present chapter has two major goals. The first is to provide the reader with an overview of the quantitative methods currently available for assessing the sense of smell, regardless of the historical traditions that led to their development. Emphasis is placed on the relative utility of various approaches for achieving this end. The second goal is to examine elements of odor mixture perception, including how well individual components can be discerned. An understanding of odor mixture processing is of value in elucidating how the olfactory system works, as its neural architecture seems to be designed to filter or collapse complex arrays of chemical information into distinct, interpretable, and manageable percepts. Although many of the examples described in this chapter come from clinical studies, the tenants of the chapter are broadly applicable to settings outside the clinic, including industrial and regulatory ones.

## 11.2 STIMULUS CONTROL AND PRESENTATION

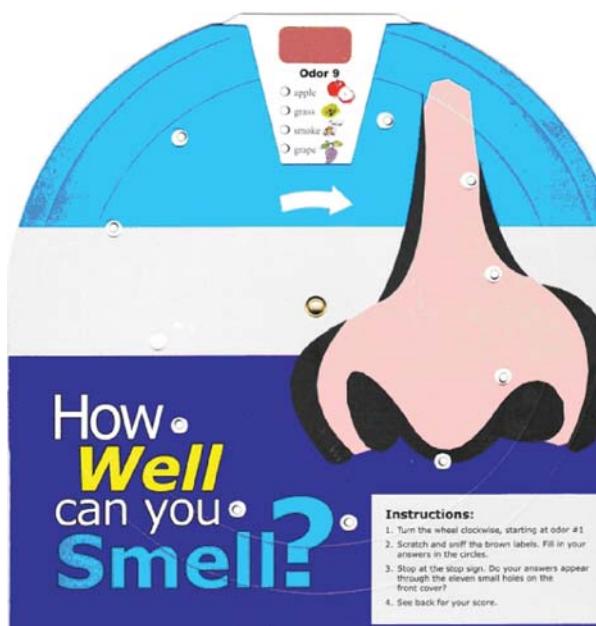

In some chemosensory paradigms, extremely accurate stimulus specification is required, and elaborate olfactometers and other devices for presenting known concentrations of odorants in specific quantities for various durations have been devised (for review, see Prah et al., 1995). This is particularly true for devices employed in human chemosensory electrophysiology (Chapter 12) and in research that requires precise measurement, such as that involved in establishing regulatory guidelines or relationships among physicochemical parameters of odorants and perceptual processes (Schmidt and Cain, 2010). In other paradigms, including those related to assessing olfactory function in patients, such precision is not necessary. The requirement is only that the odorants are presented in a reliable manner and that norms are available to establish whether a patient's responses are normal or abnormal. Thus, accurate clinical assessment of chemosensory function can be made using surprisingly simple stimulus presentation equipment.

As illustrated in Figure 11.1, devices that have been used to present odorants to humans include (a) the draw tube olfactometer of Zwaardemaker (1925, 1927), (b) glass sniff bottles and specialized cannisters (Cheesman and Townsend, 1956; Doty et al., 1986; Frank et al., 2003; Nordin et al., 1998), (c) odorized glass rods, wooden sticks, felt-tipped pens, alcohol pads, plastics embedded with odorants, or strips of blotter paper (Semb, 1968; Toyota et al., 1978; Davidson and Murphy, 1997; Hummel et al., 1997; Saito, 2006; Simmen et al., 1999), (d) plastic squeeze bottles (Amoore and Ollman, 1983; Cain et al., 1988; Doty, 2000; Guadagni et al., 1963), (e) bottles from which blasts of odorized air are presented (Elsberg and Levy, 1935; Ikeda et al., 1999), (f) microencapsulated "scratch and sniff" odorized strips (Doty, Agrawal and Frye, 1989; Cameron and Doty, 2013; Doty et al., 1984a; Richman, 1992; Doty, 1995), (g) laboratory based air-dilution olfactometers (Cheesman and Kirkby, 1959; Cook et al., 2014; Doty et al., 1988; Hayes et al., 2013; Kobal and Plattig, 1978; Johnson and Sobel, 2007; Lorig et al., 1999; Lundström et al., 2010; Philpott et al., 2009; Punter, 1983; Schmidt and Cain, 2010; Schriever, 2011; Sezille et al., 2013; Walker et al., 1990; Wenzel, 1948) and (h) exposure chambers, including mobile units with analytical equipment and subject waiting rooms (e.g., Berglund et al., 1984; Dalton et al., 1997; Springer, 1974).

Stimulus presentation devices that increase the speed and reliability of olfactory testing for both adults and children have recently been developed. These include a game-like rotating disk test for measuring function in children (Figure 11.2), an olfactometer that allows for computerized self-administration of threshold, discrimination, memory, and identification tests, among others (Figure 11.3), and stimulus presentation wands that allow

**Figure 11.1** Procedures for presenting odorants to subjects for assessment. a. Early draw-tube olfactometer of Zwaardemaker. In this apparatus, an outer tube made of rubber or another odorous material slides along a calibrated inner tube, one end of which is inserted into the subject's nostril. When the odorized tube is slid toward the subject, less of its internal surface is exposed to the inspired airstream, resulting in a weaker olfactory sensation. b. Sniff bottle. c. Perfumer's strip. d. Squeeze bottle. e. Blast injection device. The experimenter injects a given volume of odor into the bottle and releases the pressure by squeezing a clamp on the tube leading to the nostril, producing a stimulus pulse. f. Microencapsulated "scratch and sniff" test. g. Sniff ports on a rotating table connected to one of the University of Pennsylvania's dynamic air-dilution olfactometers. h. **Figure 11.2** Photograph of the front of the Smell Wheel, a game-like rotating odor identification test for assessing smell function of children. A disk containing odors rotates within a cardboard jacket, exposing one odor at a time in the top window. The child releases the odor from the microencapsulated brown taste strip and makes an answer and moves to the next odor. When all 11 items are marked, the correct answers appear in the holes around the front of the test. The test score is the number of holes that are filled in. This forced-choice test was designed to capture the child's imagination and to provide a standardized test measure with odors known to young people and a minimum number of trials. for rapid presentation of odors to subjects without removing the tops from sniff bottles or pen-like dispensers (Figure 11.4). These wands have the advantage of being able to use existing normative data and eliminate the touching of an odor source to the nose.

In addition to these approaches to stimulus presentation, intravenous administration of odorants has been used to produce chemosensory sensations. This approach, which is only rarely used today, was employed primarily by Japanese otolaryngologists in an attempt to assess whether the olfactory receptors are working when nasal congestion or blockage eliminates or mitigates airflow to the receptor region. The assumption underlying this technique is that the stimulus makes its way to the olfactory receptors via the bloodstream. Most commonly thiamine propyl disulfide (Alinamin) is injected into the median cubital vein, and recordings of the duration and latency of the onset of a garlic-like sensation experienced by the patient are made (see Takagi, 1989, for review). Although this procedure may be of value in some cases, there is controversy regarding its physiological basis (i.e., whether the stimulus reaches the receptors via diffusion from nasal capillaries,

from lung air, or both; see Maruniak et al., 1983). Furthermore, such testing is invasive, highly variable, not readily adaptable to forced-choice paradigms, and lacks normative referents.

**Figure 11.3** The self-administered computerized olfactory test system (SCOTS). The dome, which can be readily exchanged for other domes with different sets of odors, contains up to 40 odorants that can be individually released, or released in combinations, to the sniffing port. This system eliminates subject error in the presentation of test stimuli and allows for exact control of stimulus duration, interstimulus intervals, and other factors. ### 11.3 PSYCHOPHYSICAL TEST PROCEDURES

Any procedure that provides a quantitative measure of sensory function and requires a verbal or conscious overt response on the part of the examinee is generally considered a psychophysical procedure. In this section, the basic psychophysical paradigms available for measuring olfactory function are discussed and examples of their application are provided. The interested reader is referred to other sources for more detailed information about psychophysical methods, including their mathematical foundations (Ekman and Sjöberg, 1965; Gescheider, 1997; Guilford, 1954; Köster, 1975; Marks, 1974; Stevens, 1961; Tanner and Swets, 1954; Wise et al., 2000).

#### 11.3.1 Detection and Recognition Threshold Tests

A popular means for assessing chemosensory function is to establish, operationally, a measure of the lowest concentration of a stimulus that can be detected. A qualitative odor sensation (e.g., “banana-like”) is rarely perceived at very low odorant concentrations, where only the faint presence of something is noted. The absolute or detection threshold is the lowest odorant concentration where such a presence is reliably detected, whereas the recognition threshold is the lowest concentration where odor quality is discerned. In modern olfactory detection threshold testing, a subject is asked to indicate, on a given trial, which of two or more stimuli (e.g., a low concentration odorant and one or more non-odorous blanks) smells strongest, rather than to report whether an odor is perceived or not. Recognition thresholds are obtained in a similar manner, but the requirement is to report which one has the target quality. Such “forced-choice” procedures are less susceptible than non-forced choice procedures to contamination by response biases (i.e., the conservatism or liberalism in reporting the presence of an odor under uncertain conditions). In addition, they are typically more reliable and produce lower threshold values (Blackwell, 1953; Doty et al., 1995).

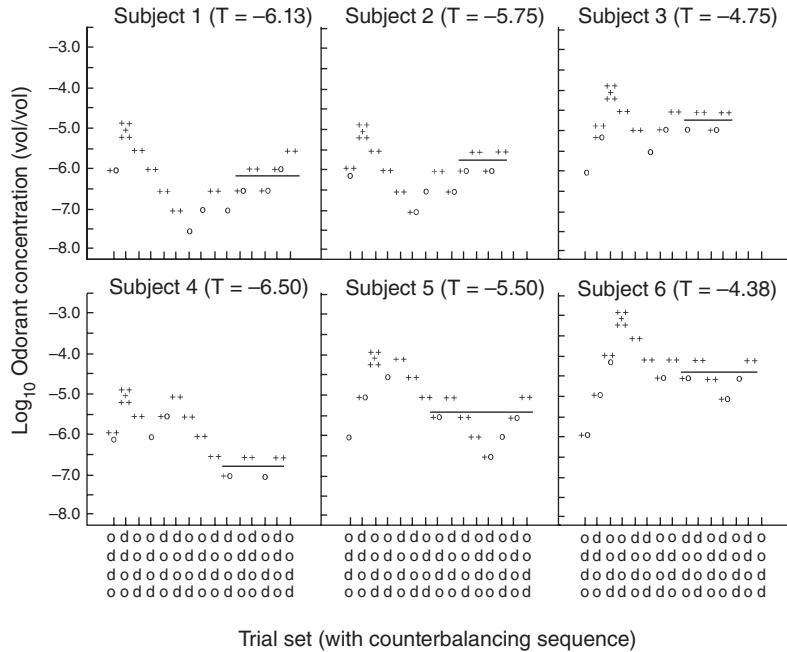

Two types of threshold procedures that have received the most clinical and industrial use are the ascending method of limits (AML) and the single staircase (SS) procedures. In the AML procedure, odorants are presented sequentially from low to high concentrations and the point of transition between detection and no detection is estimated. Forced-choice responses are required on each trial. Such a paradigm has been adopted by the water industry worldwide and codified by the American Society for Testing and Materials as E679-04 (ASTM, 2008; see also Lawless, 2010). Unfortunately, as noted in Chapter 49, this approach, as practiced following ASTM guidelines, is fraught with difficulties. In the SS method (a variant of the method of limits technique; see Cornsweet, 1962), the concentration of the stimulus is increased following

trials on which a subject fails to detect the stimulus and decreased following trials where correct detection occurs. In both these procedures, the direction of initial stimulus presentation is made from weak to strong in an effort to reduce adaptation effects of prior stimulation (see Pangborn et al., 1964).

An example of a clinical application of the AML procedure is provided by Cain (1982) who used 60-ml glass sniff bottles to present either water (diluent) or odorant (*n*-butanol dissolved in water) to 43 patients with various degrees of olfactory dysfunction. Four repeated ascending series were presented to each side of the nose in a two-alternative, forced-choice format. This test, which took approximately half an hour per patient to administer, demonstrated that the olfactory dysfunction in these cases was typically bilateral.

An example of the clinical use of a SS procedure comes from a study that demonstrates loss of olfactory function in early Alzheimer’s disease (Doty et al., 1987). In this experiment, a trial consisted of the presentation of two 100-ml glass sniff bottles to the patient in rapid succession. One bottle contained 20 ml of a given concentration of phenyl ethyl alcohol dissolved in odorless propylene glycol, whereas the other contained mineral oil alone. The patient was asked to report which of the two bottles in a pair produced the strongest sensation. The first trial was presented at a  $-6.50$  log (liquid volume/volume) concentration step. If a miss occurred on any trial before five were correctly completed at that concentration, the process was repeated at one log concentration step higher. When five consecutive correct trials occurred at a given concentration level, the staircase was “reversed” and the next pair of trials was presented at a  $0.5$  log concentration step lower. From this point on, only one or two trials were presented at each step (i.e., if the first trial was missed, the second was not given and the staircase was moved to the next higher  $0.5$  log step concentration). When correct performance occurred on both trials, the concentration of the next trial was given at one half-log unit step lower. The average of the last four of seven staircase reversal points served as the threshold estimate. Examples of individual data obtained using the SS procedure are shown in Figure 11.5.

In general, threshold values are relative and dependent upon such factors as the method of stimulus dilution, volume of inhalation, species of molecule, type of psychophysical task, and number of trials presented (Pierce et al., 1996; Tsukatani et al., 2003). A number of investigators have noted that threshold measures often exhibit considerable intra- and intersubject variability. For example, in one study of 60 subjects, intersubject variation as great as 5 log units was reported (Brown et al., 1968). In another, in which a non-forced-choice ascending threshold procedure was used (the Japanese “T&T Olfactometer”), variation on the order of 16 log units was present among groups of 430–1000 young subjects (Yoshida, 1984).

**Figure 11.5** Data illustrating single-staircase detection threshold determinations. Each plus (+) indicates a correct detection when an odorant versus a blank is presented. Each minus (−) indicates an incorrect report of an odorant. Threshold value ( $T$ ; phenyl ethyl alcohol vol/vol in light USP grade mineral oil) is calculated as the mean of the last four of seven staircase reversals. Although the geometric mean is often employed to assess such measures, given that odorant concentration is already on a log scale, the arithmetic mean is preferred. The arithmetic means are indicated on the figure. The corresponding geometric means for the six respective subjects are:  $-6.11$ ,  $-5.74$ ,  $-4.74$ ,  $-5.47$  and  $-4.38$ . The o's and d's on the abscissa indicate the counterbalancing order of the presentation sequences for each trial and are read downward (o—odorant presented first, then diluent; d—diluent presented first, then odorant). In the first reversal point (where five correct sets of pairs occur at the same concentration), the fifth order sequence is determined by the first o or d of the subsequent column of four order sequences. Modified from Doty (1991) with permission. Copyright © 1991, Raven Press.

Stevens et al. (1988) obtained 60 threshold values over the course of 30 days from three subjects (20 for butanol, 20 for pyridine, and 20 for  $\beta$ -phenylethylmethylethylcarbinol). These investigators found that the within-subject variability across test days was as great as the between-subject variability on a given test day, suggesting to these authors that the large individual differences observed in threshold values are not a reflection of big differences among stable threshold values of subjects, but reflected large day-to-day fluctuations in the test measures. Unfortunately, much of this fluctuation likely reflects the use of the single ascending detection threshold technique in which the apparent limen is traversed only once. Test procedures incorporating more trials, such as the SS procedure, produce less variable measures and, when employed, do not exhibit as marked day-to-day fluctuations. The reliability of such procedures is discussed later in this chapter.

### 11.3.2 Difference Threshold Tests

In classical psychophysics, the smallest amount by which a stimulus must be changed to make it perceptibly stronger or weaker is termed a “just noticeable difference” or JND. This value is also called a difference or differential

threshold (in contrast to an absolute threshold, as described above). The size of the increment in odorant concentration ( $\Delta I$ ) required to produce a JND increases as the comparison concentration ( $I$ ) increases, with the ratio approximating a constant; i.e.,  $\Delta I / I = K$  (Weber's law; Weber, 1834).  $K$  is a rough index of the sensory system's sensitivity (i.e., the smaller the  $K$  value, the more sensitive the system is to fine changes in stimulation). However, numerous studies suggest that  $K$  is not a constant, being influenced by the size of  $I$ , particularly at the extremes of the sensory continuum (Doty, 1991; Hidalgo et al., 2011).

An example of a brief clinical test used to establish a difference threshold is described by Eichenbaum et al. (1983). In this test, 10 binary dilutions (in water) of acetone, ethanol, almond extract, and lemon extract were presented. Initially, the highest and lowest concentrations of a given odorant were presented and the subject was required to choose the stronger stimulus. Successively stronger stimuli were then paired with the strongest stimulus until, on the last of the 10 trials, the two samples were identical. Eichenbaum operationally defined the difference threshold as the lowest concentration for which discrimination up to and including the dilution was effortless.

### 11.3.3 Signal Detection Tests

Signal detection theory (SDT) differs fundamentally from the approach of sensory measurement inherent in classical threshold theory. Thus, SDT rejects the notion of a threshold (whether absolute or differential), and focuses on (a) noise and signal plus noise as the milieu of the detection situation and (b) the influences of subject expectancies and rewards on the detection decision. Signal detection procedures provide both a measure of sensory sensitivity and the subject's response criterion or bias (Tanner and Swets, 1954). In effect, the response criterion is the internal rule used by a subject in deciding whether or not to report detecting a stimulus (e.g., the liberalism or conservatism in reporting a sensation under uncertain circumstances). For example, two subjects may experience the same subtle degree of sensation from a very weak stimulus. One, however, may report that no sensation was perceived (e.g., perhaps because of lack of self-confidence), whereas the other may report the presence of the sensation. In both cases, the stimulus was perceived to the same degree. However, the two subjects had different criteria for reporting its presence. In a traditional non-forced-choice detection threshold paradigm, the investigator would conclude that these two subjects differed in sensitivity to the stimulus, when, in fact, they only differed in regards to their response biases.

Expectation is not a trivial matter, as it can significantly increase the variability of threshold measures. A classical example of the role of expectation, as well as perhaps group pressure, was noted in class demonstration by Slosson in 1899 (p. 407):

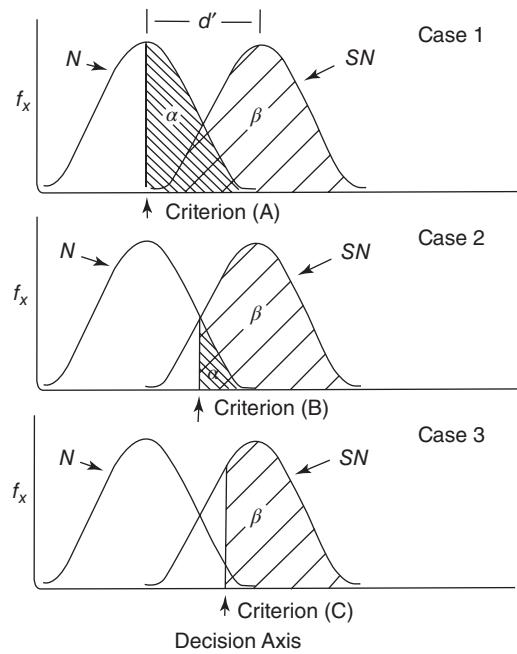

I had prepared a bottle filled with distilled water carefully wrapped in cotton and packed in a box. After some other experiments I stated that I wished to see how rapidly an odor would be diffused through the air, and requested that as soon as anyone perceived the odor he should raise his hand. I then unpacked the bottle in the front of the hall, poured the water over the cotton, holding my head away during the operation and started a stopwatch. While awaiting the results I explained that I was quite sure that no one in the audience had ever smelled the chemical compound which I had poured out, and expressed the hope that, while they might find the odor strong and peculiar, it would not be too disagreeable to anyone. In fifteen seconds most of those in the front row had raised their hands, and in forty seconds the "odor" had spread to the back of the hall, keeping a pretty regular "wave front" as it passed on. About three-fourths of the audience claimed to perceive the smell ... More would probably have succumbed to the suggestion, but that

at the end of a minute I was obliged to stop the experiment, for some on the front seats were being unpleasantly affected and were about to leave the room ...

Signal detection theory was designed not only to overcome such problems, but, as noted above, to provide a quantitative measure of the response criterion. SDT assumes that a stimulus is imbedded within a background of noise. Noise can arise from a variety of sources and can be conceptualized at a number of levels (e.g., variations in attention, stimulus fidelity, neural firing unrelated to the stimulus, fluctuations in distracting physiological processes). In most cases noise is assumed to be normally distributed (as is done here to simplify discussion). Whenever a signal is added to the "noise" (N) distribution, a "signal plus noise" (SN) distribution results. Both the N and SN distributions can be placed on the same set of axes, as shown in Figure 11.6. The measure of the subject's sensitivity is the distance between the means of these distributions, signified as  $d'$ .

The concept of the response criterion is also illustrated in this figure (Doty, 1991). Given constant sensitivity ( $d'$ ), on any given trial a low-concentration odorant (SN) or a blank stimulus (N) is presented, and the subject's task is to report whether or not an odor was presented. Reports of "yes" are represented by the areas under the N and SN curves to the right of the vertical line depicting the subject's response criterion, whereas reports of "no" are indicated by the areas to the left of this line. In case 1, the subject exhibits a very liberal criterion, reporting the presence of an odor on the majority of the SN trials ( $\beta$ ) and on half of the N trials ( $\alpha$ ). Thus, although correct detection of the odorant occurred nearly all of the time ( $\beta$ ), many false alarms ( $\alpha$ ) were present. Perhaps in this instance the subject was rewarded for reporting the detection of an odor and not admonished for making false alarms. In case 2, the subject chose a less liberal response criterion. Although fewer correct detections of the odor were made ( $\beta$ ), fewer false alarms were also made ( $\alpha$ ). In case 3, the observer chose a very conservative response criterion, making few false alarms but similarly making fewer correct detections. This would tend to result, for example, when a subject is penalized for making false positives and given few rewards for successful detection of the odor. In all three of these hypothetical cases, the sensitivity (i.e.,  $d'$ ) was equivalent, as indicated by the constant distance between the N and SN distributions.

In a typical olfactory experiment employing SDT, the subject is presented with a large number of trials of a single low concentration of odorant interspersed with blank trials (Doty et al, 1981; Semb, 1968). Even though the number of blank and odorant trials need not be equivalent, this is commonly the case. The proportion or percent of the total odor trials (S) on which a subject reports detecting an odor (the hit rate) is calculated, as is the percent of blank trials (N) on

**Figure 11.6** Hypothetical distributions of signal plus noise (SN) and noise alone (N) plotted on the same axes. When the strength of the perceived signal increases, the SN distribution moves to the right, increasing  $d'$ , the measure of the distance between the two distributions in standard deviation units (z scores). The response criterion can vary when perceptual sensitivity ( $d'$ ) remains constant. In case 1, a liberal criterion was chosen in which a relatively large number of false positives occurred (i.e.,  $\alpha$ , the reports of the presence of odor when the blank (N) is presented). In cases 2 and 3 more conservative criteria were chosen, decreasing both the number of false positives ( $\alpha$ ) and hits ( $\beta$ ). Traditional threshold measures confound the influences of perceptual sensitivity and the setting of the response criterion. Reprinted from Doty (1976) with permission. Copyright © 1976, Academic Press.

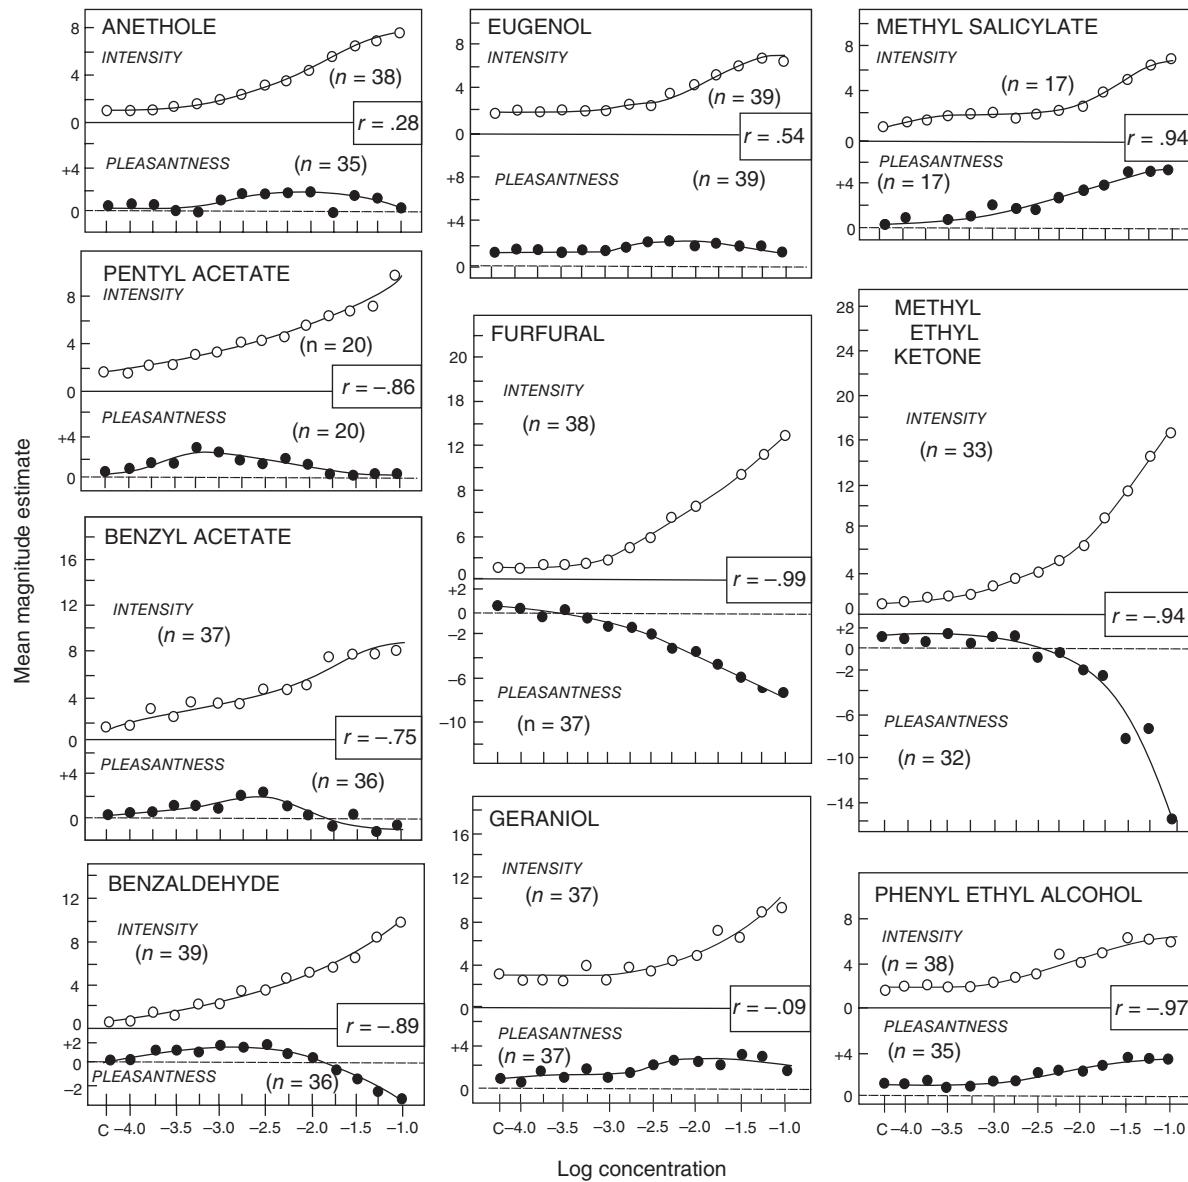

which an odor is reported (the false alarm rate). The parametric sensitivity measure,  $d'$ , can then be computed by converting the proportions to normal distribution standard deviation values (z-scores) via a normal probability table;  $d'$  equals the z-score for hits minus the z-score for false alarms. More convenient procedures for determining  $d'$  for any combination of hit and false alarm proportions include the use of the table provided by Elliot (1964) and various free online calculators, such as that of ComputerPsych LLC: [http://www.computerpsych.com/Research\\_Software/NormDist/Online/Detection\\_Theory?hits=10&fa=5&misses=5&cr=5](http://www.computerpsych.com/Research_Software/NormDist/Online/Detection_Theory?hits=10&fa=5&misses=5&cr=5). In addition, nonparametric signal detection measures are also available (Brown, 1974; Frey and Colliver, 1973; Grier, 1971; Hodos, 1970; but see Macmillan and Creelman, 1996), as are methods for testing the parametric assumptions of traditional signal detection analyses (Gescheider, 1995; Green and Swets, 1966).

The classical parametric measure of response bias is termed  $\beta$ . Not to be confused with the  $\beta$  in Figure 11.6,  $\beta$  represents the ratio, at the criterion point, of the ordinate of the SN distribution to that of the N distribution. This value can be easily calculated from the hit and false-alarm rates by use of ordinate values from the normal curve, as discussed by Gescheider (1995). The aforementioned online calculator computes both  $d'$  and  $\beta$ .

Despite the fact that hundreds of trials have been traditionally used in signal detection studies, some chemical senses studies have employed far fewer trials, largely due to practicality. For example, Potter and Butters (1980) and Eichenbaum et al. (1983) computed  $d'$  using only 30 test trials. Even though such estimates are somewhat unstable (because a test's reliability is usually a function of its length), they may be less so than typically assumed, and there is at least some empirical rationale for the use of abbreviated signal detection tests. Thus, O'Mahony et al. (1979b), in a study of gustatory sensitivity to sodium chloride, found that Brown's (1974) nonparametric R index fell, after 40 trials, within 5% of the values obtained after 200 trials in slightly over half the subjects tested. However, an analogous olfactory study has not been performed, and ideally all of the subjects should evidence such response stability. For these reasons, it is prudent to use as many trials as possible in signal detection tasks.

### 11.3.4 Suprathreshold Scaling Procedures

A number of psychological attributes can be assigned to odors, including strength, hedonics (i.e., pleasantness/unpleasantness), and quality. These attributes change as a function of concentration, although odor quality is more stable and hedonics is more variable and idiosyncratic (Doty, 1975). Importantly, associations between hedonics and intensity are not always linear and are dependent upon odorant concentration (Figure 11.7). Because the intensity of a stimulus is related to the number of neurons that are recruited and the frequency at which they fire, suprathreshold measures of intensity may relate to the extent of neural damage present in the afferent pathway (Drake et al., 1969). However, suprathreshold rating or scaling methods may be less sensitive, at least in some cases, to olfactory dysfunction than a number of other methods (e.g., detection threshold tests and tests of odor identification). They do, however, have the advantage of being relatively brief, easy to administer, and less susceptible than threshold tests to subtle stimulus contamination. Moreover, negative findings must be conservatively interpreted. While it is true that suprathreshold rating scales have completely missed major changes in olfaction observed by other methods (e.g., the influences of age on olfactory function; see Rovee et al., 1975), it is also possible that they may be

**Figure 11.7** Relationship of pleasantness and intensity magnitude estimates to odorant concentration (log vol/vol) in propylene glycol for 10 odors. C = control (propylene glycol alone).  $r$  = Pearson product moment correlation between intensity and pleasantness estimates across data points differing significantly in intensity from control. All correlations significant beyond the 0.01 level with the exception of those for anethole ( $p > 0.20$ ), eugenol ( $p > 0.06$ ), and geraniol ( $p > 0.20$ ). Lines fitted to data points by visual inspection. Modified from Doty (1975).

measuring processes quite different from those measured by thresholds and most other tests and that such processes are, in fact, preserved in aging and some age-related diseases. In other words, they could be measuring aspects of perceptual activity that go undetected by many other methods (Doty et al., 1994; see, however, Doty et al., 2014).

Rating scales are a popular means for assessing the relative amount of a suprathreshold sensory stimulus or psychological attribute perceived by a subject. Such scales have been used for more than a thousand years (for review,

see McReynolds and Ludwig, 1987). Galen, for example, employed a rudimentary hot-cold scale that later led to hot and cold body temperature scales employed by physicians until the nineteenth-century development of practical clinical thermometers. Christian Thomasius (1655–1728) used rating scales to measure such psychological attributes as acquisitiveness, sensuousness, and social ambition and, in 1807, the British navy adopted a 12-point rating scale for assessing wind strength (0 = calm, 12 = hurricane). The first use of a rating scale in the chemical senses appears to be that of Fernberger (1932), who had subjects categorize

the taste of a bitter tasting agent, PTC, into the categories of “tasteless,” “slightly bitter,” “bitter,” “very bitter,” and “extremely bitter.”

In olfactory assessment, two types of scales are most popular: category scales, where the relative amount of a sensation is signified by indicating which of a series of discrete categories best describes the sensation, and line scales (also termed visual analog or graphic scales), where the subject or patient indicates the strength of the sensation by placing a mark along a line that has descriptors (termed anchors) located at its extremes (e.g., very weak–very strong). For discussions of the general properties of these and other scales, including the influence of category number on their psychometric properties, see Anderson (1970), Guilford (1954), Hjermstad et al. (2011), Markon et al. (2011), and Preston and Colman (2000).

As pointed out by Bartoshuk and her associates in Chapter 34, across-group comparisons using traditional rating scales can be problematic for a number of reasons. One problem is that labels at the ends of scales, such as “very strong,” do not necessarily mean the same to all persons and are context dependent. As she noted elsewhere (Bartoshuk et al., 2005, p. 122),

A woman giving birth might describe her pain as “very strong,” but she might also describe a cup of tea as “very strong.” Clearly the sensory intensities of the experiences are different; a listener understands that “very strong” depends on the sensory context to which it is applied. It is useful to think of sensory descriptors as printed on an elastic ruler; their relative positions on the ruler are essentially fixed, but the entire ruler can be stretched or compressed to fit the domain of interest.

Classic rating scales also suffer from the tendency of subjects to group responses at the extreme end of the scale (i.e., a ceiling effect). In an attempt to overcome this problem, a number of scales have been developed in which logarithmic-like elements have been incorporated into their design in an effort to more closely mimic ratio-like properties of magnitude estimation procedures (see below) (e.g., Borg, 1982; Neely et al., 1992; Green et al., 1996). In some such scales, verbal anchors are positioned along strategic points of the scale where they seem most appropriate.

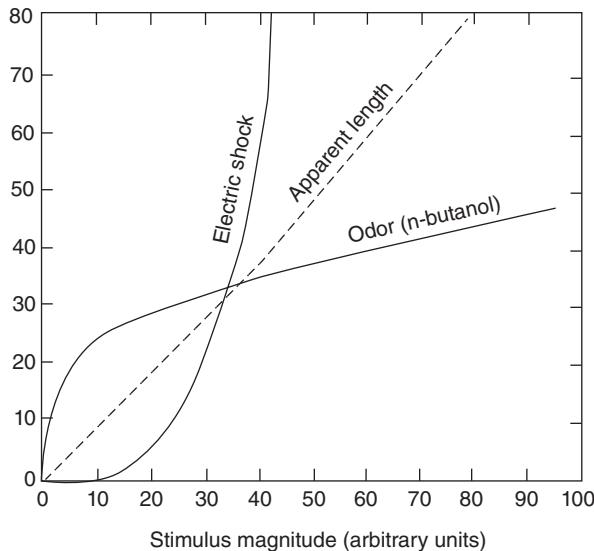

A more sophisticated means for understanding the build-up of odor intensity as a function of stimulus concentration involves magnitude estimation. In this procedure, the relative magnitude of each member of a stimulus set is estimated by employing some other sensory modality or cognitive domain in making the assessment. A key difference between this procedure and rating scale procedures is that the *ratio relations among the intensities (or other attributes) of the stimuli are estimated*, and a subject’s responses are not confined to categories or a short response

line. Continua commonly used in magnitude estimation tasks for intensity include number (e.g., assigning numbers proportionate to an odor’s intensity) and distance (e.g., pulling a tape measure a distance proportional to an odor’s intensity) (Berglund et al., 1971; Stevens, 1961).

In the most common magnitude estimation procedure, the subject assigns numbers relative to the magnitude of the sensations. For example, if the number 60 is used to indicate the intensity of one concentration of an odorant, a concentration that smells four times as intense would be assigned the number 240. If another concentration is perceived to be half as strong as the initial stimulus, it would be assigned the value 30. In some cases, a standard for which a number has been pre-assigned (often the middle stimulus of the series) is presented to the subject in an effort to make his or her responses more reliable. In other cases, the individual is free to choose any desired number system, so long as the numbers are made proportional to the magnitude of the attribute (the “free modulus method”). The important point is that, in this specific paradigm, the absolute values of the numbers are not the key element of interest, only the relations between the numbers.

To obtain an index of suprathreshold function, magnitude estimation data are most commonly plotted on log-log coordinates (log magnitude estimates on the ordinate and log odorant concentrations on the abscissa) and the best line of fit determined using linear regression. The resulting function,  $\log P = n \log \Phi + \log k$ , where  $P$  = perceived intensity,  $k$  = the Y intercept,  $\Phi$  = stimulus concentration, and  $n$  = the slope, can be represented in its exponential form as a power function,  $P = k\Phi^n$ , where the exponent  $n$  is the slope of the function on the log-log plot. In olfaction,  $n$  varies in magnitude from odor to odor, but is generally less than 1, reflecting a negatively accelerated function on linear-linear coordinates (Figure 11.8). As noted elsewhere, various investigators have made modifications in these equations in an attempt to take into account differences in such factors as threshold sensitivity, vapor pressures, and adaptation (Doty, 1991; Jones, 1958; Overbosch, 1986).

It is noteworthy that magnitude estimation, like most other sensory procedures, can be biased or influenced in systematic ways by procedural and subject factors (Doty, 1991; Jones, 1966; Marks, 1974). The magnitude estimation task is relatively complex in that accurate responses to a stimulus require a good memory for the prior stimulus. If too much time lapses between the presentations of stimuli, the memory of the prior stimulus fades. On the other hand, if the trials are spaced too closely together, adaptation can distort the relationship. Not all subjects consistently provide ratio estimates of stimuli, and a number do not understand the concept of producing ratios (Baird et al., 1970; Moskowitz, 1977). Comparison stimuli can alter the stimulus function; for example, moderately intense odor is reported to be more intense when presented with weak com-

**Figure 11.8** Relationship between perceived magnitude of three types of stimuli, as measured by magnitude estimation, and stimulus magnitude. Note that the perceived intensity of the example odorant increases in a negatively accelerated fashion, indicating a power function exponent less than 1 (i.e., in this case 0.33). parison stimuli than with strong comparison stimuli) (Helson, 1964; Eyman et al., 1975). Moreover, the magnitude of the exponent is dependent on the choice of the stimulus scale (i.e., the units in which the stimulus concentration is expressed), although in olfaction this is probably of minor consequence (Myers, 1982). As in other sensory systems, the assignment of a standard will influence the obtained slope as will the range of presented stimuli. In general, subjects have a preferred range of numbers they assign to whatever range of stimuli that is presented. Sets of stimuli of a restricted range generally yield larger exponents than those of a more expansive range; that is, spreading the same set of numbers over a smaller stimulus range yields a steeper slope (Jones and Woskow, 1966).

The degree to which these and other potential shortcomings hinder the use of magnitude estimation procedures in applied settings, such as the clinic, is not known; however, it is likely that such problems can be minimized by ensuring that the instructions, test procedures, and test stimuli are carefully standardized and monitored. Comparative assessments of nine-point rating scales, line scales, magnitude estimation scales, and a hybrid of category and line scales suggest that, for untrained or mathematically unsophisticated subjects, category scales and line scales may be superior to magnitude estimation when such factors as variability, reliability, and ease of use are considered (Lawless and Malone, 1986a,b). For such reasons, the use of labeled

scales that take into account the exponential aspects of sensory perception, such as the scale developed by Green et al. (1996), would seem preferable.

Since the magnitude estimation function's intercept and height above the origin depend on idiosyncratic differences in the use of numbers and the specific magnitude estimation method employed (e.g., fixed vs. free modulus), only its slope has traditionally been used as an index of sensory function. In an attempt to gain additional information from the function's ordinate position, investigators have employed the method of cross-modal magnitude matching, which provides, at least theoretically, information about the perceived intensity of stimuli from the absolute position of the magnitude estimation function and corrects, to some degree, for differences among subjects in number usage or other idiosyncratic responses (for a detailed discussion of this procedure, see Marks et al., 1988). In a common application of this method, judgments of the intensity of sensations from two sensory modalities (e.g., loudness and odor intensity) are made on a common magnitude estimation scale (Marks et al., 1986). Under the assumption that subjects experience stimuli on one of the continua (i.e., loudness) in a similar manner (an assumption that some question), differences among their loudness ratings would be expected to reflect differences in number usage. The odor intensity continuum can then be adjusted accordingly. Such normalization allows, theoretically, for a direct comparison of scale values across subjects; thus, if the adjusted odor intensity magnitude value for one subject is 10 and for another subject is 20 at the same concentration level, the second subject is presumed to experience twice the odor intensity as the first subject.

### 11.3.5 Quality Discrimination Tests

The most straightforward chemosensory quality discrimination test requires individuals to decide whether two stimuli have the same or different quality. In one scenario, a series of same-odorant and different-odorant pairs is presented, and the proportion of pairs that are correctly differentiated is taken as the measure of discrimination (Potter and Butters, 1980; O'Mahony, 1979a,b). Variants on this theme include picking the “odd” stimulus from a set from which only the “odd” stimulus differs, either at a constant delay interval (Frijters et al., 1980; Hummel et al., 1997) or at varying delay intervals (Choudhury et al., 2003), the latter allowing for the assessment of short-term memory in addition to basic discrimination. A recently developed discrimination test employs a set of 15 stimuli representing pairs of different ratios of two odorants from a set of six odorants (Weierstall and Pause, 2012).

Another form of discrimination test is based on a procedure called multidimensional scaling (MDS). In one variant of this procedure, ratings are made for all possible

pairs of stimuli (or selected subsets of pairs) on a line scale anchored with descriptors like “completely different vs. exactly the same,” and the correlation matrix among these ratings is subjected to an algorithm that places the stimuli in two or more dimensional space relative to their perceived similarities (e.g., Schiffman et al., 1981). The process is akin to constructing a map of a country from a list of distances available between the cities of that country. Persons with poor discrimination abilities fail to discern differences and similarities among stimuli, as illustrated by multidimensional spaces that have no distinct or reliable groupings. Because of its time-consuming nature and the fact that statistical procedures for comparing one person’s MDS space to another’s (or to a norm) are poorly worked out, MDS has not been used routinely in the clinic. Interestingly, when subjects are asked to rate the similarity of stimuli that are only indicated to them by name (i.e., the odorants, *per se*, are never presented), stimulus spaces derived by MDS are analogous to those obtained by the actual use of the odorants (Carrasco and Ridout, 1993; Ueno, 1992). This implies that well-defined imagery, or at least conceptual representations, exist for odorous stimuli.

Wise and Cain (2000) used a response latency approach to determine the discriminability of unmixed odors and mixed odors. A clear monotonic relationship was found between latency and accuracy, with latency decreasing with accuracy. In addition, subjects required more time and made more errors in discriminations between binary mixtures and their unmixed components than between the unmixed components. It was concluded that this approach may provide a novel measure of differences in odor quality, since latency provides information about discriminability.

### 11.3.6 Quality Recognition Tests

Two general classes of quality recognition tests can be defined. In the first class, the subject is asked whether each stimulus of a presented set is recognized. Identification is not always required. As indicated at the beginning of the chapter, this procedure is relatively crude, despite the fact that it is perhaps the most common means used by neurologists to measure olfactory function (e.g., Sumner, 1962). In the second class, a patient is presented with a “target” stimulus and subsequently asked to select the target from a larger set of stimuli. The number of correct responses of a series serves as the test score.

A variant on this theme is the stimulus matching task, in which a set of stimuli are provided and the subject is required to match the stimuli, one by one, to those of a set of identical stimuli. As an example, Abraham and Matha (1983) presented patients with eight vials that contained four odorants (two vials per odor). The task was to pair up the equivalent two-vial containers. The number of pairs

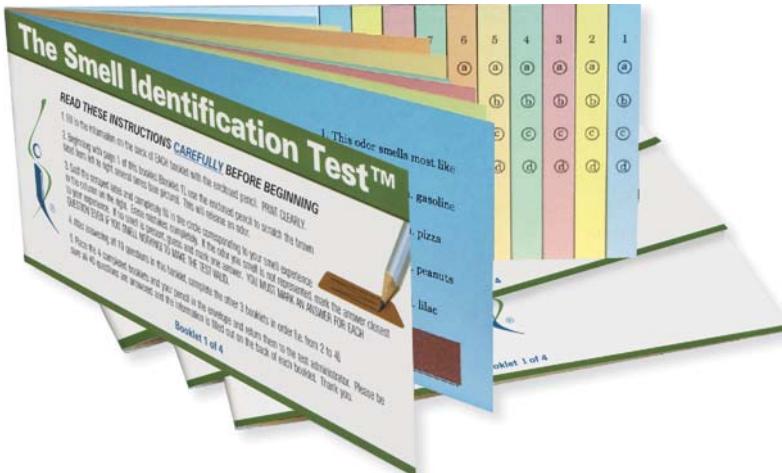

correctly matched on each of two administrations of the test was the test score.

### 11.3.7 Odor Identification Tests

Among the most popular procedures for assessing taste and smell function are those that require stimulus quality identification. Such tests can be divided into three groups: naming tests, yes/no identification tests, and multiple-choice identification tests. The respective responses required, on a given trial, in these three classes of tests are: (1) to provide a name for the stimulus, (2) to signify whether the stimulus smells like an object named by the examiner (e.g., does this smell like a rose?), and (3) to identify the stimulus from a list of names or pictures.

Odor naming tests in which no response alternatives are provided have been used clinically (e.g., Gregson et al., 1981), but are of limited value since many normal individuals have difficulty in naming or identifying even familiar odors without cues. Yes/no identification tests are much more useful, since they require a patient to report whether or not each of a set of stimuli smells like a particular substance named by the experimenter. Two trials with each stimulus are usually given, with the correct alternative provided on one trial and an incorrect one on the other (e.g., orange odor is presented and the subject is asked on one trial whether the odor smells like orange and on another trial whether the odor smells like peppermint). Although such a test requires the patient to keep the percept in memory long enough to compare it with the target word (which, of course, must also be recalled from memory), some of its proponents argue that it is less influenced by cognitive and memory demands than multiple-choice identification tests (see below). Since chance performance on this type of test is 50% compared to 25% on a four-alternative multiple-choice identification test, its range of discriminability is lower and therefore more trials are needed to obtain the same statistical power as the multiple-choice odor identification test.

Numerous multiple-choice odor identification tests have been described in the clinical literature (Bensafi et al., 2003; Cain et al., 1983; Doty et al., 1984a; Gregson et al., 1981; Wood and Harkins, 1987; Hummel et al., 1997; Simmen et al., 1999; Nordin et al., 1998; Wright, 1987). These tests are conceptually similar and, in the few cases that have been examined, strongly correlated with one another (Cain and Rabin, 1989; Doty et al., 1994; Wright, 1987). The most widely used of these tests — the University of Pennsylvania Smell Identification Test (UPSIT) — examines the ability of subjects to identify, from sets of four descriptors, each of 40 “scratch and sniff” odorants (Doty, 1995; Doty et al., 1984a,b) (Figure 11.9). The number of correct items out of 40 serves as the test measure. This value is compared to norms and a percentile rank is determined, depending on the age and gender of the subject (Doty, 1995). This

**Figure 11.9** The University of Pennsylvania Smell Identification Test (UPSiT; known commercially as the Smell Test) (Doty et al., 1984a). This test, developed in the early 1980's, is comprised of 40 microencapsulated odorants located next to forced-choice questions on each page of 10-page booklets. A subject's test score can be compared to peers employing norms based upon ~4,000 persons, allowing for a determination of absolute loss (mild, moderate, severe, total) as well as a percentile rank relative to the age and gender of the subject. Copyright © 2004, Sensonics International, Haddon Heights, New Jersey.

test has several unique features, including amenability to self-administration and a means for detecting malingering (see Section 11.6). Furthermore, it is available in 15 different language versions. The popularity of this test is attested to by the fact that hundreds of scientific publications have arisen from its use by investigators from many laboratories and clinics.

Several odor identification confusion matrix tests have been described that are applicable to clinical settings (Köster, 1975; Wright, 1987). The test that has been most widely applied is that of Wright (1987). In Wright's test, each of 10 suprathreshold stimuli are presented to a patient in counterbalanced order 10 times (100 total trials). The response alternatives are the names of the 10 stimuli: ammonia, chlorine bleach, licorice, mothballs, peppermint, roses, turpentine, vanilla, Vicks vapor rub, and vinegar. No feedback as to the correctness of the subjects' responses is given. The percentage of responses given to each alternative for each odorant is determined and displayed in a rectangular matrix (stimuli making up rows and response alternatives making up equivalently ordered columns). Responses along the negative diagonal therefore represent correct responses, whereas those that fall away from the diagonal represent "confusions." The percentage of correct responses is used as the main test measure, although some of its proponents argue that the confusions (off-diagonal responses) may provide meaningful clinical information.

The main limitations of Wright's confusion matrix are its long administration time (approximately 45 min) and the lack of evidence that the off-diagonal responses provide any meaningful clinical information (although such responses may be of value in detecting malingering; see Kurtz et al., 1999). It would seem that if off-diagonal responses are to be sensitive to aberrations or distortions seen in most clinical cases, more subtle differences in the response alternatives need to be employed within the matrix. Should subtle aberrations be reliably categorized, this approach would have considerable clinical value.

### 11.3.8 Memory Tests

As described in detail in Chapter 15, the measurement of odor memory is not always straightforward, particularly in relatively short tests applicable to clinic settings. In a typical odor recognition memory test, a subject is required to smell an odorant or a small set of odorants (termed the target or inspection stimulus or stimulus set) and to select, after an interval of time ranging from less than a minute to hours or even days, that odorant or set of odorants from foils (distractors). Repeated trials may be performed at one or more retention intervals for each of several stimuli or sets of stimuli.

Unfortunately, despite attempts to minimize labeling of the inspection odor with a familiar word or item on the part of a subject, such labeling often occurs and, thus, what is being measured across intervals is the memory of the label, not the memory of the odor. In other words, once an individual recognizes an odor as that of an orange, for example, all that has to be remembered over time is the concept "orange," not the specific smell of the orange. Later, when given stimuli from which to select the earlier perceived odor, the subject simply looks for the smell of an orange (which has been known and stored in long-term memory for much of his or her life). In effect, the odor is not what is being uniquely remembered over the retention interval, only its name or concept and remembrance of having smelled the substance.

For this reason, investigators have attempted to employ novel, nondescript, and unfamiliar odorants in such tasks (Møller et al., 2004). Unfortunately, it is difficult to find target odors that are not labeled by subjects as pleasant or unpleasant, fruity or non-fruity, medicine-like or non-medicine like, chemical-like or non-chemical like, etc. Importantly, it is important to recognize that performance across the delay intervals is what is assessing the "memory" component of the task, not necessarily the overall test score. A number of odor memory tests are,

in fact, essentially odor discrimination tests with varying inspection (delay) intervals. When scores on a nominal odor memory task differ between two groups (as evidenced by a main group effect in an analysis of variance), then a significant interaction term between delay interval and group would indicate an effect on memory, *per se*. Without an interaction with delay interval, the difference could simply reflect discrimination, not memory.

A number of examples of clinical applications of odor memory tests are available from the literature, although convincing evidence for a true odor memory deficit is lacking in most cases.

Campbell and Gregson (1972) developed a test of short-term odor memory in which four odors in a row were presented and the patient was asked if the fourth, which was the same as one of the first three, was equivalent to the first, second, or third odorant. No delay interval, *per se*, was defined between the presentation of the stimuli, but presumably the trials were presented closely after one another. Seven three-odor combinations of 12 inspection stimuli were administered. Patients who had difficulty with this task were subsequently given two-odor combinations. The test score was the number of odors that were consistently recognized by the subject. This test was shown to be sensitive to olfactory deficits due to schizophrenia (Campbell and Gregson, 1972), Kallmann's syndrome (Gregson and Smith, 1981), and Korsakoff psychosis (Gregson et al., 1981).

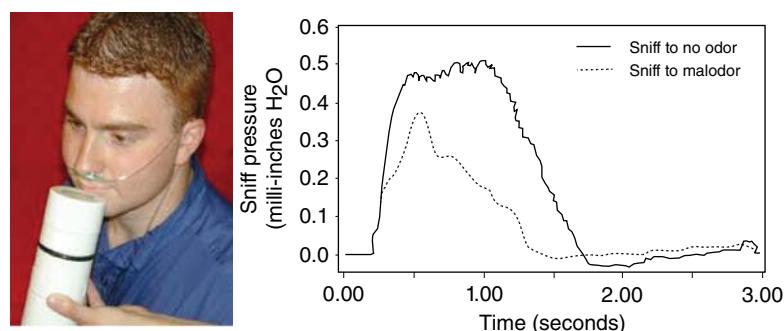

Jones et al. (1975) presented 20 pairs of odorants at 0- and 30-sec delay intervals to 14 alcoholic Korsakoff psychosis patients, 14 alcoholic controls, and 14 nonalcoholic controls. On a given trial, the subject's task was to report whether the second stimulus was the same as or different from the first. In the 30-sec delay interval, the subjects counted backward by threes in an effort to minimize semantic labeling. Since the Korsakoff psychosis

patients performed significantly more poorly than did the control groups at *both* the 0- and 30-sec retention intervals, it is questionable whether odor memory, *per se*, is the main trait being influenced in this case.

Jones-Gotman and Zatorre (1993) reported that—in patients having undergone surgical cerebral extirpation for control of epilepsy—odor memory impairment was evident between the controls and two of the eight surgical groups evaluated; namely, those who had received excision from the right temporal or right orbitofrontal cortices. The memory task consisted of eight target odors and eight new foils, and the yes-no recognition testing was performed twice after the initial testing—20 minutes later and 24 hours later. The authors interpret their findings as evidence of a “right hemisphere predominance in odor memory.”

### 11.3.9 Sniff Magnitude Test

In 2003, a novel test was developed which measures the change in respiration that occurs when an odorant, usually an unpleasant one, is smelled for the first time (Frank et al., 2003; Figure 11.10). Upon sniffing the canister, either fresh air or a malodor is released. Upon perceiving a malodor, subjects with a normal sense of smell inhibit their inhalation, with the timing and degree of the inhibition being related to the intensity and unpleasantness of the odor. The negative pressure is monitored by a tube at the base of the nose that is connected to a piezoelectric pressure transducer. Sniff pressure measurements are calculated every 10 ms once a sniff is detected and continue until return to ambient air pressure occurs. The *sniff magnitude ratio* is the ratio of the integrated sniff magnitude value given to a malodor to that obtained when sniffing non-odorized air. When suppression occurs more to an odorant than to air, this ratio is less than one.

**Figure 11.10** Left: Sniff Magnitude Test canister positioned for a sniff. Upon sniffing the top of the canister bad smelling odor or odorless air is released. The pressure changes during inhalation are signaled from the nasal cannula at the base of the nares to a pressure transducer. The digitized signal allows for the dynamics of the entire sniff epoch to be recorded by computer. Right: Top tracing represents a sniff to no odor (air); Bottom tracing represents a sniff to malodor. Note abrupt attenuation of sniff response upon encountering the malodor. Reprinted from Frank et al. (2004). Copyright © 2004 Elsevier Inc.

This type of test may be particularly useful in detecting malingering and in assessing persons who have difficulty verbalizing their responses. It does require, however, that an individual perceives and reacts to odor quality. Correlations ranging from 0.33 to 0.57 have been found between sniff magnitude ratios and measures of odor identification, memory and threshold detection (Tourbier and Doty, 2007), although, like some psychophysical tests (see Tsukatani et al., 2005), it does not differentiate well between various degrees of hyposmia. Principal component analyses suggest that the SMT may evaluate aspects of olfactory function somewhat distinct from those measured by most other tests, probably reflecting suprathreshold hedonics. A hood and well ventilated room is required for this test, given the very unpleasant nature of its stimuli.

## 11.4 TEST RELIABILITY

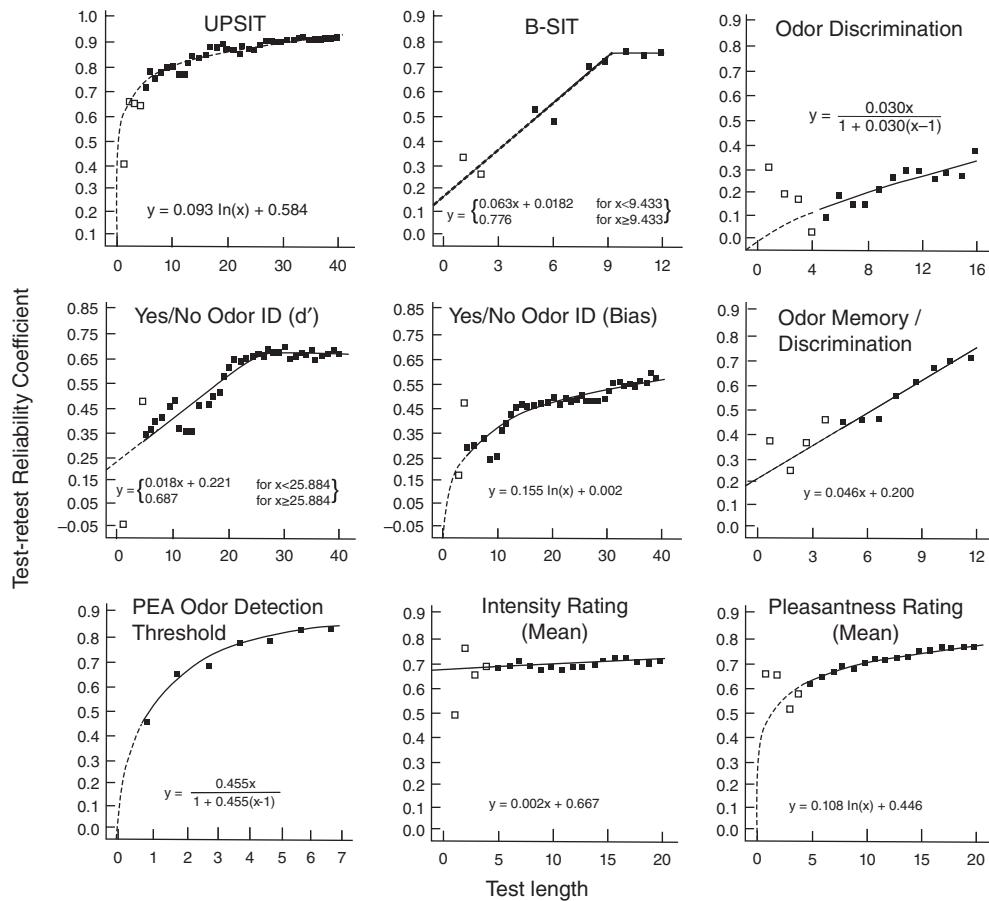

The utility of an olfactory test reflects the degree to which it is reliable (consistent, dependable, or stable) and valid (accurately measures what it portends to measure). Related to a test's validity are its sensitivity (ability to detect abnormalities when present) and specificity (ability to detect abnormalities with a minimum number of false positives). Although a test cannot be valid without being reliable, the reverse is not the case; that is, a test can be reliable but not valid. Despite the fact that measures of test reliability and validity are available for many medical and psychological tests, this is not the case for most olfactory tests. Indeed, measures of validity (other than a few intercorrelations among different tests) are extremely rare; hence, in this section studies of reliability are emphasized (for more discussion on this point, see Schwartz, 1991).

The reliability of a test can be determined in several ways. First, the test can be administered on two occasions to each member of a group of subjects and a correlation coefficient computed between the test scores on the two occasions (termed the *test-retest reliability coefficient* or the *coefficient of stability*). Second, when parallel forms of a test are available, the two forms can be administered to the same set of subjects and a correlation coefficient computed between the two forms. Third, subsections of some types of tests (e.g., multiple-item odor identification tests) can be correlated with one another to provide an estimate of test stability. The test is viewed, in this case, as consisting of parallel forms and the resulting coefficient, when based upon the correlation of half of the items with the other half of the items, is termed the *split-half reliability coefficient*. Since reliability is related to test length, as will be noted below, a statistical correction for test length must be applied to the correlation coefficient obtained in this way to provide the estimated reliability coefficient for the full test

(Guilford, 1954). A widely employed statistic, Cronbach's coefficient alpha, assesses the internal consistency of a test and is mathematically equivalent to the average of all possible split-half reliability coefficients of the test's items, given certain assumptions (e.g., that the item standard deviations are equal) (Cortina, 1993).

The magnitude of reliability coefficients depends, to a large degree, on the variation of the test scores of the group upon which they are computed. If all members of a group score exactly the same on a test administered on two test occasions, the reliability coefficient would be suspect, since there is no inter-individual variability. If only a small variation occurs among the subjects, then the reliability coefficient may be spuriously low. Importantly, if test scores are included from normal and patient groups, the reliability coefficient can be inflated. Thus, in assessing reliability one must have some understanding of the variation among the test scores. Also, it should be noted that while a high reliability coefficient indicates that a group of individuals scored similarly *relative to one another* on a test from one test occasion to the other, all of the individual's test scores still may be lower (or higher) on the second than on the first test occasion. In other words, systematic changes in the test values can occur which are not reflected in the reliability coefficient. In such a case, a high reliability coefficient is misleading to the extent that the overall stability of the test may vary systematically over time.

Since it has been reported that olfactory thresholds vary considerably among individuals and evidence considerable day-to-day fluctuations within the same individuals (e.g., Stevens et al., 1988), one might expect their reliability to be suspect. Indeed, reliability coefficients for various threshold tests do vary considerably from study to study, and extremely low reliability coefficients have been reported in some cases (e.g., Heywood and Costanzo, 1986; Punter, 1983). Nonetheless, particularly in cases where repeated estimates of the threshold are obtained, respectable reliability coefficients are evident. In general, forced-choice odor identification tests with a relatively large number of items exhibit a high degree of reliability, whereas shorter identification tests evidence lower reliability. Very short tests (e.g., three items) may exhibit spuriously high reliability coefficients, since smell abilities are forced into three broad categories. In general, longer tests exhibit higher reliabilities. The relationship between test length and reliability is shown for a number of olfactory tests in Figure 11.11. A listing of a number of olfactory test procedures applicable to clinical situations is provided in Table 11.1, along with reported reliabilities when indicated in the literature. Note that many of these

**Figure 11.11** Relationship of reliability to cumulative test length for test measures amenable to such an evaluation. Best fit formulae are indicated. Modified from Doty et al. (1995). Copyright © 1995 Oxford University Press.

reliabilities are unlikely to be statistically different from one another.

## 11.5 OTHER CONSIDERATIONS

### 11.5.1 Comparing Test Results from Nominally Distinct Olfactory Tests

Many studies make comparisons across olfactory tests having different names and operational constraints, for example, tests of odor identification, detection, discrimination, and memory. One must keep in mind, however, that despite their different names, such tests are not mutually exclusive and are usually correlated with one another (Doty et al., 1994). Thus, a test of odor identification requires the ability to detect an odor, as well as to remember the odor. A forced-choice threshold test requires a comparison of an odor or a weak sensation with alternatives, a task that again requires memory as well as discrimination. Differing degrees of semantic labeling may occur in odor discrimination tasks, just as occurs in odor identification tasks, again pointing to communalities among the procedures.

When differences are observed in findings among different “types” of olfactory tests, caution is warranted in their interpretation, not only for the reasons noted above, but because of test-related differences in reliability or sensitivity, employment of different odorants, and variations in non-olfactory operational elements of testing (e.g., ability to discriminate or identify independent of the ability to smell) (Hedner et al., 2010). Ideally, non-olfactory controls (e.g., tests in another modality to require the same operational tasks) should be employed to be certain that any deficits that are observed on a given test are not due to such non-olfactory factors. This is particularly true when mentation may be altered, as in head trauma or dementia. It is for this reason that we often employ the Picture Identification Test, a test essentially identical to the UPSIT but which uses pictures rather than odors as test stimuli (Vollmecke and Doty, 1985). If persons do well on this test, we know that the putative olfactory deficits are not due to lack of understanding the concepts involved in the test or to the non-olfactory operational procedures involved in taking the test.

**Table 11.1** Basic information for modern olfactory tests amenable to clinical settings. Abbreviations: ID, identification; DT, detection threshold; RT, recognition threshold; IR, intensity rating; DIS, discrimination; MEM, memory

Test	Type of Test	# of Odors or Items	Test-Retest Reliability Coefficient	Estimated Test Duration	Availability of Norms
<b>Alberta Smell Test</b> (Green & Iverson, 1998)	ID	8	Not Reported	10 min	NO
<b>Alcohol Sniff Test</b> (Davidson et al., 1998; Davidson & Murphy, 1997)	DT	1	0.80	<5 min	NO
<b>Amoore Threshold Test</b> (Amoore & Ollman, 1983)	DT	1	0.70	<10 min	NO
<b>Barcelona Smell Test</b> (Cardesin et al., 2006)	DT & RT	24	Not Reported	~30 min	NO
<b>Biolfa® Olfactory Test</b> (Bonfils et al., 2004)	DT & RT	3 & 8	Not Reported	~30 min	NO
<b>Brief Smell ID Test™</b> (aka Cross-Cultural Smell ID Test) (Doty et al., 1996; Liu et al., 1995)	ID	12	0.73	<5 min	YES

**Table 11.1** (Continued)

Test	Type of Test	# of Odors or Items	Test-Retest Reliability Coefficient	Estimated Test Duration	Availability of Norms
<b>University of Pennsylvania Smell Identification Test</b> (UPSIT; aka Smell Identification Test) (Doty, 1995; Doty et al., 1984a)	ID	40	0.94	10–15 min	YES
<b>Utrecht Odour ID Test</b> (Geur Identificatie Test Utrecht (GITU) (Hendriks 1988)	ID	18 or 36	0.68–0.77	30–45 min	NO
<b>Viennese Odor Test</b> (Lehrner & Deecke, 2000)	ID	20	0.75	15 min	NO

<sup>1</sup>Cain and Gent (1991) computed correlations between left:right sides of the nose (which some might consider an index of reliability) were much higher—butanol, 0.68; phenyl ethyl methyl ethyl carbinol, 0.96; isoamyl butyrate, 0.86; pyridine, 0.83.

<sup>2</sup>Reflects 15 pairs of stimuli, each pair being a mixture of two odorants selected from a total of six chemicals.

<sup>3</sup>Based upon sample containing normal subjects and patients with Parkinson's disease.

<sup>4</sup>These values are inflated given that only three response scores (1,2, or 3) were possible.

<sup>5</sup>When computed in a study population containing normosmics and patients with olfactory dysfunction, these values increased to 0.80 (discrimination), 0.88 (identification) & 0.92 (threshold) (Haehner et al., 2009).

<sup>6</sup>Doty et al. (1995) found test-retest reliability coefficients for DTs of the five odorants of this non-forced choice test (skatole, isovaleric acid,  $\gamma$ -undecalactone,  $\beta$ -phenyl ethanol, cyclotene) to range from 0.56 to 0.71; RT coefficients ranged from 0.22 to 0.45.

This brings up the question of whether one should add the results of tests of nominally different domains together, such as commonly done with Sniffin' Sticks in producing a “TDI” score (Hummel et al., 1997). There are, in fact, numerous problems with this simple additive approach. The most obvious one is that if one assumes that the elements to be combined are measuring different entities (e.g., identification, detection, discrimination), one person may do well on identification but poorly on detection, for example, and another may do well on detection but poorly on identification, with both ending up with the same combined score for quite different reasons. Thus, simply adding test scores together results in differential arbitrary weightings of the test components for each subject—weightings that are differentially influenced by each test's response scale or range of test scores. Importantly, the tests within the composite have different non-olfactory test demands, employ different stimuli, and have different reliabilities. The proper statistical solution, if one feels the need to combine such data, would be to convert the scores of each test to standardized z-scores and then perform the addition or averaging of the scores. One is still left, however, with the issue of knowing the relative contributions of the various tests for a given composite score, making the composite difficult to conceptually interpret.

## 11.5.2 Unilateral Versus Bilateral Testing

Most individuals with chemosensory dysfunction evidence the dysfunction bilaterally (Cain and Rabin, 1989; Gudziol et al., 2007). In cases where unilateral losses are present, they often go unnoticed. When time is at a premium, bilateral testing is preferable to unilateral testing since it reflects clinically meaningful deficits. However, there are a number of occasions when unilateral olfactory testing is of considerable value (e.g., in the detection of some types of tumors and in differentiating between some disease subtypes) (Doty, 1979; Good et al., 2002; Mainland et al., 2005), and the ideal assessment of a patient includes unilateral, as well as bilateral, testing. In normosmic subjects, directionally lateralized left:right differences in threshold and identification test scores are not present (Betchen and Doty, 1998; Brand et al., 2004; Good et al., 2003; Gudziol et al., 2007). Interestingly, odor recognition memory is better under bilateral than unilateral test conditions (Bromley and Doty, 1995) and, in the menopause, estrogen replacement therapy appears to influence asymmetry noted on such memory tasks (Doty et al., 2008).

Unilateral testing is straightforward. Although it is possible to present a stimulus to one naris and obtain

mainly unilateral stimulation, the possibility of the crossing of odorant to the contralateral side within the rear of the nasopharynx upon exhalation cannot be excluded. Thus, it is prudent to close the contralateral naris without distorting the septum [e.g., by using a piece of Microfoam™ tape (3M Corporation, Minneapolis, MN) cut to fit tightly over the borders of the naris] and have the patient exhale through the mouth after inhaling through the nose (Doty et al., 1992). As in the case when both nares are blocked, this precaution decreases the likelihood for air to enter the blocked nasal chamber via the nasopharynx.

Furukawa et al. (1988) noted that seven of 94 patients (7%) they examined, all of whom evidenced no bilateral threshold deficits, evidenced significant unilateral threshold deficits. They reported a similar phenomenon in six of 12 patients who had had brain surgery. Of 82 consecutive nonanosmic patients presenting to the University of Pennsylvania Smell and Taste Center with chemosensory dysfunction, 14 (i.e., 17%) were observed whose unilateral detection thresholds were discrepant from one another by at least three orders of magnitude (Doty, unpublished). Interestingly, nine of these 14 individuals were anosmic on one side of the nose, even though only three had bilateral detection threshold values that were obviously abnormal. Larger more recent studies have suggested that up to 25% of patients presenting with chemosensory disturbance exhibit meaningful left:right differences in olfactory test scores (Welge-Lüssen et al., 2010) which, interestingly, may precede the onset of bilateral dysfunction (Gudziol et al., 2010) and may relate to lateralized differences in nasal chamber and olfactory bulb volumes (Altundag et al., 2014).

### 11.5.3 Detection of Malingering

Because considerable compensation can be involved in accident cases that alter the ability to smell, malingering on chemosensory tasks is not uncommon. It is frequently suggested in the medical literature that if a patient cannot readily perceive the vapors from an irritating substance presented to the nose, he or she is malingering (e.g., Griffith, 1976). However, this is not a definitive method for detecting malingering. Thus, individuals who, on other grounds, are believed to be feigning anosmia usually have difficulty in denying experiencing the effects of NH<sub>4</sub> or other irritants, particularly since these stimuli often produce eye watering, coughing, and other reflexes that are manifested overtly. Furthermore, there appears to be considerable variability among normal individuals in trigeminal responsiveness to such stimulants and persons with smell loss may have less trigeminal sensitivity (Frasnelli and Hummel, 2007).

A more valid approach for detecting cheating on the basis of psychophysical testing is to examine response strategies of patients on forced-choice tests, since malingeringers often avoid the correct response more often than expected on the basis of chance. This is well

illustrated by responses to the UPSIT. Since the UPSIT is a four-alternative forced-choice test, approximately 25% of the test items (i.e., 10) are correctly answered, on average, by an anosmic, although obviously there is a sampling distribution around this number. The probability of scoring 5 or less on the UPSIT and not having at least some ability to smell is less than 5 in 100. The probability of scoring zero on the UPSIT and having no sense of smell is less than 1 in 100,000.

Electrophysiological testing, such as described in Chapter 12, can be useful, in some cases, in detecting malingering. However, it must be kept in mind that electrophysiological measures are not immune to malingering (e.g., patients can move or provide less cooperation during testing) and care must be made to differentiate between subtle EEG changes, such as event-related potential amplitudes or latencies, that arise from the trigeminal nerve and perhaps other sources. Considerable variability can be present in such measurements. The Sniff Magnitude Test, described earlier in this chapter, may also be useful in detecting malingering, since the presented odorants are so vile that it is difficult not to suppress a sniff once they are perceived. To date, no one has explored the usefulness of this novel test in such detection.

It should be noted that chemosensory malingeringers differ in many ways from psychiatric malingeringers. While the latter typically exaggerate their general health problems, chemosensory malingeringers do the opposite. Thus, in a study which compared responses to an intake questionnaire of 22 chemosensory malingeringers (based on improbable responses in forced-choice testing) to 66 non-malingeringers matched on etiology, the malingeringers significantly exaggerated symptom severity, including weight loss, appetite change, and interference with everyday activities, and underreported factors that might be construed as contributing to their dysfunction, including smoking behavior, medication use, nasosinus problems, dental problems, nasal or oral surgical operations, and allergies (Doty and Crastnopol, 2010). Interestingly, the two groups did not differ on sex, education, and how many words were used in an intake questionnaire to describe the purported chemosensory problem.

### 11.5.4 Subject Variables

The reader should be aware that numerous factors influence olfactory function in “normal” individuals and that these factors can significantly alter the ability to smell. Among variables that meaningfully alter such ability are age, gender, and smoking habits. Of these three variables, age is the most important (for review, see Doty and Kamath, 2014). Indeed, over the age of 80 years nearly three out of four persons exhibit marked olfactory dysfunction; half of those between the ages of 65 and 80 years evidence such dysfunction (Doty et al., 1984b; see also Murphy et al., 2002).

Estimates of heritability of olfactory function are less in old persons than in young persons (Doty et al., 2011), likely reflecting, among other things, cumulative damage to the olfactory epithelium from environmental insults, such as from viruses and pollution. Age-related declines in olfactory performance are observed for a variety of olfactory tests, including tests of odor detection threshold, identification, discrimination, adaptation, and suprathreshold odor intensity perception (Doty and Kamath, 2014). In addition, age influences the responsiveness of the nasal mucosa to volatile chemicals that produce irritation and other skin sensations (Stevens and Cain, 1986). In general, (a) large individual differences are present in the test scores of older individuals, (b) olfactory dysfunction is most evident after the sixth decade of life, and (c) women, on average, exhibit age-related declines in odor perception later in life than do men. The age-related decline in the ability to smell is not inconsequential. Thus, in older persons, an olfactory deficit, particularly in combination with the ApoE-e4 allele, has been associated with greater subsequent cognitive decline (e.g., Graves et al., 1999; Olofsson et al., 2009). Importantly, a disproportionate number of older persons die from accidental gas poisoning (Chalke et al., 1958), and many complain that their food has no flavor (Doty et al. 1984b). The latter phenomenon, which can lead to decreased interest in food, may explain some cases of age-related nutritional deficiencies and weight loss. As documented clinically (e.g., Deems et al., 1991), decreased “taste” perception during deglutition largely reflects the loss of stimulation of the olfactory receptors via the retronasal route (Burda and Doty, 1987; Mozell et al., 1969).

In general, women of all ages outperform men on tests of odor identification, detection, discrimination, and suprathreshold intensity and pleasantness perception (for review, see Doty and Cameron, 2009). Such differences are present for a wide variety of odorants, including human breath and bodily secretions (Doty et al., 1975, 1978b, 1982), and are observed as early as such testing can be reliably performed (Doty, 1986). The fact that female babies more readily show a preference for odors from their own mothers than do male babies suggests that such sex differences are present at birth and are either inborn or due to early sexually dimorphic developmental influences (Makin and Porter, 1989; see Chapter 14).

The influence of tobacco smoking on olfactory function is less marked, on average, than that of age or gender (e.g., Doty et al., 1984b). This influence, however, is dose-related and present in both previous and past smokers (Frye et al., 1990). Moreover, second-hand smoke can adversely influence the ability to smell, even in children (Nageris et al., 2002). Interestingly, cessation from smoking results in some improvement of olfactory function over time—improvement that is related to the amount of

previous smoking and the duration of such cessation (Frye et al., 1990).

Both reversible and irreversible changes in smell function have been observed following exposure to a wide variety of environmental agents, including industrial chemicals and dusts (see Chapter 20). In the most extensive study on this point, the olfactory function of 731 workers at a chemical plant that manufactures acrylates and methacrylates was tested (Schwartz et al., 1989). Decrements in odor identification test scores proportionate to the estimated dose exposure levels of these acrylates were found. Interestingly, individuals who had never smoked cigarettes but who had been exposed to acrylates were six times more likely than their non-exposed counterparts to evidence olfactory decrements. Long-term decrements in smell function of workers exposed to airborne toxins during the cleanup of the World Trade Center debris in 2001 have been documented (Altman et al., 2011; Dalton et al., 2010).

Prior experience with odors, particularly that obtained on taste and smell organoleptic panels, clearly influences measures of the ability to smell. For example, repeated testing within the perithreshold odorant concentration range results in decreased thresholds or enhancement of signal detection sensitivity measures (Dalton et al., 2002; Doty et al., 1981; Engen, 1960; Rabin and Cain, 1986; Wysocki et al., 1989); practice with feedback influences the ability to name odors (Desor and Beauchamp, 1974; Engen and Ross, 1973). Interestingly, the hedonic quality of odorants can be influenced by repeated exposure, making unpleasant odors less unpleasant and pleasant odors less pleasant (Cain and Johnson, 1978). Assuming that adaptation is not the primary basis for this phenomenon, affective components of odors appear to habituate somewhat independently of odor intensity.

Bodily conditions such as hunger or satiety also have been reported to influence measures of olfactory function. For example, Albrecht et al. (2009) reported the paradoxical finding that thresholds for the food-related odor amyl acetate were actually lower under conditions of satiety than hunger, an effect not observed for the non-food related odorant n-butanol. In contrast, Cameron et al. (2012) found that fasting for 24 hours enhanced performance on tests of odor identification, detection, and discrimination. However, Janowitz and Grossman (1949) found no evidence that hunger or satiety altered recognition thresholds for coffee odor, as measured using the blast injection method.

### 11.5.5 Adaptation

Exposure to an odorant, if recent, of sufficient strength, and relatively continuous, can produce a temporary decrease in its ability to be perceived, empirically reflected by heightened detection threshold values or decreased intensity ratings (for a review, see Cometto-Muñiz and Cain, 1995).

Some chemicals produce a decrement in the perception of other chemicals (termed cross-adaptation). Fortunately, most modern clinical olfactory tests are either little influenced by adaptation or operationally are standardized in such a way that any adaptation that occurs is unlikely to meaningfully influence the test results. For example, the UPSIT was designed to minimize adaptation by (a) employing largely multicomponent “natural” odorants, (b) requiring minimal sampling of each odorant, (c) having verbal, rather than odorous, response alternatives, (d) ordering the presentation of odorants such that dissimilar odorants follow one another (thereby minimizing cross-adaptation), and (e) allowing adequate time between the smelling of each odorant item (Doty et al., 1984a).

Several general rules have emerged from studies of adaptation that are worthy of note (Cometto-Muñiz and Cain, 1995; Frank et al., 2010; Goyert et al., 2007; Jacob et al., 2003; Köster and De Wijk, 1991; Stuiver, 1958). First, the amount of adaptation induced is a function of the duration of exposure and the concentration of the adapting stimulus. Second, the subject’s attention level influences the degree of adaptation. Third, pleasant odors may adapt less than unpleasant ones, although intensity is often confounded with pleasantness. Fourth, the rate and degree of recovery from adaptation are a function of the magnitude and duration of the adapting stimulus. Fifth, cross-adaptation is most commonly asymmetrical. For example, while exposure to odorant A decreases the perceived intensity of odorant B, exposure to odorant B may not decrease the exposure to odorant A to the same degree. Sixth, the sensitivity to a given odorant is reduced more by the exposure to that odorant than to any other odorant. Seventh, an odorant may have a larger adapting effect on the sensitivity to another odorant than it does on itself. Eighth, the sensitivity to an odorant which self-adapts strongly is usually also reduced strongly by other odorants. Ninth, adaptation of one side of the nose produces adaptation, albeit less, in the other side of the nose. Tenth, adaptation to complex odorants (i.e., odorants made up of more than one chemical) is generally less than adaptation to single-component odorants. Eleventh, adaptation to a component odorant of a mixture can “unmask” the perception of other odorants within the mixture, a process which varies as a function of exposure time to the adapting stimulus. Finally, adaptation to odorants can be relatively rapid. For example, Aronsohn (1886) found that subjects continuously exposed to the vapors of lemon or orange oil reported complete loss of olfactory sensations, on average, in three minutes (range: 2.5 to 11 min). Recovery occurred in about the same time as that required to produce the loss.

The issue of adaptation comes up in practical matters regarding the direction of trial sequences in threshold tasks, that is, ascending vs. descending trials. In one

study it was found that better performance, that is, more frequent stimulus detection, occurred at lower perithreshold concentrations for the odorant phenyl ethyl alcohol relative to a mineral oil blank when the trials began at higher concentrations and subsequently descended to lower concentrations (Doty et al., 2003). Conversely, better performance occurred at higher perithreshold odorant concentrations when trials began at lower concentrations and ascended to higher concentrations. Importantly, no meaningful differences between ascending and descending trials were evident at concentrations in the range that would typically be used in the calculation of a threshold, that is, at 75% correct performance in a two-alternative forced-choice task. This suggests that threshold estimates are little influenced by the direction of trial sequences, at least for phenyl ethyl alcohol.

### 11.5.6 Responsivity Versus Sensitivity

A number of persons report being hypersensitivity to odors, such as women in the first stages of pregnancy (Cameron, 2014) and persons who report hypersensitivity to environmental odors (Doty et al., 1988). However, such hypersensitivity is not generally detected by odor identification or odor detection threshold tests (Caccappolo et al., 2000; Doty et al., 1988; Nordin et al., 2005). To date, such persons have not been evaluated using signal detection analysis, but it is conceivable that, in some cases, their “sensitivity” to odors reflects response factors and personality. Karnekull et al. (2011) recently demonstrated, in a non-clinical population, a positive correlation between neuroticism and both negative responses to environmental odors and noise. Those highest on the measure of neuroticism also rated odors presented to them as more intense. Other work suggests that beliefs about odors can determine the amount of attention paid to them and how strongly they are rated. For example, when subjects are told they are being exposed to an unhealthy odor, their ratings of its intensity are greater, and the time required for adaptation is longer, than if they are told the odor is healthy (Dalton, 1996, 1999; Zucco et al., 2008). Such findings demonstrate how attitudes towards odors can influence their perception.

## 11.6 THE PERCEPTION OF ODORANT MIXTURES

As noted above, a number of modern olfactory tests, including the UPSIT, employ stimuli that, for the most part, are complex mixtures of chemicals, mimicking stimuli encountered in everyday life. More often than not such stimuli are perceived as a unitary gestalt, and given a name

associated with the object or source from which they are known to emanate; for example, cinnamon, pizza, cheese, gasoline, orange, lemon, walnut, etc. (see Livermore and Laing, 1998b). There is considerable clinical utility in using such tests, since many receptor types are activated. This is in contrast to threshold tests employing single odorants, as they presumably examine the responses of the olfactory system to a much smaller subset of the ~450 receptors. It has been shown that rodents who have sustained damage to 80–90% of their olfactory receptor cells still retain their ability to detect some single odorants. Similarly, odor sensitivity is retained unchanged when large lesions have been made in the bulb. Therefore, from at least a theoretical standpoint, major changes in the olfactory system can occur and not be detectable by the use of some single odorants. In contrast, the perception of mixtures invariably involves inhibitory interactions at the bulb (and possibly other olfactory centers) that occur through complex neural circuitry. Lesions that disrupt the circuitry are likely to alter the characteristic suppression effects observed between odors in mixtures. Rat data indicate that lesions involving much of the bulb can result in the failure to re-learn a mixture analysis task, compared to their successful retention of odor sensitivity and ability to discriminate between odor qualities (Slotnick et al., 1997).

How is it that mixtures of chemicals end up providing a largely unitary perceptual gestalt? How much information, in terms of discriminating individual components, can humans obtain from complex mixtures? If one odorant suppresses the odor of another (as is seen in the case of deodorants or room fresheners), how does this relate to the relative concentrations of the odorants within the mixture? Are there psychophysical rules or laws explaining mixture relationships? These and other questions related to odorant mixtures are the basis of the remainder of the chapter.

### 11.6.1 Effects of Mixing Odorants on their Perceived Intensity

Usually when two single compound odorants are mixed together, the perceived intensity of one or both is altered substantially, the net result being a lowering of the intensity of the components. However, on rare occasions enhancement may occur. In early mixture studies, Aronsohn (1886) reported that the odor of camphor was neutralized by such odors as gasoline, cologne water, and oil of juniper, and Nagel (1897) found that counteraction between two odorants could result in both being rendered almost odorless. Zwaardemaker (1900), the most famous of early olfactory scientists, confirmed these observations for a number of mixtures using an olfactometer (Figure 11.1), and demonstrated that the extent of perceptual interactions between two odorants was more dependent on their concentrations than on their qualities. Similar results have been reported

by others, including Moncrieff (1959) and Jones and Woskow (1964), the latter reporting that the perceived intensity of a binary mixture, although less than the sum of its component intensities, is more than a simple average of the two.

Zwaardemaker (1930) conceptualized the mutual weakening of the perceived intensity of a mixture of two components as follows: “The two sensations can be imagined as two vectors representing two forces counteracting each other in our intellect.” The interaction between two odorants was later formalized by Berglund et al. (1973) in a mathematical model that incorporated the application of vector addition to odor mixtures for the prediction of the overall intensity of mixtures. Although the vector model has received widespread attention (e.g., Berglund, 1974; Berglund et al. 1976; Cain and Drexler, 1974; Cain, 1975; Moskowitz and Barbe, 1977; Laing et al. 1984; Berglund and Olsson, 1993a; Berglund and Olsson, 1993b; Olsson, 1994), after decades of investigation its best predictions have been for simple binary mixtures. Other models for predicting the perceived intensity of simple mixtures include the Strongest Component Model and the U (Pattie and Laffort, 1979) and UPL (Laffort and Dravnieks, 1982) models. Both represent modifications of the vector model but did not widen the application of the original model to multi-component mixtures. The most recent model in this series was the UPL2 model (Laffort, 1989) which incorporated the power function that normally relates perceived odor intensity to concentration. The ERM model of Schiet and Frijters (1988) was also based on a power function relating these factors and, although applied with some success to simple gustatory mixtures, was not an improvement in the models just described for olfactory mixtures. As summarized by Cain et al. (1995), “the principle by which psychophysical information on single components reflects itself in a model of interaction seems to evade the psychophysical models presented here” (all the above).

Clearly, none of the aforementioned models adequately describes the changes in perceived intensity for all pairs of odorants examined, and none have been demonstrated to reliably predict the intensity of mixtures containing more than two odorants. Booth (1995) provides an interesting critique on the modeling of odor interactions, but provides no firm ground for future studies to proceed. Amongst a number of shortcomings, none of the above models have been based upon the receptive and neural processes that underlie the perception of mixtures, nor has attention been given to choosing odors that have physicochemical features that might provide some basis for antagonistic interactions. Furthermore, these models have provided no insight as to the nature of the sensory processes, and none adequately predicts the intensity of multi-component mixtures. Present evidence suggests that addition or partial

addition of the perceived intensities of the components of mixtures occurs with binary and ternary mixtures; beyond this number of components neural processes limit intensity addition (Berglund et al., 1976; Moskowitz and Barbe, 1977; Laing et al., 1994).

The interactions noted above concern suprathreshold concentrations of odorants and provide examples of where the sense of smell compresses rather than adds intensity information. In contrast, additivity of neural input appears to be inherent in mixtures containing only sub-threshold quantities of odorants (Laska et al., 1990; Laska and Hudson, 1991). Indeed, in mixtures with only three odorants, the magnitude of the addition was noted by Laska et al. to be substantial and to often exceed that obtained from simple summation. Patterson et al. (1993) reports instances of near-true additivity of sub-threshold components, and suggested additivity may function to enhance sensitivity to the typically complex (and often sub-threshold) odor stimuli encountered in everyday life. They noted that the number of chemicals activating the system could be as important as the strength of any one of the odorants, providing a type of “biological economy” of the input.

## 11.6.2 Discrimination of Components in Odorant Mixtures

Since, as mentioned earlier, odors are commonly encountered as mixtures in our environment, an important characteristic of the human sense of smell is to discriminate differences between mixtures. Discriminating the odors of fresh and “off” milk, ripe and overripe fruit, cork taint in wine, and various perfumes are examples. In the area of pollution control, changes in the complex odor of sewage provide engineers with an insight as to the part of the treatment process that is not functioning properly; sulfides emanate if the anaerobic process is malfunctioning, and sour, rancid, and acid odors appear if the sludge treatment is inappropriate. In studies with binary mixtures, Rabin (1988) and Rabin and Cain (1989) showed that humans are particularly sensitive to the presence of small amounts of odorants that are not normally found in a stimulus. They reported that (a) high familiarity with a major component and the ability to label it consistently facilitates the detection of a minor component, (b) the minor component is not detected as readily if it is unfamiliar, and (c) unpleasant stimuli are more detectable than pleasant ones, although the effect was not as large as the effect of familiarity. Experience, therefore, and to a lesser extent pleasantness, improves discrimination between two single odorants or two mixtures, suggesting that similar cognitive processes operate with the two types of stimuli.

Although the Rabin studies suggested humans are very sensitive to small changes in an olfactory stimulus, Laska and Hudson (1992) reported that relatively large changes

in the composition of mixtures are sometimes required for discrimination to occur. Thus, discrimination of 3-, 6-, or 12-component mixtures from the same mixtures minus one component produced error levels of 20–40%, with the level depending on the type of odorant that was removed. Accordingly, the dependence on the type of odor removed precluded defining a limit in the ability of humans to discriminate between two complex mixtures.

## 11.6.3 Identification of Components in Odorant Mixtures

Prior to studies of the abilities of humans to analyze mixtures, informal information from perfumers and flavorists suggested that between 5 and 30 components may be identified in mixtures (Laing, 1994b). Over the past decade, it has become clear that these numbers are an overestimate, as most individuals, including perfumers, are only able to identify up to three, or rarely, four components. An early hint that only a small number of odorants can be identified in mixtures was apparent in the report by Berglund (1974), who suggested from studies of the addition of the perceived intensities of components, that an analytic or additive process occurred up to three components, whereupon above this number an interactive process predominated. The latter was apparent as an asymptote in the total perceived intensity of a mixture, with little change occurring as the number of components increased. In accord with this notion, Moskowitz and Barbe (1977) found that in some instances the overall intensity of five-component mixtures was less than that of mixtures with fewer components. More recently it was shown that mixtures with 30 or more equal intensity components smell alike, suggesting that the single non-descript odor represents an ‘olfactory white’ that is equivalent to white noise in addition (Weiss et al., 2012).

In perhaps the first formal scientific studies on this topic, Laing and Francis (1989) and Livermore and Laing (1996) reported that training and experience did not increase the number of components identified with subjects that had been trained for a few minutes, three weeks, or who were perfumers and flavorists, the maximum still being three to four. Varying the task or the odorants resulted in no improvement in the number identified; thus, in another study a selective attention procedure was not more efficient than a procedure which required subjects to identify as many components as possible during an air sampling method (Laing and Glemairec, 1992). Furthermore, this maxima was not altered if the odorants used were those classified by perfumers as ‘poor blenders,’ that is, odorants that they used to ‘stand out’ in mixtures (Livermore and Laing, 1998a). Schiet and Frijters (1988), using another approach to this problem, reported that subjects invariably underestimate the number of components in mixtures

containing up to four components. A similar result was obtained by Jellinek and Köster (1979), whose subjects found the odor of single chemicals to be as complex as that of mixtures.

Clearly, the data of the aforementioned studies indicate that there is a significant limitation in the olfactory system in the processing of information from more than about three odorants. Mixtures of complex odors tend to behave like mixtures of single odorants, with a maximum of about three being identified in stimuli containing up to eight complex odors. The possibility that the entry of hundreds, perhaps thousands, of odorants into the nose would produce a non-identifiable smell sensation has not yet eventuated (Livermore and Laing, 1998b).

#### **11.6.4 Mechanisms Involved in Odor Mixture Perception**

The limited ability of humans to discriminate and identify odorants in mixtures is likely due to a number of mechanisms. Changes in spatial processing arising from competition for receptor sites and cells at the periphery, and inhibition in the bulb and at other olfactory centers, would be expected to reduce the information within the activated receptor cell arrays, making it difficult to recognize the patterns of activation due to different odorants. Since temporal processing favors the first processed odorant, the initial odorant has the opportunity to act as an antagonist towards other odorants at the periphery and to inhibit neural activity arising from other odorants in the bulb. However, if the delivery of different odorants in ternary or more complex mixtures to the nose is less than the time for processing two odorants in working memory, the latter becomes the ultimate limiting factor as regards the number of odorants identified. These mechanisms are discussed in detail below.

**11.6.4.1 Spatial Processing.** As noted elsewhere in this volume, a given odorant activates unique arrays of receptor cells in the nose (Mackay-Sim et al. 1982; Kauer, 1991) which, in turn, are reflected by patterns of activation of glomeruli and mitral/tufted cells in the olfactory bulb. Different odors produce different arrays that represent the spatial codes of identification. However, when a mixture of two odorants is sensed and the perception of one or both are suppressed to some degree, the arrays representing the two stimuli in the bulb show a reduction in the number of glomeruli that are activated (Bell et al., 1987; Joerges et al., 1997). If the suppression of one of the odorants is such that it cannot be perceived, little of the normal array of activated glomeruli is seen (Bell et al., 1987). The suppression may be due to fewer receptor cells being activated (Kurahashi et al., 1994; Ache et al., 1988; Simon and Derby, 1995) because of competition by the odorants for the same receptor sites, resulting in less input to the bulb. Suppression can

also be caused by lateral inhibition between glomeruli or mitral cells in the bulb (Pinching and Powell, 1971; White, 1979; Shepherd and Greer, 1990). The loss of identity of up to five odorants in eight-component mixtures (Livermore and Laing, 1998a) prompted Jinks and Laing (1999a) to propose that the competition and inhibition between odorants could result in no odorant being identified in mixtures containing double this number of components. Their psychophysical study showed that one and zero components were identified in 12- and 15-component stimuli, respectively. The fact that the 15-component stimulus had an odor, albeit not one that could be associated with any of the components or an object or source, indicates that neural input from some or all of the arrays characterizing the components was registered.

In light of such observations, it is interesting to note that, in the rat, neural images of complex olfactory stimuli, including rat nest odors comprised of volatiles from urine, feces, and bodies (Stewart et al., 1979), have shown that the number of activated glomeruli is similar to that found with a simple single odorant such as limonene (Bell et al., 1987). Therefore, spatial processing of single and complex odorants involves both peripheral and bulbar interactions that reduce and simplify identification. Accordingly, the olfactory system uses spatial coding to analyze and identify single odorants when presented alone and in simple mixtures, and simplifies identification of complex mixtures by combining the remaining parts of the arrays into a single characteristic array that is associated with the object or source of the stimulus. This interpretation is in agreement with the finding of Jellinek and Köster (1979) noted above that single odors are perceived to be as complex as that of mixtures.

But there is another aspect to spatial processing. An intriguing feature of single odorants and odor mixtures is that they can be characterized by several qualities or ‘notes’ (Moskowitz and Barbe, 1977; Laing and Willcox, 1983). Hexenal, for example, is described as having ‘green’ and ‘fatty’ qualities, and ethyl butyrate as ‘sweet’ and ‘fruity’. However, when single odorants are components of mixtures but cannot be identified, often one or more of their qualities can be discerned. Jinks and Laing (2001) investigated the qualities of binary, ternary, and quaternary mixtures of four dissimilar odorants to determine the information about odor quality that needs to be retained for identification of the odorant. The data indicated that failure to identify an odorant could occur with the loss of some but not all of the qualities. However, failure could also occur when the major qualities were present but the ratios of their perceived intensities were substantially altered. This suggested that a different smell could be produced using the same qualities but in different ratios. Identification, therefore, was affected by the type and/or the perceived intensity of the qualities of an odorant. These results were interpreted in

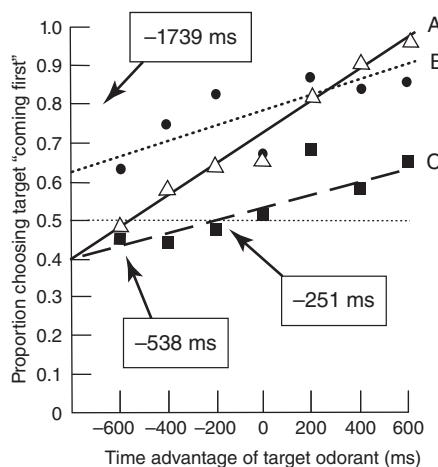

terms of a Configurational Hypothesis of Olfaction, in analogy with the Configurational Hypothesis of Facial Recognition (Enns and Shore, 1997; Rakover and Teucher, 1997). In brief, in the case of a face, identification of a person requires not only certain features to be present in a drawing or photograph, but these features must be in the correct proportion to each other. Similarly, identification of an odorant or a complex mixture requires some of the characteristic qualities in the correct proportions to be perceived.

But what is the neural basis of a quality or ‘odor note,’ and how is it represented in the spatial code? Thanks to advances in molecular biological studies of the chemoreceptive process, an insight to this problem is possible. For example, as noted throughout this volume, it is commonly accepted that each human receptor cell has only one type of receptor (Rawson et al., 1997) and that there are nearly 500 functional receptor types in humans, as indicated by the number of receptor genes. Stimulation of receptor cells by a single odorant most commonly results in a variety of cells being activated in accordance with the degree or ‘ease of fit’ of the odorant to each receptor site type (Chapter 4 and 5). If the fit is predominantly to two or three receptor types they will be the main inputs to the array of glomeruli and mitral/tufted cells activated in the bulb. However, the conformations adopted by an odorant to fit the two to three receptor types will be dictated by the structural features of the odorant and receptor molecule. In one conformation a molecule may be aligned within a receptor site according to its length and functional group, e.g., the I7 receptor for octanal (Araneda et al., 2000), in another it may sense a structural feature common to a number of odorants, e.g., an 8 carbon chain containing a terminal carbonyl group common to aliphatic aldehydes, acids, esters, and ketone (Imamura et al. 1992). Since the overall odors of these latter aliphatic carbonyl substances are easily discriminable (Laska et al. 2000), each odorant must require at least two receptor types to be occupied for this to occur. Accordingly, it is tempting to suggest that activation of the cells with the common receptor for these odorants results in an odor quality common to each odorant, whilst activation of the cells unique to each odorant produces a quality unique to each odorant. In addition, the spatial map of each odorant should show glomeruli or mitral/tufted cells that are activated by all four odorants, and others that only one of the odorants will activate. From the limited data available, it is suggested that the conformations an odorant can adopt in different types of receptors defines the important structural features that provide the qualities perceived. This interpretation suggests the spatial code for an odorant contains information about molecular structure and odor qualities. In contrast, the spatial map of complex mixtures such as chocolate aroma, where none of dozens of odorants can be identified, will be composed of input from receptor cells representing features of many odorants

and it may be the location and magnitude of the input to the bulb rather than molecular features that define its identity. Nevertheless, several qualities can usually be discerned in complex aromas, and these are likely to be those that remain from individual odorants in the mixture which are insufficient to identify the latter but contribute to the overall aroma of the complex mixture.

**11.6.4.2 Temporal Processing.** During the 1980s, Getchell et al. (1984) reported that odorants can differ by hundreds of milliseconds in the time they take to activate receptor cells, whilst Kuznicki and Turner (1986) showed that humans require different reaction times to recognize the four common tastants. These findings prompted Laing (1987) to propose that if the time differences between the activating times of odorants at the periphery were maintained as the neural message traveled through the bulb and other olfactory processing centers in the brain that dealt with memory and identification, then a “fast” odorant would have a number of advantages if presented in a mixture with a “slow” odorant. For example, the faster odorant may be more successful in competition for receptor sites and cells. Being the first to activate the bulb, it could trigger lateral inhibition between glomeruli or between mitral cells to further reduce neural input from the slower odorant. Accordingly, it was predicted that the faster odorant would be the first odorant identified in a mixture, the slower odorant would incur the greatest suppression of intensity, and the number of cells and glomeruli in spatial arrays activated by the latter odorant would be reduced.

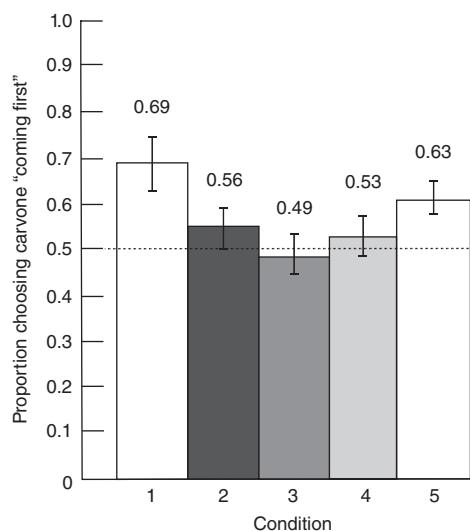

To investigate the first two of the above predictions, Laing et al. (1994) used a specially designed computer-controlled olfactometer which allowed odorants to be delivered together in a mixture or in series separated by intervals as small as 50 ms. By asking subjects which of two odorants was perceived first during a trial, and varying the time between delivery of both odorants from 100–600 ms, the processing time difference between them was established as that which produced a chance response, i.e., 50% for the forced-choice yes/no task. The magnitude of the differences varied from zero to more than a second, and was dependent on both the quality and perceived intensity of the odorants, with the latter being more important. Perceived intensity was also reduced more for the slower odorant. With both predictions upheld, the existence of temporal processing and its implications for mixture perception were demonstrated. A later study (Jinks and Laing, 1999b) confirmed that knowledge of processing time differences allowed predictions of which odor would be perceived first in other mixtures. Thus, they showed that when odor A was perceived before B and B was perceived before C, that A was perceived before C, demonstrating that transitivity had occurred (Figure 11.12). However,

**Figure 11.12** Regression lines representing the proportion of trials in which an odor in a binary mixture was perceived ‘first’ when presented with a time advantage (+ values on X axis), disadvantage (- values on X axis), or as true mixture (0 value on X axis). Arrows and times in boxes indicate when both odorants were perceived first on 50% of trials. A = stimulus of coniferan and triethylamine with coniferan being perceived 538 ms before triethylamine; B = a stimulus of carvone/triethylamine with carvone perceived first 1739 ms before triethylamine; C = a stimulus of carvone/coniferan with carvone perceived first 251 ms before coniferan.

investigation of temporal processing in ternary mixtures revealed a substantial limitation in the ability of humans to indicate which odor is perceived first, and the existence of a third mechanism that affects perception of components in odor mixtures (Jinks and Laing, 1999b). Temporal processing of ternary mixtures and the third mechanism, which is postulated to involve olfactory working memory, are discussed below.

**11.6.4.3 The Role of Memory.** The perception of the order of processing odorants in ternary mixtures, however, has proved to be very difficult (Jinks and Laing, 1999b). Initial experiments indicated that subjects recorded chance level responses when asked to indicate which odorant was perceived first or last. To investigate whether the chance results were due to a limitation in the capacity of olfactory working memory to process both order and identity of the odorants, presentation of the third odorant was delayed by 300, 600, and 900 ms. With one of the two sets of three odorants studied, the results indicated that a delay of between 600 and 900 ms was needed before the usually faster odorant was perceived first (Figure 11.13). With the other set, subjects recorded chance responses even with the 900 ms delay. The mean responses of subjects, when asked to identify the odorants in the mixture or delay conditions, showed that this was at chance level. The result is in agreement with the earlier studies of Laing and colleagues

**Figure 11.13** Proportion of trials (numbers above bars) in which subjects selected an odor ‘coming first’ in binary and ternary mixtures, and mixtures where the presentation of triethylamine was delayed. Conditions are; 1 - binary mixture of carvone/coniferan; 2 - ternary mixture of carvone/coniferan/triethylamine; 3,4 and 5 are the ternary mixture with the presentation of triethylamine delayed by 300, 600 and 900 ms, respectively. Open and shaded bars indicate that the means were significantly/not significantly different from 0.5 (chance), respectively.

who found that few subjects could identify all the components of ternary mixtures. Overall, the results with ternary mixtures indicated that a mechanism related to the speed of information retrieval about the identity or temporal order of the components was the cause. The most likely candidate appears to be the inability of olfactory working memory to process the information about the identity and order of the first two components before neural input from the third began to be processed. Although it is not fully understood, working memory is defined as the “system responsible for the temporary storage and manipulation of information, forming an important link between perception and controlled action” (Baddeley, 1998). The process of identifying an odor within working memory is likely to involve several steps; encoding of the odor by neurons, recalling of the coded representation of the odor from long term memory, comparison of the two representations, and the judging and responding to the representations. This type of process has been proposed for visual information (Eskandar et al., 1992). Indeed the interference of a third odorant with the perception of others is reminiscent of that reported for visualspatial memory where it was proposed that an irrelevant visual stimulus may have obligatory access to a visual store and interfere with the storage and processing of other visualspatial information in working memory (Toms et al. 1994). Limitations in the capacity of olfactory working memory to process more than two

odorants within 600–900 ms appears to be a major factor limiting the discrimination and identification of odorants in multi-component mixtures. Such a finding has implications for the perception of odorants released during an eating episode where many can be released within the processing time differences cited here, but only a few may be identified. Controlled release of odorants from different food media could, however, allow products to be developed with high flavor impact.

## 11.7 CONCLUSIONS

The present chapter has provided an up-to-date review of the psychophysical means for testing the human sense of smell, and has examined how the human olfactory system likely integrates information from complex arrays of odorant chemicals which, individually, would seem to produce conflicting odorous sensations. It is of interest that relatively high correlations exist among the scores derived from nominally distinct olfactory tests, regardless of whether they are based upon single- or multi-component stimuli. Test reliability has been shown to be largely a result of test length, irrespective of the nature of the stimuli included in the tests. To what extent tests employing multicomponent odors are superior to ones employing single odorants is an empirical issue, although it would seem that by sampling more elements of the system, a test should be more sensitive. Continued efforts to refine the procedural elements of olfactory tests should help in the development of test batteries sensitive to wider ranges of olfactory deficits than those that are currently available.

## Electrophysiological Measurement of Olfactory Function

ALLEN OSMAN and JONATHAN SILAS

### 12.1 INTRODUCTION

In this chapter, we introduce the fundamentals of electroencephalography (EEG) and survey its many applications in basic and applied research on olfactory function. Both classic and modern approaches to data collection and analysis are reviewed, providing a comprehensive overview of this emerging field.

In 1875, Richard Caton discovered that electrical potentials could be measured directly from the exposed surface of the cerebral cortex in animals. This paved the way for the first EEG recordings from the human scalp by Hans Berger (1929). Both Caton and Berger noted that brain electrical activity could be influenced by external sensory events. Such effects were first reported for odorants in 1890 by Fleischl von Marxow in response to ammonia presented to a rabbit's nose. It was not until the late 1960s, however, that modulation of scalp-recorded EEG by odorants was demonstrated in humans (Finkenzeller, 1965; Allison and Goff, 1967). This has now been documented in numerous studies and shown to be mediated by both the olfactory and trigeminal systems. Before turning to these studies, let us consider first the neurophysiological basis of EEG.

EEG is a time series of voltages produced by electrical fields in the brain. This chapter will focus exclusively on EEG potentials recorded from the human scalp. These electrical signals arise from the activity of a large number of neurons which summates and is conducted to scalp electrodes through brain, bone, and other intervening tissue. For summation and conduction to occur, two requirements

must be met. First, electrical activity from many neurons must overlap in time, that is, occur synchronously. Because action potentials are so brief, they are unlikely to occur synchronously. Consequently, EEG is thought to arise mainly from graded post-synaptic potentials, which have a longer duration. Second, the neurons must have similar orientations. When neurons all point in the same direction, they produce "open" electrical fields that can be detected at a distance. But, when arranged randomly or radiating from a common center, they produce "closed" fields that are not conducted far and cannot be detected at the scalp.

Thus, scalp-recorded EEG is merely the tip of an electrical iceberg, comprising mostly synchronous postsynaptic potentials from populations of neurons that produce open fields. Open fields are obtained when neurons are organized in layers, as is the case in the cerebral cortex, which is also proximal to the scalp. Indeed, cortical pyramidal cells are especially well suited to generate measurable electric fields, given that their apical dendrites are aligned in common perpendicular to the cortical sheet. It is important to recognize, however, that the synchrony of cortical neurons is modulated by afferents from subcortical sources.

When recorded from the scalp, EEG provides a non-invasive tool for studying neural states and responses in humans. In comparison to other neuroimaging measures, it has a relatively direct connection to neural activity, albeit a subset. Perhaps one of its most useful features is its good temporal resolution. Modern signal acquisition allows voltage to be sampled at intervals of less than 1 msec. Though temporal resolution depends on other factors as well, including inherent temporal variability of

the measured processes, it is greater for EEG than most neuroimaging techniques.

EEG time series have been analyzed quantitatively in at least three ways. A separate section of this chapter is devoted to each as employed in modern studies of olfaction. The oldest is to compute power spectra based on extended recordings lasting several seconds or minutes. Like light, sound, and other wave phenomena, “brain waves” contain periodic components at specific frequencies whose power can be represented as a spectrum (see Section 12.2). Another form of analysis computes event-related potentials (ERPs) by averaging multiple short EEG segments that proceed or follow repeated “events” (stimuli or responses). ERPs, which reflect that portion of the EEG with a constant time-relation to the event, often have a temporal resolution on the order of msec (see Section 12.3). These two types of analysis can be thought of as emphasizing, respectively, EEG in the “frequency domain” (power as a function of frequency) and “time domain” (amplitude as a function of time). The most recent type of analysis (“time-frequency”) examines EEG changes simultaneously in both the time and frequency domains with a high degree of resolution in both (see Section 12.4).

## 12.2 OSCILLATORY CHANGES IN EEG DURING OLFACTION

Berger and other early researchers observed changes in on-going EEG rhythms induced by non-olfactory stimuli, for example, visual ones. Modern studies have shown that odorants can induce analogous effects. In this section of the chapter we turn to these latter studies and the type of EEG analyses they employ.

### 12.2.1 Neuronal Mechanisms

Decreases or increases in power, at any particular frequency, caused by a specific event of interest are thought to reflect the synchronicity of the firing of an underlying neuronal population. Absolute power is a measure of the intensity of energy (in  $\mu\text{V}$ ) squared and calculated in a series of frequency bands (termed the power spectrum) for selected periods of time. A desynchronization of neuronal firing results in a decreased measure of power in the EEG. Conversely, a synchronization of the underlying neuronal population results in increased power. In most cases, more synchronization and greater power usually indicates less cortical processing and vice versa (Pfurtscheller and da Silva, 1999).

Changes of power, at any particular frequency, measured while olfactory processing takes place do not necessarily reflect low-level perceptual components of olfactory processing. Rather, these frequency changes have

been commonly viewed as an indication of higher-order cognitive or conscious processes associated with the “olfactory percept” and not necessarily activities germane to activity within the olfactory pathways, per se (Kobal, 2003). Nevertheless, some research has demonstrated a relation between cortical frequency changes and olfactory processing that are relevant here, even if not associated with so-called “sensory” mechanisms.

As research in the field of continuous changes in the on-going EEG develops, it now appears that these measures may, in fact, be more useful or specific than other electrophysiological changes classically associated with olfactory sensory processing. Furthermore, to what degree so-called “sensory” and cognitive components are dissociable in the formation of any percept, including an olfactory one, is questionable (see Doty et al., 1994).

### 12.2.2 Early Research

One of the early documentations of quantitative odorant-induced changes in the on-going EEG was that by Lorig et al. (1988). Using a method of analyzing changes in power at different frequencies for discrete time periods, these investigators noted distinct differences in EEG power when comparing the inhalation of room air through the nose to inhalation through the mouth. Specifically, they documented a more widely distributed decrease in frequency power across the scalp during nasal than during mouth inhalation in the beta (13–64 Hz) frequency range as well as a greater decrease in the alpha (8–13 Hz) frequency bandwidth over the left hemisphere. This suggested that nasal inhalation recruits an olfactory processing network, whereas oral inhalation does not. This explanation likely holds under the constraints of their paradigm, although under other circumstances retronal nasal olfactory processing via the oral cavity could also be in play (Halpern, 2009).

Alpha and beta rhythms are often associated with attentional, motoric, and higher-order perceptual cortical processes that are believed to be largely independent of sensory processing (Pfurtscheller and da Silva, 1999). Lorig et al. (1988) suggested, however, that odor-related cortical changes demonstrate the effect of unaware or unconscious olfactory processing in a distributed system in the central nervous system (CNS). However, other explanations of this phenomenon are possible. For example, such changes could simply reflect changes in oxygen intake. That being said, subsequent research has shown that different odorants can be differentiated by a decrease in alpha frequency power at different electrode locations on the scalp (van Toller and Reed, 1989). Indeed, alpha and beta decreases in power seem to reflect the involvement of cortical processes involved in olfactory perception.

Early investigations also revealed some interesting findings in relation to modulations of power within the

theta frequency range (~4–8 Hz). Sensory stimulation, regardless of the modality, tends to decrease theta activity (Morruzzi and Magoun, 1949). This is thought to be reliant upon a direct link between the ascending reticular formation and clusters of neurons involved in sensory processing (Motokizawa and Furuya, 1973). However, despite the connection from primary olfactory cortical structures to the ascending reticular formation, some evidence seems to suggest an *increase* in power in the theta frequency bandwidth after odorant stimulation (see Lorig, 1989). Theta increases are most prominent when measured at posterior areas on the scalp and occur across different types of odors, whereas inhalation of odorless air seems to produce a decrease in theta activity (Klemm et al., 1992).

Some have suggested that an increase in theta activity is associated with decreased arousal perhaps due to some kind of cognitive associative function that olfaction has with food (Lorig, 1989). However, given that these increases tend to occur across different odors, even non-food ones, this seems somewhat unlikely.

That being said, one study examining a modulation of the theta frequency bandwidth found a consistent *decrease* in theta activity during the perception of food-related olfactory stimuli (Martin, 1998). This discrepant finding in the theta range is difficult to reconcile with studies finding an increase in theta activity and could reflect some mediation by subjective state or mood of the individual (Lorig and Schwartz, 1988). It is also possible that such an inconsistency could reflect noise associated with the analytical technique that was employed, that is, a “discrete” method of frequency analysis. Later in the chapter (Section 12.4) we discuss in greater detail why discrete methods of frequency analysis likely confer a decreased signal to noise ratio.

### 12.2.3 Coherence

In addition to power, it is possible to examine the *coherence* of EEG oscillations. Coherence, in this context, is the correlation between measurements of the EEG signal at two sites in phase at a specific frequency. Harada et al. (1996), in a pilot study, presented two different odors to participants, methyl-cyclopentenolone (a nutty maple smell) and scatol (a feces-like smell) and measured coherence changes relative to rest. For methyl-cyclopentenolone olfactory perception, coherence in the delta frequency bandwidth decreased in frontal regions, whereas alpha coherence increased bilaterally in temporal regions. For stimulation with scatol, delta coherence decreased in the frontal region but alpha coherence increased in frontal and occipital regions.

Coherence is thought to represent the information associated with a state or stimulus in a distributed cortical network. Increased coherence in the alpha frequency range may reflect a distributed processing of the subjective and psychophysical aspect of the olfactory percept. Harada

et al. (1996) give little in the way of interpretation for their findings but suggest further work may build on these results; unfortunately little exists. To our knowledge only one other study had examined coherence during olfactory processing (Cherninskii et al., 2009). This more recent account of coherence reports an increase in coherence in the beta frequency bandwidth measured over left temporal regions. Cherninskii et al. (2009) suggest that this may be indicative of higher-order cognitive functions related to the formation of semantic concepts associated with olfactory perception. Although more research is needed, analysis of frequency coherence during olfaction may prove to be a fruitful method for better understanding the role of distributed cortical processes.

### 12.2.4 Clinical and Hedonic Significance

Changes in the EEG as a result of olfactory stimulation have also been used to better define or diagnose a range of diseases. It is well established, for example, that olfactory deficits are an early sign of a number of neurodegenerative diseases, including Alzheimer’s disease (AD) and Parkinson’s disease (PD) (Doty et al., 1991; Doty, 2012). Seal et al. (1998) report differences in resting state EEG power between patients with AD and patients with generalized vasculature dementia (VaSD). Furthermore, changes in EEG power during an odor detection task were better than resting state EEG activity at identifying those with AD. Specifically, greater increases in theta wave power and lesser decreases in beta and alpha wave power were found among the AD participants, compared to those with VaSD, during an odor detection task. The authors suggest the changes in the theta frequency bandwidth may reflect a general slowing of the EEG signal common among those with AD (Berg et al., 1984). However, during the odor detection task the decreased power of the beta frequency bandwidth was best at differentiating between those with AD and vascular dementia, conceivably reflecting cortical processes specifically related to odor detection.

Some studies import a primacy to the hedonic, or “pleasantness,” perceptual component of olfactory stimuli (e.g., Khan et al., 2007). Proponents of this concept assume that the perceptual hedonic component can be mapped onto the physiochemical properties of an odorant, thereby suggesting a partially innate aspect of olfactory liking (Khan et al., 2007). This indicates that the liking of olfactory stimuli is fundamental to forming an olfactory percept.

Unfortunately, only a few studies have examined modulations of frequency components of the EEG in relation to the hedonic aspect of odor perception. Brauchli et al. (1995) recorded EEG activity during the suprathreshold

presentation of phenylethyl alcohol (PEA; a pleasant “floral” smell) and valeric acid (VA; an unpleasant “cheesy” smell). Overall, perception of VA was associated with a relatively greater increase in an upper alpha frequency bandwidth (i.e., 9.78–12.5 Hz) than PEA at frontal and parietal electrode locations. These authors opined that the increased alpha power reflected a decrease in cortical activation since “olfactory processing occupies large subcortical areas” (p. 513). This suggested to them that unpleasant stimuli recruit a primary subcortical olfactory system to a greater degree than pleasant ones and that this resulted in a suppression of cortical activation. Their conclusion, based only on five participants and two odorants, was supported by Owen and Patterson (2002), who noted that an odor rated as unpleasant by one group of participants tended to increase alpha activity in frontal locations compared to those who rated the same odor as pleasant. It should be noted, however, that unlike PEA, VA is a relatively strong stimulus for intranasal trigeminal (CN V) afferents, implying a potential confound of the involved neural activity (Doty et al., 1978).

Observations of cortical suppression during olfactory processing contrast with observations of decreased alpha activity during the presentation of non-olfactory suprathreshold stimuli thought to reflect attentional orienting towards the stimuli. However, more recent research has found an olfaction-related decrease in alpha power over the occipital cortex, similar to the traditional decrease seen in other sensory modalities. Interestingly, in one study approximately 66% of patients who reported being anosmic from head injury still displayed a definite decrease in power of the alpha frequency during olfactory stimulation (Bonanni et al., 2006). This so-called “olfactory stop response” of the alpha frequency suggests that, despite self-reports of olfactory perceptual deficits, cortical processing of the stimuli may in some cases still be detectable. Further research, including control groups and an examination of the relation between alpha modulation and standardized smell tests, is required to further understand this finding. It is possible that residual cortical functioning in the olfactory system is detectable without conscious perception of a given odorant. Moreover, most persons with head trauma related olfactory deficits do not have complete loss of olfactory function, despite beliefs to the contrary (Doty et al., 1997).

### 12.2.5 Temporal Resolution

The research reviewed in Section 12.2 is representative of the majority of work that has examined gradual changes in on-going EEG activity during olfactory stimulation. The measures employed all involve basic techniques commonly used to analyze changes in the on-going EEG over an extended period of time. Sections 12.3 and 12.4 review

research on olfaction employing EEG techniques that allow for much greater temporal resolution. We now turn to work involving what is perhaps the most well-established approach to precise measurement of the time-course of EEG changes, the use of Event-Related Potentials (ERPs).

## 12.3 CHEMOSENSORY EVENT-RELATED POTENTIALS

ERPs are the portion of the EEG elicited by a specific event, for example, the presentation of a stimulus or the start of an overt movement. The ERP associated with a single event is usually very difficult to observe in an EEG recording because, like the ripples from a stone tossed into a strong current, it is dwarfed by the background activity in which it is embedded. The most common method for extracting ERPs from the background EEG involves a process of averaging. An event is repeated many times while the EEG is recorded and the EEG is then divided into segments, each “time-locked” to the event. An average segment is calculated by averaging the voltages at corresponding time-points from individual segments, where “corresponding” means preceding or following the start of an event by the same amount of time. As more individual segments are added to the average, variations in amplitude of the background EEG diminish. This is because these variations are random fluctuations around an expected mean voltage that is the same at any given moment relative to the event. The ERP, in contrast, is a systematic pattern of voltage changes that occur at the same time relative to each repetition of the event. Thus, it remains (relatively) unscathed by the averaging process while fluctuations in the background EEG are cancelled out.

### 12.3.1 Measurement

ERPs elicited by odorants are most often referred to as chemosensory event-related potentials or CSERPs (Evans et al., 1993). Two factors have made the measurement of CSERPs especially challenging. First, as highlighted above, the measurement of ERPs is crucially dependent on the occurrence of brief events with abrupt onsets. Punctate stimulation is more difficult to achieve for the chemical senses than for vision, audition, or touch. Second, it is difficult to stimulate the olfactory nerve without also stimulating the trigeminal nerve, whose intranasal free nerve endings signal such sensations as warm/cool, irritation, and pungency. To do so, requires (a) the presentation of olfactory stimuli without concomitant changes in pressure, temperature, or humidity, and (b) the use of odorants that stimulate only the olfactory nerve. These two problems were a central concern of early work involving CSERPs and caused the field to have a somewhat rocky start.

CSERPs were first reported by Finkenzeller (1965) and Allison and Goff (1967). However, enthusiasm for CSERPs as a means to study olfaction soon diminished after Smith et al. (1971) found them to be solely the result of trigeminal stimulation. We now know that CSERPs can arise from either the trigeminal or olfactory systems. Most odorants stimulate both (Doty et al., 1978) and thus elicit composite CSERPs (Kobal and Hummel, 1988). A few, such as vanillin and PEA, are not generally detectable by anosmics with preserved trigeminal function, particularly at low to moderate concentrations. Thus, they mainly stimulate the olfactory nerve alone (Doty et al., 1978). Such odorants elicit CSERPs in individuals with normal olfactory function (Kobal and Hummel, 1988; Kobal and Hummel, 1998), but not in anosmics (Kobal and Hummel, 1998). In contrast, odorless carbon dioxide is used to selectively stimulate the trigeminal nerve (Kobal and Hummel, 1988; 1998). The disparity between Smith et al. (1971) and later studies was probably due to the subsequent development of more effective methodologies for adequately stimulating the olfactory system and preventing trigeminal stimulation.

Chief among these advances were specialized olfactometers (e.g., Benignus and Prah, 1980; Evans and Starr, 1992; Kobal and Plattig, 1978; Kobal, 1981; Kobal and Hummel, 1988; Lorig et al., 1999). The first, originally developed by Kobal and Plattig (1978), became commercially available and added considerable impetus to the study of CSERPs. In their device, one of two concurrent air streams is directed to the olfactometer outlet, which consists of a teflon tube inserted into one of the subject's nostrils. Both streams have the same flow rate, temperature, and humidity. They differ only in that one contains a mixture of air and odorant, while the other contains air alone. Switching which stream exits the olfactometer into the nose, which can occur in less than 20 msec, is used to present a series of brief odorants embedded in a background of odorless air without producing any concomitant changes in stimulation.

Other foundational methodological developments concern parameters of odorant presentation, such as duration, inter-stimulus interval, and flow rate. Highlighting the need for abrupt onsets, CSERPs result primarily from the initial portion (e.g., 100 msec.) of odorant presentation (Kobal, 2003). The duration of inter-stimulus intervals is important because of habituation at short intervals. Though the degree of habituation depends on the odorant type and concentration, CSERP amplitude can be reduced substantially at intervals of less than 30 sec (Kobal and Hummel, 1991). Odorant flow rate is important because it influences the number of molecules reaching and being absorbed into the olfactory mucosa. Another factor that has received considerable attention is breathing. Subjects are often asked to mouth breath, while odorants are presented asynchronously with their respiratory cycle. Under such

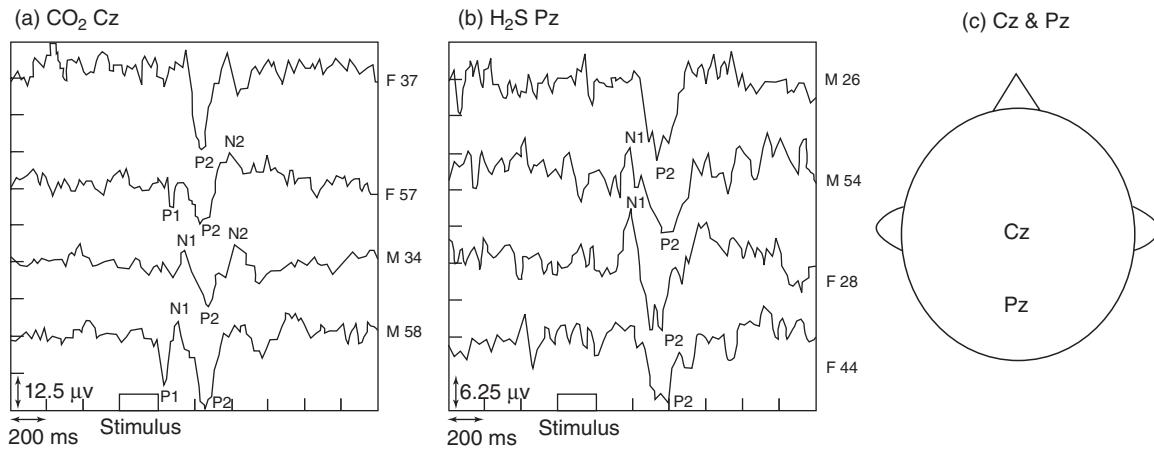

conditions, CSERPs appear to be larger in response to odorants presented during inhalation than exhalation (Haehner et al., 2011; but see Pause et al., 1999). To prevent mouth breathing from influencing airflow in the nasal cavity, and thus odorant presentation, subjects are sometimes taught a technique involving velopharyngeal closure (Kobal, 1981). Reviews of these and other methodological issues can be found in Kobal and Hummel (1991), Lorig (2000), and Kobal (2003).

In contrast to the methodological hurdles posed by the presentation of olfactory stimuli, the recording of CSERPs is straightforward relative to that of other ERPs. In many cases (see Section 12.3.2 below), it is sufficient to record EEG from a small number of electrodes along the midline near the vertex. The range of frequencies recorded (online filter settings) is usually similar to what is typically employed for recordings of late cortical ERPs (e.g., 0.01–100 Hz), which easily includes all the frequencies that carry information examined in current CSERP analyses. The scalp recordings are typically referenced to recordings at one of the mastoid bones or the algebraic average of recordings at both. Earlobes are also popular. Following the session, segments of the recordings containing electrical contamination from blinks, eye-movements, or other artifacts are removed or corrected. After some additional offline filtering, the EEG recordings are ready to be averaged to form CSERPs.

### 12.3.2 Representation

CSERPs have been represented in a number of ways. The most common form to date is as a time-series of voltages recorded at one or a few locations on the scalp. These time-series are often conceived of as comprising a series of distinct "components," each arising from a specific neural population during a specific type of information processing. Components are operationally defined by their polarity, latency, shape, topography over the scalp, and sensitivity (or lack thereof) to various experimental manipulations. Though not always the case, each component is often identified with a specific peak or trough that occurs (more-or-less) consistently in the voltage time-series.

Figure 12.1 provides an example of voltage time-series with labeled components from a study by Hawkes et al. (1997). Each is the average of recordings from an individual subject in response to odorants stimulating either the trigeminal ( $\text{CO}_2$ , Panel A) or olfactory (Hydrogen Sulfide,  $\text{H}_2\text{S}$ , Panel B) nerve and was obtained at the location on the scalp where each type of CSERP is maximal (Panel C). They are representative of a general pattern in which the first of a series of large deflections is positive and occurs at about 250 msec. after stimulus onset, the second is negative, and the third is positive and may be a complex of several deflections (Kobal, 2003). The three labeled

(b) CSERPs from four healthy subjects in response to olfactory stimulation (200 msec. pulses of H<sub>2</sub>S) recorded at electrode site Pz. Time and voltage (negative up) are shown respectively on the horizontal and vertical axes. Each subject's age and sex is shown to the right of their CSERP. (c) Scalp locations of electrode sites Cz and Pz. Adapted with permission from “Olfactory dysfunction in Parkinson’s disease,” by C.H. Hawkes, B.C. Shephard, and S.E. Daniel, 1997. *Journal of Neurology, Neurosurgery, and Psychiatry*, 62(5), p. 438. Copyright 1997 by BMJ Group.

components—P1, N1, and P2—are identified with these deflections and named on the basis of their polarity and order (Evans et al., 1993). Most often measured are the peak amplitude and latency of N1 and P2, which have test-retest reliabilities comparable to those of cortical components elicited by visual, auditory, and tactile stimuli (Thesen and Murphy, 2002; Welge-Lussen et al., 2003; Nordin et al., 2011). These CSERP components arise from cortical areas involved in early stages of sensory processing (Pause and Krauel, 2000) but occur later than analogous cortical components in other sensory modalities. This delay may be due, at least in part, to the time required after presentation for odorants to reach and stimulate receptors in the nose (Kobal, 2003).

Figure 12.2 provides examples of several alternative ways to represent CSERPs. The figure comes from a study by Lascano et al. (2010) and shows the grand average of responses from 12 healthy subjects to H<sub>2</sub>S. Panel A shows a voltage time-series which, though in the same format as those in Figure 12.1, displays broader N1 and P2 components. This is to be expected in a grand average, given the variability in their peak latencies between subjects. Panel B shows a butterfly plot displaying the voltage time series for each of 64 recording sites across the scalp. As can be seen, the variability of voltages across scalp sites at a given time point (vertical spread) increases at times when components are evident in the display above (A). This is because the difference in voltage between locations across the scalp at a given moment is proportional to the overall strength of the neural response. Panel C displays a measure of this spatial variability in voltage called the Global Field Power (GFP; Lehmann and Skrandies, 1980). GFP is represented by the contour of the plot. The colored segments under the

contour indicate “micro-states” (Lehmann and Skrandies, 1980), which are likewise based on the topographic distribution of voltages. Changes in ERP topography indicate changes in the identity, orientation, and/or relative strengths of its neural generators. Microstates correspond to intervals of time during which the topography, and hence the configuration of neural generators, remains relatively constant. The ones shown here were inferred using a clustering algorithm. The average topography corresponding to each microstate is shown in Panel D. Those for States 2 and 4 provide a good idea of the voltage distribution across the entire scalp around the time of N1 and P2.

A final example shown in Figure 12.3 is based on work by Kayser et al. (2010) and involves grand average CSERPs from 35 healthy subjects in response to H<sub>2</sub>S. The approach employed here was motivated in part by two problems associated with ERPs in general. First, they are very much influenced by the choice of reference electrode. Second, recordings from multiple electrode sites need somehow to be integrated. Both problems are in fact solved by GFP, which is a single measure based on the entire voltage topography and independent of reference. Kayser et al. chose a different approach that provided detailed inferences about components. First, they transformed their recordings at each electrode site from voltage to current source density (CSD), a reference-free measure. A set of components underlying the resulting CSD time-series at all electrode sites was then derived by Principal Component Analysis (PCA). These components are displayed in Panel A, which shows their time-courses and the percentage of the variance accounted for by each. Kayser et al. interpreted the earliest two (peaks at 305 and 630 msec) as corresponding to the

**Figure 12.2** Olfactory CSERPs 0–1200 msec. following left-nostril stimulation from 12 healthy subjects. (a) Grand average of time-series recorded at electrode site Pz. (b) Butterfly plot of overlaid grand average time-series at all 64 electrode sites. (c) Temporal extent (colored segments) and global field power (contour) of the microstates identified by a cluster analysis of the 64 grand average time-series. (d) Scalp topographies of the microstates (red, positive voltage; blue, negative voltage). traditional N1 and P2 components and the two later components as related to a motor response performed by subjects. Panel B displays the topographic distribution of the N1 and P2 CSD components for weak and strong odorants, as well as the difference between the two (intensity effect). Of particular interest are the locations of maximal current flow for each component, which are consistent with the putative neural sources discussed in the next section.

### 12.3.3 Neural Sources

The neural generators of CSERPs are not yet well known. This is in part because few studies have so far attempted to locate them, and also because of difficulties inherent in ERP source localization. One prerequisite for inferring the neural generators of ERPs from electrical measurements on the scalp is a “head model,” that is, an estimate of the resistance and geometry of each type of tissue comprising the head. Electric fields, however, are accompanied by magnetic ones that arise from the same sources and are uninfluenced as they pass through these tissues. Thus, because it minimizes the need for a head model, it is somewhat more tractable to infer sources from magnetic

than electrical measurements. In most cases, however, neither type of measurement at the scalp provides sufficient information to uniquely specify a set of underlying sources. It is therefore necessary to constrain the range of possibilities by making a number of physiologically plausible assumptions, including adoption of a model concerning the nature and/or number of sources. The earliest and perhaps best known “source models” involve a small number of current dipoles (source and sink), each of which can vary in location, orientation, and strength.

For these reasons, most extant studies providing information germane to the sources of CSERPs have employed magnetoencephalography (MEG) and dipole modeling along with concurrent recording of EEG. Two of these studies, including the earliest, employed CO<sub>2</sub> stimulation of the trigeminal nerve in an effort to elucidate the neural basis of pain (Huttenen et al., 1986; Hari et al., 1997). Both found a source that was most active around the time of N1 and located bilaterally in the upper bank of the Sylvian fissure near the lateral end of the central sulcus in the vicinity of the secondary somatosensory area. The later study (Hari et al., 1997) found this source to have a right-hemispheric dominance and detected a second source located in the

**Figure 12.3** Principal Component Analyses (PCA) of current-source density (CSD) measures of olfactory CSERPs to  $\text{H}_2\text{S}$ . (a) Factor loadings of the first four PCA factors (labels indicate peak latency and variance explained) extracted from olfactory CSD waveforms. (b) PCA-CSD factor score topographies corresponding to N1 sink (top) and P2 source (bottom) for 35 healthy subjects. Topographies are shown for responses to low- and high-intensity stimuli, as well as the difference (high minus low). Rolandic area, that is, around primary sensorimotor cortex. Other studies have involved odorants affecting primarily the olfactory nerve. Most have found dipole sources during the P1-N1-P2 interval located bilaterally in the Sylvian and superior temporal fissures, as well as the intervening superior temporal lobe (Kettenmann et al., 1996, 1997; Sakuma et al., 1997). These all lie in cortical areas with hypothesized connections to the primary olfactory cortex, including anterior-central parts of the insula and parainsular cortex (Kettenmann et al., 1997). Bilateral sources have been reported also in inferior parietal cortex (Sakuma et al., 1997) and near the orbitofrontal sulcus (Tonoike et al., 1998).

Though magnetic fields are generally preferred for source localization, electric fields do have some advantages. Magnetic fields measurable over the scalp arise from only a subset of the sources that produce measurable electric fields, specifically ones closer to the scalp involving current flow tangential to the scalp, for example, from the walls of sulci. Electric fields can be used to detect these sources as well as somewhat deeper ones and radial ones in gyrii. So far, the only attempt to model the sources of CSERPs based directly on the ERP signals has been the study discussed above by Lascano et al. (2010). Besides taking into account the electrical resistance of tissues, there were two other noteworthy methodological differences from the above MEG studies. First, Lascano et al. used a

distributed source model. Such models involve a 3-D volume comprised of a large number of voxels, in which each voxel “contains” a dipole with a specific strength and orientation. The volume used here corresponded to grey matter of the cerebral cortex and limbic structures segmented from an average MRI (Montreal Neurological Institute). Second, they separately modeled the voxels active during each of the four microstates shown in Figure 12.2. As mentioned, each microstate corresponds to a time interval with a stable ERP topography and hence a stable configuration of generators. During the first microstate, activation ipsilateral to the stimulated nostril was found in the medial temporal lobe (parahippocampal gyrus and amygdala) and lateral temporal lobe (middle and superior temporal gyrus, inferior insular cortex). During the second and third microstates, activation spread to the same structures in the contralateral hemisphere. The inferior frontal gyrus became activated bilaterally during fourth state.

### 12.3.4 Functional Significance

A rough idea has begun to emerge as well about the relation between CSERPs and olfaction at the functional level. Relevant information has come from the examination of effects on CSERPs of factors and manipulations that influence the efficacy or quality of olfactory perception, as well as correlations between CSERPs and other olfactory measures.

Included are the effects of stimulus properties, such as concentration. When odorants stimulating the olfactory and/or trigeminal nerve are strong enough to be perceived, further increases in intensity decrease the latency and/or increase the amplitude of the P1 component, N1 component, and at least part of the late positive complex (Kobal and Hummel, 1991; Pause et al., 1997; Tateyama et al., 1998; Wang et al., 2002). Consistent with the stimulus-intensity effects, these components have been found to be larger (Murphy et al., 1994) or earlier (Tateyama et al., 1998) in individuals with lower olfactory thresholds, that is, a more sensitive sense of smell. The amplitude of CSERP components is influenced also by the state of olfactory adaptation or habituation, as manipulated by the rate of odorant presentation. Wang et al. (2002) reported such effects, as well as an impressive correlation between component amplitudes and detection performance across experimental conditions defined by different combinations of stimulus intensity and rate of presentation.

Olfactory perception is known to vary with traits that vary among individuals, including age and gender. The decline of olfactory function throughout the lifespan of healthy adults is well established, including increased thresholds for detection and diminished ability to identify odorants (e.g., Doty et al., 1984; Murphy et al., 2004). Likewise, olfactory CSERP components become progressively smaller (P2 and N1-P2 difference) and slower (N1) over much of the course of normal adult aging (Murphy et al., 1994; Evans et al., 1995; Hummel et al., 1998; Covington et al., 1999; Murphy et al., 2000). Within each age group, women have been found to have lower thresholds and better identification than men (for a review, see Doty and Cameron, 2009). So, it is perhaps not surprising that women have larger CSERPs (Becker et al., 1993; Evans et al., 1995; Morgan et al., 1997; Olofsson and Nordin, 2004; Stuck et al., 2006).

CSERPs are also influenced by psychological states. Especially susceptible to such effects is a constituent of the late positive complex thought to be a P300.<sup>1</sup> The P300 is not exclusively an olfactory ERP component; it can be elicited by stimuli in any sensory modality and is thought to arise from brain regions, such as the hippocampus and amygdala (Halgren et al., 1980) and/or cortical association areas (Polich and Squire, 1993), not devoted solely to any particular modality. The P300 is a response to unexpected stimuli and is studied most often using the “oddball” paradigm, which involves sequences comprised of frequently and infrequently repeated stimuli. P300 amplitude is larger in response to the infrequent stimuli, even when “frequent” and “infrequent” are defined by

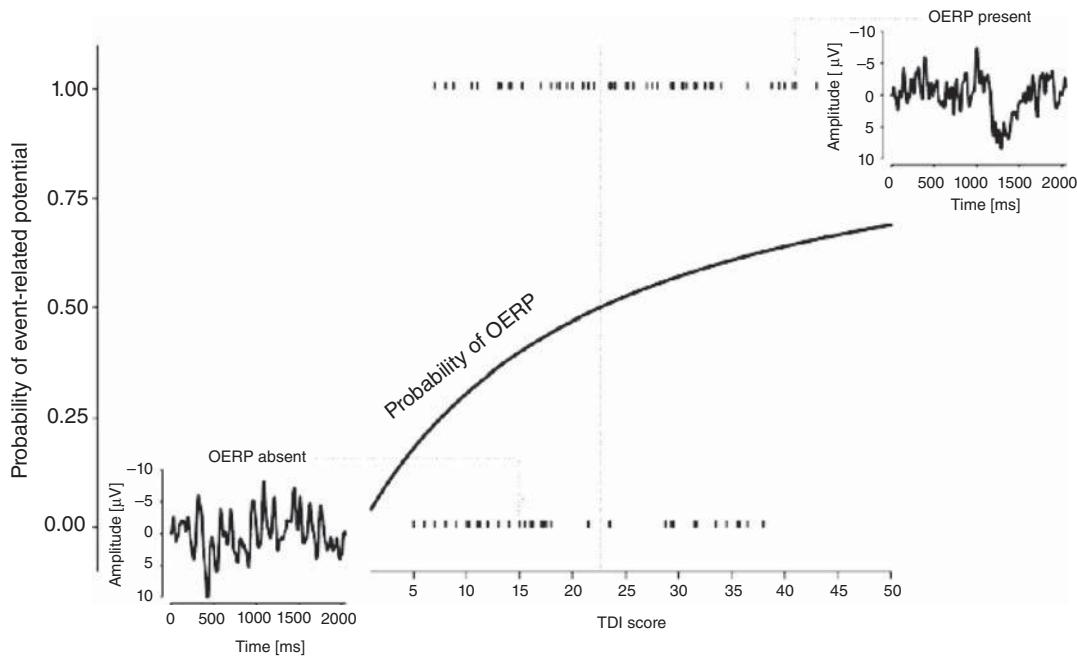

membership in an abstract category based on a semantic feature, for example, gender in a list of names (Kutas et al., 1977). A number of studies employing oddball paradigms have demonstrated robust P300s in response to infrequent odorants (e.g., Durand-Lagarde and Kobal, 1991; Pause et al., 1996; Pause and Krauel, 2000). Perhaps because it is related to “surprise,” P300s can be elicited also by a single repeated odorant when the intervals between repetitions are as long as those typically employed to avoid habituation (e.g., Morgan et al., 1999; Geisler and Murphy, 2000).

P300s elicited by olfactory stimuli have the same characteristics as those elicited by stimuli in other sensory modalities. They require attention to the stimuli (Krauel et al., 1998; Geisler and Murphy, 2000) and are sensitive to their subjective significance (Pause et al., 1996; Laudien et al., 2008; Bulsing et al., 2010) and emotional valence (Pause and Krauel, 2000). These effects are consistent with the idea that the P300 reflects cognitive states that can be induced through any sensory channel. They also indicate that the contribution of P300s to the CSERP is likely to be reduced under conditions with equally probable odorants of little intrinsic significance to which subjects need not attend. It is noteworthy, however, that the N1 and P2 are also sensitive to manipulations of attention and stimulus significance (Krauel et al., 1998; Geisler and Murphy, 2000; Laudien et al., 2008; Bulsing et al., 2010). This would suggest that the neural processes that directly produce these olfactory ERP components either perform cognitive functions or receive feedback from other (more central) processes that do. Further clues concerning the functional significance of CSERPs are contained in the next two sections, which detail some of their applications.

### 12.3.5 In the Olfactory Clinic

There has been considerable interest in applying CSERPs in clinical settings devoted to olfactory disorders. This interest stems in part from their potential to detect olfactory responses in individuals who might be unwilling (e.g., malingering) or unable (e.g., infants or those with cognitive disabilities) to provide accurate responses on behavioral tests. Moreover, as a psychophysiological measure, they hold the promise of detecting subtle responses that may evade behavioral tests. CSERPs have been obtained from patients with olfactory disorders due to a variety of causes, including nasal disease, upper respiratory infection, poisoning or adverse reactions to medications, traumatic head injury, neurological problems, and congenital or idiopathic causes. So far, the feature of CSERPs most often employed has been their presence vs. absence as judged by trained observers. As mentioned earlier, the absence of CSERP responses to olfactory stimuli has been demonstrated in anosmics (Cui and Evans, 1997; Kobal and Hummel, 1998). However, as illustrated in Figure 12.4, they can

<sup>1</sup>Despite its name, this component often follows the stimulus by more than 300 msec. For reviews see Donchin (1981), Donchin and Coles (1988), and Verleger (1988).

**Figure 12.4** Probability of detecting an olfactory CSERP as a function of TDI score (sum of a patient's test scores for odor threshold, discrimination, and identification). Dots indicate the presence or absence of a CSERP from individual patients, and the vertical dotted line indicates a 0.5 probability at a TDI of 22.6. TDIs of less than 15.5, between 15.5 and 30.5, and greater than 30.5 indicate respectively functional anosmia, hyposmia, and normal function. The two inserts depict examples of the absence of a CSERP from a hyposmic patient (left bottom, TDI score indicated with an arrow) and presence of a CSERP from a normosmic patient (right top, TDI score indicated with an arrow). Reprinted from “The clinical significance of electrophysiological measures of olfactory function,” by J. Lotsch and T. Hummel, 2006. *Behavioral Brain Research*, 170, p. 80. Copyright 2006 by Elsevier B.V. Reprinted with permission.

be undetectable as well in patients for whom behavioral measures have demonstrated some preserved olfactory function.

Figure 12.4, from Lotsch and Hummel (2006), shows the probability of detecting olfactory CSERPs from patients as a function of their combined threshold, discrimination, and identification (TDI) score on a behavioral test (Kobal et al., 2000). The patients consisted of 59 men and 64 women (ages 19–89) who visited a smell and taste clinic with chemosensory complaints due to all of the causes mentioned in the previous paragraph. As can be seen, those with TDI scores in the “functional anosmia” range (0–15) sometimes produced detectable CSERPs, those with scores in the middle (around 23) of the hyposmic range (16–30) had a 50% chance of producing detectable CSERPs, and those with scores in the normosmic range (31–50) did not always produce detectable CSERPs. Overall CSERPs were detected in 20%, 48%, and 70% of patients with scores in the three TDI ranges. A similar relation between TDI score and detection of olfactory CSERPs was observed at an outpatient rhinology clinic for 107 males and 122 females (ages 15–75+) with a similar variety of problems (Rombaux et al., 2009). Overall, though trigeminal CSERPs were detectable in 99% of 221 recordings, olfactory CSERPs

were detectable in only 29% of 224 recordings. Moreover, while TDI scores differed significantly between patients with problems due to different etiologies, the probability of detecting olfactory CSERPs did not.

The interpretation of CSERPs as currently used in the olfactory clinic would appear to be as follows. An olfactory CSERP implies the presence of at least some olfactory function. Thus, when detected with a high degree of confidence, it should call into question a diagnosis of complete anosmia. A detectable olfactory CSERP in hyposmic patients may even be associated with a greater chance of improvement (Rombaux et al., 2010). In contrast, a failure to detect an olfactory CSERP does not necessarily imply diminished olfactory function, though alternative explanations involving methodological problems can be ruled out to some extent by detection of trigeminal CSERPs in the same recording session. In sum, though still somewhat limited, the utility of CSERPs in the olfactory clinic is likely to increase as a result of promising developments on the horizon. For example, given the functional interactions between the olfactory and trigeminal systems and robust presence of trigeminal CSERPs, these latter CSERPs might be used to assess olfactory function (Rombaux et al., 2009). Perhaps most importantly, methodological advances may enhance

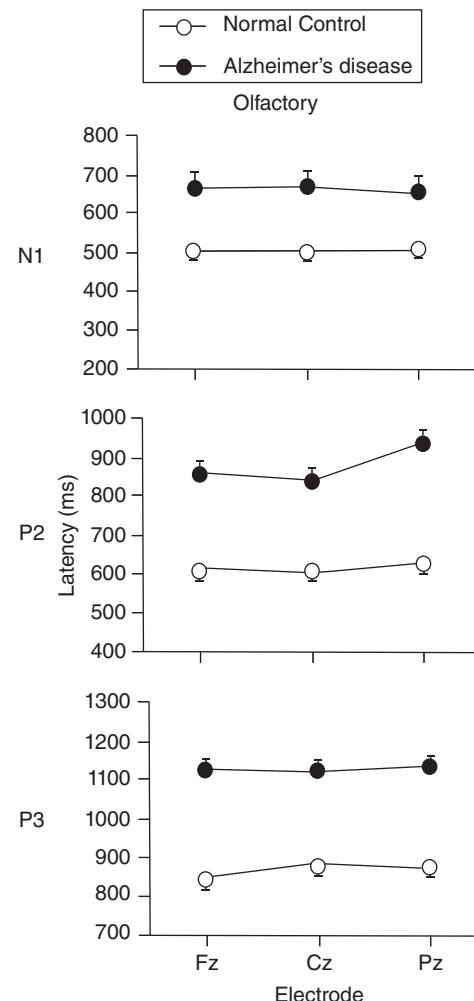

the detection of olfactory responses in the EEG (Rombaux, et al., 2012), including one to be discussed in Section 12.4 (Huart et al., 2012).

### 12.3.6 Effects of Brain Disease

An increasing number of neurological and neuropsychiatric diseases have been found to be associated with early olfactory dysfunction. Moreover, such olfactory signs often antedate more classic symptoms. The search for early biomarkers of these diseases, as well as insight into their development, has thus spurred considerable research on their relation to olfaction. Given the potential of CSERPs to index specific neural and functional components of the olfactory system, it is only natural that some of this work has involved their measurement. Chief among the brain diseases studied so far with CSERPs are Alzheimer's disease (AD), Parkinson's disease (PD), and schizophrenia.

Both AD and PD have been reported to be associated with increases in the latency of olfactory CSERPs but with little change in their amplitude (Barz et al., 1997; Hawkes et al., 1997; Wetter and Murphy, 2001; Morgan and Murphy, 2002; Corby et al., 2012). Figure 12.5, which compares component latencies from 12 AD patients and 12 age- and gender-matched controls (Morgan and Murphy, 2002), shows just how robust these differences in AD can be. As can be seen, N1, P2, and P3 latencies are longer for AD patients by approximately 150–300 msec. These components have likewise been found to occur later for individuals at risk for AD, that is, those who test positive for the E4 allele of the apolipoprotein gene (Wetter and Murphy, 2001; Corby et al., 2012). In PD, both the N1 and P2 have been found to be delayed for olfactory but not trigeminal CSERPs (Barz et al., 1997; Hawkes et al., 1997). Delays in N1 associated with AD and PD would seem to indicate a slowing of early (possibly subcortical) olfactory processing. Slowing of early olfactory processes would likewise be expected to delay the P2 and P3 components, though additional slowing of later olfactory and/or cognitive processes could also contribute to their observed delay in AD and PD.

In contrast to AD and PD, olfactory CSERP amplitudes have been found to differ from normal in schizophrenia. Reduced N1 and P2 components have been recorded from both schizophrenics (Turetsky et al., 2003; Kayser et al., 2010) and unaffected first-degree relatives of schizophrenics (Turetsky et al., 2008). Latency differences have also been reported. Turetsky et al. (2003) found P2 latency for strong stimuli to be prolonged in schizophrenics, while Pause et al. (2008) found N1 and P2 latencies to be reduced. This latter finding, which was most evident in responses to an unpleasant odor (rotten-butter-like isobutyraldehyde), was interpreted by Pause et al. as reflecting increased sensitivity to emotionally negative odors. Other neurological

**Figure 12.5** Olfactory CSERP latencies for N1, P2, and P3 components as a function of electrode site for normal controls and Alzheimer's disease patients. Adapted from "Olfactory event-related potentials in Alzheimer's disease," by C.D. Morgan and C. Murphy, 2002. *Journal of the International Neuropsychological Society*, 8(6), p. 760. Copyright 2002 by Cambridge University Press.

diseases studied so far with CSERPs include Down's syndrome (Wetter and Murphy, 1999), Huntington's disease (Wetter et al., 2005), multiple sclerosis (Hawkes, 1996), motor neuron disease (Hawkes et al., 1998), and epilepsy (Hummel et al., 1995).

The influence of brain pathology on CSERPs has provided insight as well into the functional anatomy of the olfactory and trigeminal systems. One example involves unilateral epileptic foci in the temporal lobes. Hummel et al. (1995) found foci in each hemisphere to be associated with later N1 and P2 components when olfactory stimuli were presented to the ipsilateral than to the contralateral nostril. This is congruent with an ipsilateral dominance of early olfactory processing that extends to

cortical areas in the temporal lobe. In contrast, N1 and P2 components occurred later when trigeminal stimuli were presented to the left than to the right nostril, regardless of the side of the foci. Another example concerns evidence for right-hemispheric dominance in the olfactory system obtained by Daniels et al. (2001) from subjects with unilateral tumors located mainly in the temporal and frontal lobes. Right-hemisphere tumors were associated with diminished P2 and P3 amplitudes at parietal sites and a frontal shift in topography regardless of which nostril was stimulated. With left-hemisphere tumors, these effects were less pronounced and associated mainly with left-nostril stimulation. Finally, grouping patients based on their CSERPs can help identify structures in which olfactory or trigeminal responses are compromised by brain pathology. For example, Welge-Lussen et al. (2009) compared fMRI responses between hyposmic Parkinson patients with and without detectable olfactory CSERPs. Stronger responses were found for the group with detectable CSERPs in the amygdala, parahippocampal cortex, inferior frontal gyrus, insula, cingulate gyrus, striatum, and inferior temporal gyrus.

## 12.4 RECENT ADVANCES IN ANALYSIS OF EEG ACTIVITY

In Section 12.2, we reviewed research using older methodologies that examined changes in the on-going EEG at each of several frequency ranges over an extended period of time. Section 12.3 presented research involving ERPs which, though they provide much better temporal resolution, do not distinguish between different frequencies. Moreover, as discussed below, ERPs are sensitive only to a portion of neural responses to stimulation. In this section, we discuss recent advances in analyzing EEG activity that combine the capabilities of both traditional EEG and ERP methodologies. As we shall see, it is now possible to examine changes in power induced by a stimulus at individual frequencies with a high degree of temporal precision.

### 12.4.1 Discrete Frequency and Continuous Time-Frequency Measures

The processing and analysis of *induced* power modulations at any given frequency is unlike the processing of *evoked* ERPs (see Section 12.3). A change in the on-going EEG activity can be time locked to a specific event but not necessarily *phase* locked to that event. As the induced signal is not phase-locked and the phase varies randomly in relation to the event, a process of averaging, as is conducted in ERP analysis, would eliminate the signal of

interest (Pfurtscheller and da Silva, 1999). Therefore, a more complex form of signal processing must be implemented in order to measure power modulations, at any given frequency range, during a specific event; this is known as *frequency analysis*.

There are several analytical techniques under the umbrella of frequency analysis that are used to measure specific modulations of power largely divisible into two broad categories: discrete and continuous. The most common form of discrete frequency measures is the Fast Fourier Transform (FFT). This process effectively expresses a complex signal (such as that measured with EEG) as a summation of a series of simple sine and cosine terms. These distinct sinusoidal components of a signal can be converted into continuous time-specific data in the frequency domain. The FFT therefore produces measures of power, of any specified frequency, for a given *discrete* time period. These power values are then usually made relative to a baseline measure. This is by far the most common method used in the literature, as reviewed in Section 12.2.

There are specific limitations in using an FFT to reliably measure power. The better the signal is located in the time domain the less accurate the location of the signal is in the frequency domain and vice versa (formalized in the “uncertainty principle”; Heisenberg, 1927). More modern “continuous time-frequency” analysis techniques allow for more accurate measurements in the time domain as well as in the frequency domain, the most common of which is known as the Continuous Wavelet Transform (CWT).

The CWT is unlike the Fourier Transform in that it passes a series of small frequency windows, or “wavelets,” over every sample that is subject to spectral calculation. Effectively, the resulting CWT measurements describe the evolution of power for specific frequencies over the time period of interest. Moreover, the spectral calculation is relative to a specified time period, much like the baseline period used in ERP analysis.

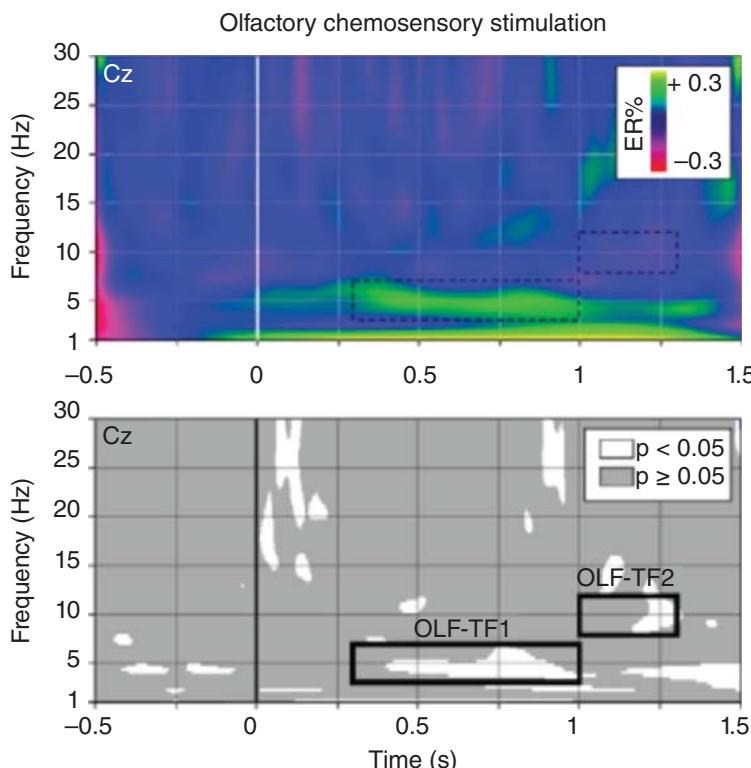

The ability to observe an evolution of frequency power over time confers several advantages over discrete methods (i.e., FFTs). For example, psychological questions pertaining to the speed or timing of cognitive processes can be better answered as power is described over short time intervals. Further, when no modulation power is found using an FFT calculation, this may be due to the lengthy time period incorporated by the FFT, obscuring modulation that may only occur over shorter time periods. Wavelet analysis is better at minimizing this problem. These methods also incorporate non-phase locked information that is eradicated in the averaging process of ERPs.

Discrete methods of frequency analysis are not temporally specific enough to examine event related changes. Rather, a coarse time period is taken and either one, or several odors in the same experimental condition, is presented

to the participant. This method increases the likelihood of the modulation of brain frequencies by higher-order cognitive processes and decreases the signal to-noise ratio. Indeed, this is one reason why event-related potentials are more widely used in olfactory research than discrete methods of frequency analysis.

### 12.4.2 Continuous Time-Frequency EEG

To our knowledge, only two studies have used continuous time frequency measures at the onset of an olfactory event (Huart et al., 2012; Lorig and Randol, 1996). The study by Lorig and Randol (1996), only available as a conference presentation abstract, describes a modulation of power across a wide range of frequency bandwidths only 1.5 seconds after olfactory stimulation. Further, only low frequency modulations were found to show a variable response in relation to the odor presented. This research suggests that the temporal evolution of the frequency power is somewhat slower than ERP modulations, implying that EEG and ERP modulations may be tapping into different components of the olfactory network. However, this is only a preliminary report of findings; calculations of both EEG and ERP modulations of the stimuli to the same EEG signal would allow for a better examination of the association between the two components.

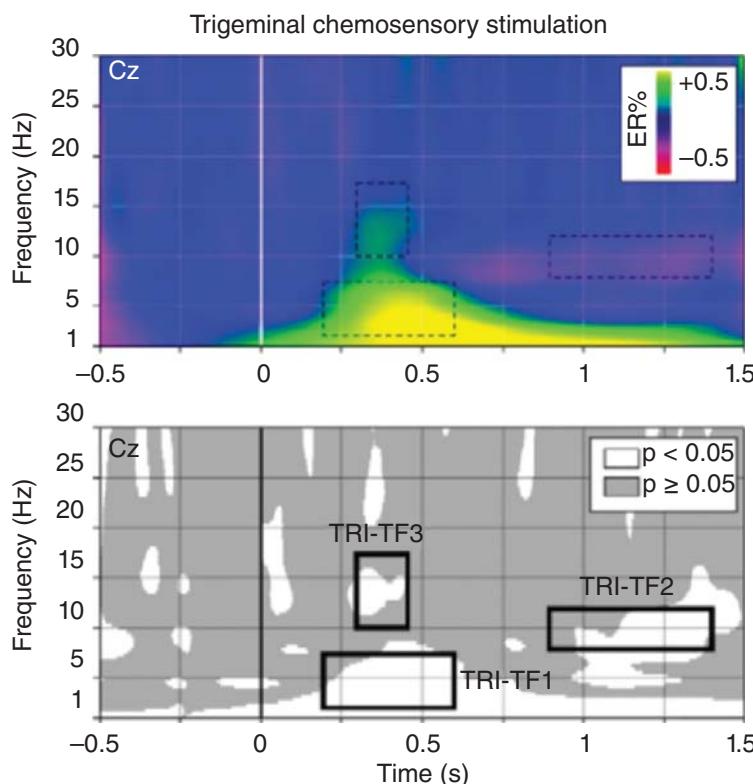

Exploring EEG changes in response to olfactory and trigeminal stimulation in 11 individuals with normal smell function, Huart et al. (2012) characterized both the phase locked component of the EEG (the traditional ERP; discussed in greater detail above) and the non-phase locked continuous changes in a frequency spectrum. Via an olfactometer, participants were presented with CO<sub>2</sub> for trigeminal stimulation and with PEA for olfactory stimulation.

Huart et al. (2012) used a wavelet analysis, described above, to assess the evolution of EEG power across time during olfactory stimulation for a frequency spectrum ranging from 0.3 to 30 Hz (see Figure 12.6). The results showed a long lasting increase in power around the theta frequency range (~5 Hz), followed by a shorter decrease in alpha power (~10 Hz). Modulations in power were most prominent over the central electrode Cz in a similar fashion to the olfactory ERP. The authors suggested that this common topography indicates that both the ERP and the changes in time-frequency reflect the same stimulus-evoked cortical activity.

In their study, trigeminal nerve stimulation resulted in an increase in power in a high frequency range (~10–15 Hz) and, similar to olfactory stimulation, was followed by a long lasting decrease in alpha power (See Figure 12.7). The early high frequency component was thought, tentatively, to suggest specific processing of trigeminal stimulation and the alpha to reflect a decrease in neuronal idling related to cortical processing of the trigeminal stimulus. The similarity

(See plate section for color version.)

**Figure 12.7** Modulation of EEG power across time during trigeminal stimulation. Top panel: continuous power changes in color. Bottom panel: only those power changes that differed significantly from zero. Adapted from “Time-frequency analysis of chemosensory event-related potentials to characterize the cortical representation of odors in humans,” by C. Huart et al., 2012. *PLoS ONE*, 7(3), p. 6. (See plate section for color version.)

between olfactory and trigeminal nerve stimulation in cortical functioning, as indicated by alpha power modulations, may reflect a functional overlap in trigeminal and olfactory processing. This functional overlap may suggest that the processing of nasal somatosensory and olfactory information is non-independent. This is in line with recent research and theoretical positions that suggest that “the sniff is part of the olfactory percept” (Mainland and Sobel, 2006).

Huart et al. (2012) also compared the time-frequency modulations induced by olfactory and trigeminal stimulation to time-frequency information taken from background EEG noise to determine the “discriminability” of the signal. The ability to discriminate between the presence and absence of olfactory cortical processing is obviously useful for clinical examinations of olfactory functioning, as well as for the validity of the method as a whole. Importantly, the time-frequency signal was able to discriminate significantly better than the olfactory ERPs between background noise and olfactory induced modulations. This peaked with a sensitivity of 81.8% and a specificity of 90.9%.

Perhaps most importantly, Huart et al. (2012) report that above all other EEG and ERP measures, increases in power at the theta frequency range were positively ( $r = 0.7$ ,  $p = 0.02$ ) correlated with a behavioral measure of olfactory function. This suggests that, in fact, time-frequency EEG modulations in response to olfactory stimulation

reflect olfactory related cortical processing of functional relevance.

## Structural and Functional Imaging of the Human Olfactory System

JAY A. GOTTFRIED

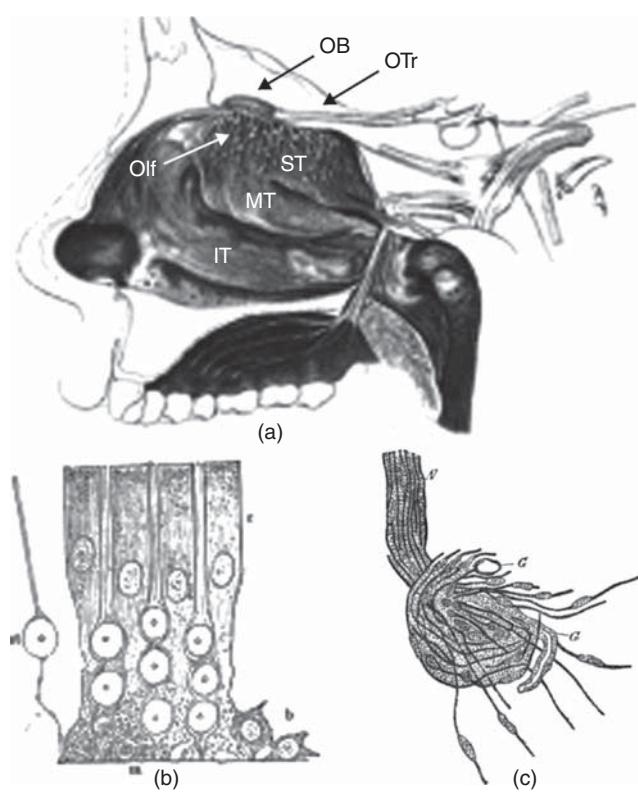

### 13.1 INTRODUCTION

An image is a visual reproduction or rendition of an object externally presented to the eye. (In the case of Art, an image might be the visual reproduction of an object *internally* presented to the mind's eye.) Imaging is thus the process of generating these images. From prehistoric cave pigments to extraterrestrial Mars rovers, technological advances and human curiosity have shaped our ability to generate images of the very near and very far, the very big and very small, and everything in between. Imaging of the human nervous system has moved closely in step with scientific progress to make the unobservable observable: from the classical techniques of pen-and-ink, camera lucida, dry-plate photography, silver staining, and light microscopy, to the incipient clinical milieu of roentgenograms (x-ray) and pneumoencephalography, and onward to the modern era of computed axial tomography (CAT scan), single photon emission computed tomography (SPECT), positron emission tomography (PET), and magnetic resonance imaging (MRI). These last two methods have revolutionized our understanding of the human brain, particularly its functional aspects, and constitute the primary focus of this chapter.

Since the Second Edition of the *Handbook* appeared approximately ten years ago, the field of human olfactory imaging has grown by sniffs and bounds. Technical and methodological innovations have made it possible to test scientific hypotheses that could not have been previously tested. New imaging approaches have induced a paradigm shift from the “where” to the “how” of odor information processing, providing novel mechanistic insights into the structural and functional organization of human olfaction.

Work in patient populations has helped inform basic understanding of the human olfactory system, and translational studies have identified putative imaging biomarkers to optimize medical diagnostic decisions. The main goal of this chapter is to review these recent research developments and advances. In line with the *Handbook*'s important message that the research present (and future) are inextricably linked to the research past, this chapter will briefly discuss human olfactory imaging in a historical framework. To begin we must retreat to the wood-paneled theaters of the 19th-century German anatomists, where the first images of the human olfactory system were generated.

One of the first scientific treatises dedicated to human olfactory imaging was published in the early 1800s by the German physician, anatomist, and inventor, Samuel Thomas Sömmerring (1755–1830). Among his more notable achievements was the first systematic characterization of the cranial nerves, development of a protective inoculation against smallpox, and an influential though ultimately misguided description of the pterodactyl (stating it was a batlike mammal rather than a reptile). Sömmerring's 1809 monograph, *Abbildungen der menschlichen Organe des Geruches* (i.e., *Images of the Human Smell Organs*), provided one of the first faithful anatomical renderings of the human peripheral olfactory system, including the distribution of olfactory nerve fibers along the superior turbinate, their penetration through the cribriform plate, the position of the olfactory bulb in the anterior cranial fossa, and the posterior course of the olfactory tract (Figure 13.1a). These macroscopic images remained the definitive source of information regarding human olfaction, up until the advent of microscopic and histological studies half a century later,

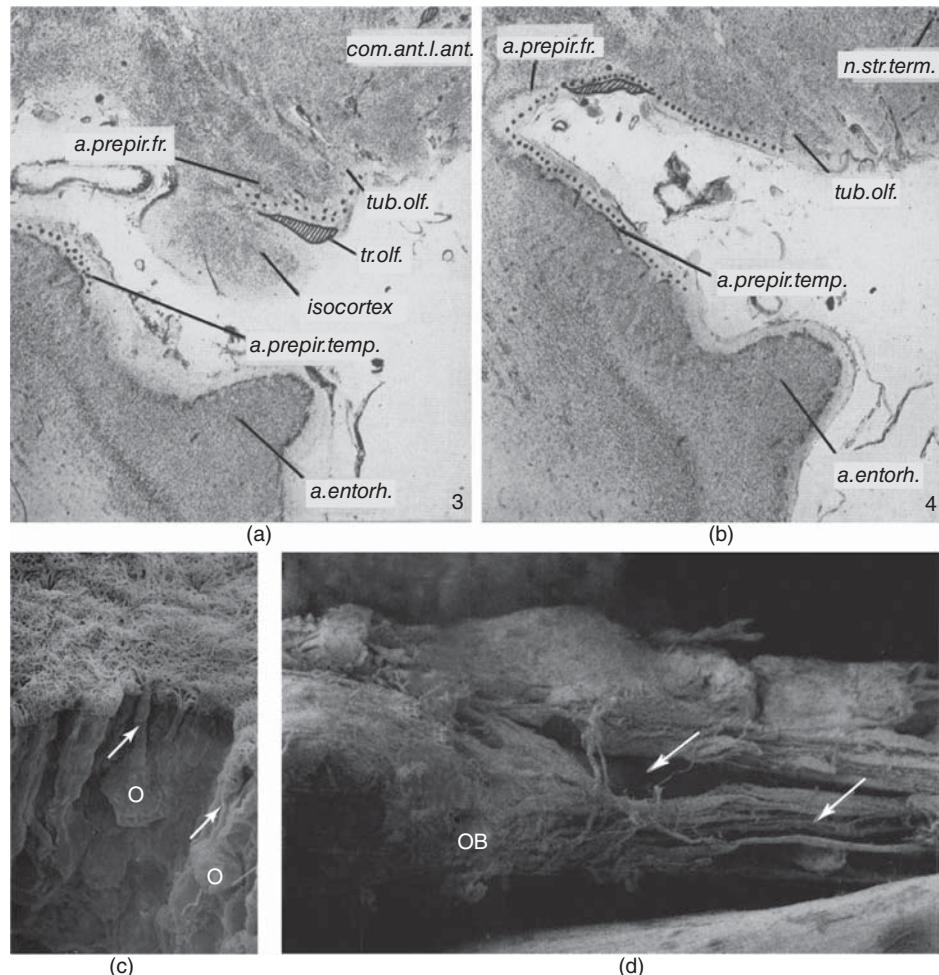

**Figure 13.1** Pre-Golgi images of the human olfactory system, 19th century. (a) Anatomical rendering of the right lateral wall of the nasal cavity (septum removed), viewed in sagittal cross-section. Olf, olfactory nerves, resembling a lace-like sheet of fibers concentrated along the surfaces of the superior turbinate and upper middle turbinate, en route to the olfactory bulb (OB) and olfactory tract (OTr). IT, inferior turbinate; MT, middle turbinate; ST, superior turbinate. From Sömmerring, 1809. (b) Vertical cross-section through the neuroepithelium of the human olfactory region, after exposure in 1% osmic acid solution for 15 minutes. Note three different cell types, including basal cells (at the bottom edge of the image), olfactory sensory neurons (with cell bodies in the lower third of the image, tapering towards the top), and supporting cells (with cell bodies in the upper third of the image). From Krause and Krause, 1876. (c) Microscopic image of the human olfactory bulb, in which a spherical aggregation of cells and fibers (glomerulus) is joined by olfactory nerve fibers coursing from the upper left of the image, and by dendrites of mitral cells approaching from the bottom right and right side of the image. From Meynert, 1872.

again from the German school of anatomy, including the pre-Golgi work of Schultze (1856), Meynert (1872), and Krause (1876) that depicted the cellular organization of the human olfactory epithelium and olfactory bulb glomerulus (Figure 13.1b,c). This work first identified three of the fundamental cell types in the olfactory epithelium, including ciliated receptor neurons, columnar supporting cells, and basal cells, and described the spherical masses in the olfactory bulb (glomeruli) where afferent inputs and

mitral cell fibers converged (Meynert, 1872; Krause and Krause, 1876).

Only sporadic progress on human olfactory imaging was made over the next 100 years, again of a gross macroscopic or histological disposition. In 1954 A. C. Allison had a rare opportunity to examine the brain of a 52-year-old man whose olfactory peduncle had been accidentally transected on one side during a prefrontal leucotomy two years prior to death (Allison, 1954). Using different staining methods to evaluate neurons, axons, and myelin, he was able to delineate the secondary projection areas of the human olfactory bulb, based on regional patterns of fiber degeneration and trans-synaptic cellular atrophy (Figure 13.2a,b). These findings provided the most systematic anatomical images of the human olfactory brain yet available, with insightful descriptions of the anterior olfactory nucleus, olfactory tubercle, frontal and temporal piriform cortex, and medial and cortical nuclei of the amygdala. Around the same time that Allison was toiling with tissue stains, Engstrom and Bloom (1953) used electron microscopy (EM) to obtain high-resolution images of the human olfactory mucosa. In an ingenious step, Morrison and Costanzo (1990, 1992) used freeze-fracture scanning EM to describe the fine microstructure of the human olfactory epithelium in three dimensions (Figure 13.2c,d), considerably extending prior EM studies of olfactory epithelial surface features (Engstrom and Bloom, 1953; Naessen, 1971; Nakashima et al., 1984). Their breathtaking images revealed the ultrastructural details of the dendrites, knobs, and cilia originating from the cell bodies of human olfactory sensory neurons, and captured the olfactory fibers of passage coursing from the epithelium to the olfactory bulb. One important take-home message from this work was that the distribution of olfactory epithelium within the nasal mucosa was highly patchy and irregularly interspersed with respiratory epithelial tissue.

These pioneering forays into olfactory imaging held one distinct disadvantage for investigators and subjects alike: the reliance on post-mortem material. The advent of noninvasive imaging techniques, arguably beginning with the first CT scanner in the early 1970s, has provided new ways to probe the structure and function of the human brain, both in health and disease. However, it was also apparent from the earlier anatomical data that most olfactory-related structures in the human brain were small, implying that successful imaging of these regions would require a technique with sufficient spatial resolution. The development of magnetic resonance imaging (MRI), and its many cousins of image “contrast” methods—most famously the blood oxygen level-dependent [BOLD] contrast utilized for functional MRI—have revolutionized our understanding of the human olfactory brain. The next section of this chapter will briefly review the principles and methodology of MRI scanning, given its domineering

**Figure 13.2** Pre-MRI images of the human olfactory system, 20th century. (a) and (b) Coronal cross-sections through the human basal forebrain and dorsomedial temporal lobe (cresyl violet stain, x7.5). Cross-hatching represents the olfactory tract, with dots indicating presumptive terminations of the olfactory tract. Key: *a.entorh.*, entorhinal area; *a.prepir.fr.*, frontal portion of the piriform area; *a.prepir.temp.*, temporal portion of the piriform area; *com.ant.l.ant.*, anterior limb of the anterior commissure; *n.str.term.*, nucleus of the stria terminalis; *tr.olf.*, olfactory tract; *tub.olf.*, olfactory tubercle. From Allison, 1954. (c) and (d) Freeze-fracture electron microscopy images of the human olfactory epithelium (c) and bulb (d). Panel (c) (x4,400 magnification) shows olfactory sensory neurons (O) in the epithelial layer, with their dendrites (arrows) projecting up toward the epithelial surface, which is densely covered with a mossy mat of olfactory cilia. Panel (d) (x44 magnification) shows a view of the dorsal cribriform plate in the floor of the anterior cranial fossa, with the olfactory bulb (OB) lying in place, with axon bundles of the olfactory nerves (arrows) from the nasal cavity projecting to and enveloping the anterior end of the OB.

contribution to modern imaging techniques. Subsequent chapters will focus on key advances in structural and functional imaging of human olfaction, with an emphasis on recent data that have emerged over the last 10 years.

## 13.2 A BRIEF PRIMER ON MRI SCANNING

This short overview of MRI scanning will administer a minimal dose of physics to answer three questions. First, how does an MRI scanner work? Second, how is the MRI signal generated? Third, how is the MR signal transformed into a

spatial image? For detailed discussion of these topics, the reader is referred to many excellent textbooks (Toga and Mazziotta, 1996; Jezzard et al., 2002; Huettel et al., 2008; Buxton, 2009; Poldrack et al., 2011); much of this section is specifically drawn from the book, *Functional Magnetic Resonance Imaging*, 2nd Edition (Huettel et al., 2008).

### 13.2.1 How Does an MRI Scanner Work?

The historical antecedent to modern MRI was nuclear magnetic resonance, that is, NMR. This technique was

founded on the idea that atomic nuclei resonate (oscillate) at a specific magnetic frequency, and that if placed within an external magnetic field resonating at that same frequency, the nuclei would absorb energy. Subsequent emission, or radiation, of this electromagnetic energy could then be measured and quantified. Thus, at the heart of NMR, and also of MRI, are three components: a static magnetic field to generate an external magnetic perturbation; a transmitter coil to convey the magnetic field to the sample of interest; and a receiver coil to read out the electromagnetic emission from the sample. It is important that the magnetic field is spatially homogeneous, because local and unexpected variations in the field can induce signal distortion and measurement error. In addition, a larger magnetic field is generally preferable because it increases the signal-to-noise ratio (though this can come at the expense of increased signal artifact, an early confound that plagued olfactory functional MRI). Achieving very stable and high-strength magnetic fields (1.5-Tesla and higher) requires the use of superconducting electromagnets that are cooled to temperatures near absolute zero, typically using liquid helium, reducing electrical resistance within the electromagnet wires to optimize current flow while minimizing electrical power requirements.

### 13.2.2 How is the MRI Signal Generated?

Generation of the MRI signal follows from several basic physics principles. Thermal energy causes atomic nuclei (being a composite of protons and neutrons) to spin. If these nuclei have a net positive charge, as in the case of odd numbers of protons (e.g.,  $^1\text{H}$  or  $^{31}\text{P}$ ), then the spinning motion creates an electrical current, which in turn creates a small internal magnetic field. Given that humans are approximately 70% water, MRI scanning of human biological tissue is most commonly tuned to imaging of hydrogen nuclei (a single proton, i.e.,  $^1\text{H}$ ).

Normally, the spin axes of the nuclei are randomly oriented with regard to each other, so that the aggregate of nuclei within a tissue sample does not generate a net magnetic field. However, in the presence of an MRI scanner's strong magnetic field, the spin axes of all of the atomic nuclei become aligned, resulting in net magnetization longitudinal to the scanner's magnetic field. Interestingly, the spin axes are not rigidly aligned with the magnetic field, but instead exhibit rotation, or "precession," around the main magnetic field, similar to the wobbling motion of a gyroscope or spinning top. The resonance frequency of precession, that is, the frequency at which the nucleus will absorb energy, is specific to the type of nucleus (for protons it is 42.58 MHz/Tesla) and is known as the Larmor frequency.

Note that the process of magnetization does not itself constitute the MRI signal. In order to measure the signal,

a radiofrequency "excitation pulse" is delivered from the transmission coil to inject energy and perturb the system. This pulse consists of a burst of electromagnetic energy waves, set to oscillate at the same frequency as the resonant (Larmor) frequency of the nucleus of interest. The immediate effect is to tip the spins of the atomic nuclei from the longitudinal axis (a low-energy state) into the transverse plane (a high-energy state), shifting the orientation of net magnetization. With ongoing excitation there is increasing loss of spin phase coherence among nuclei, resulting in reduced net magnetization in the transverse plane.

Once radiofrequency excitation ceases, the nuclei gradually transition back to their low-energy state, during which time they emit energy (also at the same Larmor frequency). An MRI receiver coil tuned to the same frequency is used to detect changes in electrical current between excitation and recovery. This is the essence of the recorded MR signal. Recovery, or "relaxation," of magnetization along the longitudinal axis follows the time-constant,  $T_1$ , typically a few hundred milliseconds, whereas recovery within the transverse plane follows the time-constant,  $T_2$ , typically a few tens of milliseconds. Thus, by adjusting the timing parameters of signal acquisition within the relaxation phase, one can control the relative contributions of  $T_1$  signal and  $T_2$  signal to the MR image. In  $T_1$ -weighted brain scans, gray matter appears bright, whereas white matter, water, and cerebrospinal fluid (CSF) appear dark, providing excellent structural anatomical information. In  $T_2$ -weighted scans, water and CSF appear bright, making this imaging sequence sensitive to tissue edema and other pathological changes. A related sequence protocol,  $T_2^*$ -weighted imaging, is the basis for acquisition of BOLD signal during functional MRI, which will be described later in the chapter.

### 13.2.3 How is the MR Signal Transformed into a Spatial Image?

A critical early innovation of MR technology was to convert single-point measurements of bulk matter into two-dimensional spatial images. Although static magnetic fields could be used to excite an entire tissue slice in two dimensions, the fact that all points within the slice were excited at the same resonant frequency meant that all points within the slice *would also emit an MR signal at the same frequency*. Thus, there was no way to resolve different spatial locations using this basic technique. An initial attempt to overcome this issue was to collect MR data from one voxel in space at a time, then stitch together the data from all voxels to create an MR image. This approach was laborious, time-consuming, and impractical.

In the early 1970s Dr. Paul Lauterbur devised a solution to the spatial encoding problem. He determined that by spatially varying the strength of the external magnetic

field, different points within the slice would resonate at different frequencies. (This is because the precession frequencies of atomic nuclei linearly scale with MR signal intensity.) The use of these imposed spatial gradients meant that each point in space was effectively tagged with its own unique resonant frequency, making it possible to reconstruct spatial information from the slice. Further, by applying spatial gradients in all three dimensions (*x*, *y*, and *z*) of the sample, a complete three-dimensional image could be assembled, providing a way to view the MR scans in any orientation. A further breakthrough came a few years later, when Dr. Peter Mansfield developed new mathematical algorithms to reduce the time of MR data acquisition from minutes or hours to tens of milliseconds. Known as echo-planar imaging (EPI), this profoundly faster acquisition sequence ushered in the use of MRI in the clinical setting, and has also been essential to the success of functional MRI, in which different cognitive or perceptual states evoke activity-dependent changes in MRI activity on the order of a few seconds. In recognition of their influential contributions, Lauterbur and Mansfield were awarded the Nobel Prize in 2003.

### 13.3 STRUCTURAL IMAGING

Structural noninvasive imaging of the human olfactory system has particular technical, almost existential, constraints due to the fact that the anatomical boundaries of most olfactory areas in the human brain (especially the piriform cortex and OFC) are just not evident. Adding to this problem is the fact that even the best structural MRI sequences cannot achieve a spatial resolution much below  $1\text{ mm}^3$ , so that morphological descriptions remain fairly coarse, without finer characterization of laminar organization or cellular or architectural features. Indeed, the use of functional MRI techniques (as discussed in the next section) has played a more important role in defining the “structural” organization of human olfaction, insofar as these approaches have identified brain areas that are consistently involved in processing smells. There is one brain area that structural imaging has excelled over functional imaging, and that is the olfactory bulb. The small slender size of the olfactory bulb, and its artifact-prone location near an air-tissue interface, make this region extremely challenging to visualize using fMRI. Olfactory structural imaging has also found a role in clinical diagnostics. These topics are presented below.

#### 13.3.1 Structural Imaging of the Human Olfactory Bulb

Efforts in the 1980s to image the human olfactory system (Schellinger et al., 1983) using computed tomography (CT) were laudatory, but sub-optimal, because skull-based

artifacts substantially reduced visualization of the olfactory bulbs and adjacent structures. The first systematic MRI investigation of the human olfactory bulb was conducted using a  $T_1$ -weighted sequence, though identification of the olfactory bulbs and tracts was inconsistent across participants (Suzuki et al., 1989). In subsequent work by Yousem, Doty, and colleagues (Yousem et al., 1996a; Yousem et al., 1996b; Yousem et al., 1998), a high-resolution MR surface coil was placed over the nasion (where the frontal bone meets the two nasal bones in the midline) to help improve signal recovery. In healthy subjects, coronal  $T_1$ -weighted images clearly demonstrated olfactory bulbs and tracts, in position between the ventromedial prefrontal cortex and the ethmoid sinuses (Figure 13.3a,b). By comparison, in patients with congenital or posttraumatic anosmia (smell loss), the anatomical volumes of the bulbs and tracts were reduced, with relative preservation of central structures, suggesting a primarily peripheral basis for their olfactory perceptual impairments.

In related work examining volumetric changes across the life span in healthy subjects (Yousem et al., 1998), olfactory bulb volumes were observed to peak in the fourth decade of life ( $\sim 150\text{ mm}^3$ ), then progressively declined into the eighth decade ( $\sim 120\text{ mm}^3$ ), hinting at one possible explanation for why the sense of smell diminishes with age. However, the lack of a significant correlation between MRI bulb volumes and odor identification scores failed to support this hypothesis. One other cautionary note from this study is that considerable variation was seen across individuals and age groups, implying that volumetric data of the olfactory bulb might have limited diagnostic applicability at the level of single subjects.

More recent imaging studies from the Hummel laboratory have in fact shown that the volume of the olfactory bulb correlates with odor perceptual performance, not only in healthy subjects (Rombaux et al., 2006; Buschhuter et al., 2008) but also in patients with postinfectious and posttraumatic olfactory impairment (Mueller et al., 2005; Rombaux et al., 2006). Again, prominent interindividual variation in the healthy population was evident, with over two-fold changes between different subjects (e.g., a range of  $37\text{ mm}^3$  to  $98\text{ mm}^3$  for the left olfactory bulb (Buschhuter et al., 2008). A longitudinal study of patients with hyposmia and anosmia (Haehner et al., 2008) demonstrated that over a mean time interval of 15 months, changes in odor detection thresholds correlated with changes in olfactory bulb volume (interestingly, both increases and decreases were observed). To the extent that odor thresholds are a reflection of peripheral olfactory processing, these findings suggest a potential causal link between peripheral afferent input and structural integrity of the olfactory bulb. Similarly, in patients before and after surgical treatment for chronic rhinosinusitis with polyps, increased olfactory bulb volumes (up to 19%) were correlated to improvements in odor

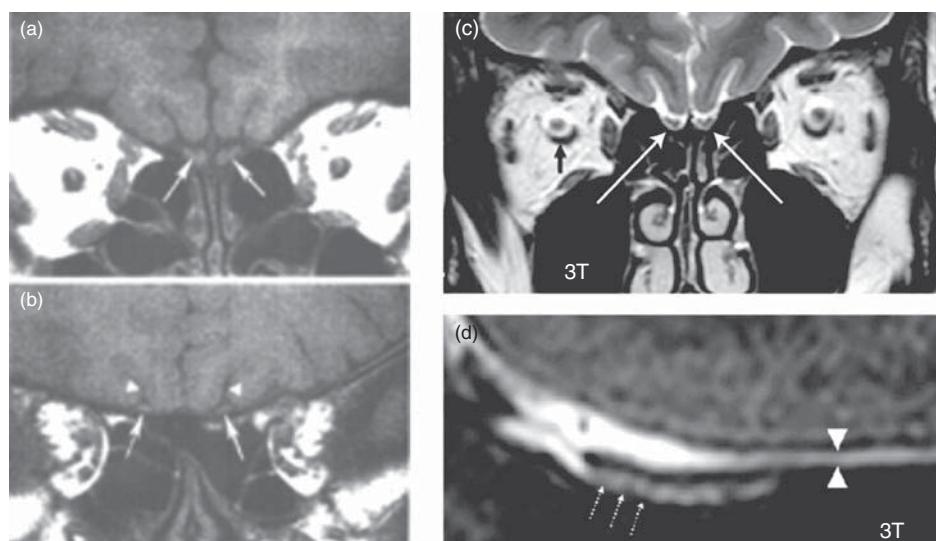

detection, but not to odor discrimination or identification, following a three-month interval (Gudziol et al., 2009). That these changes were observed in patients with an average age of 53 underscores the point that even the aging human olfactory system has a capacity to regenerate.

An unanticipated finding to emerge from MR volumetric imaging is that the depth of the olfactory sulcus in healthy subjects is predictive of odor perceptual performance, summed over tests of olfactory threshold, discrimination, and identification (Hummel et al., 2003). The olfactory sulcus represents the cleft between the lateral border of the gyrus rectus and the medial border of the medial orbitofrontal gyrus, forming a groove where the olfactory tract resides. Examination of patients with isolated anosmia (smell loss) indicates that the depth of this sulcus is a good indicator of the presence of the olfactory tract (Abolmaali et al., 2002).

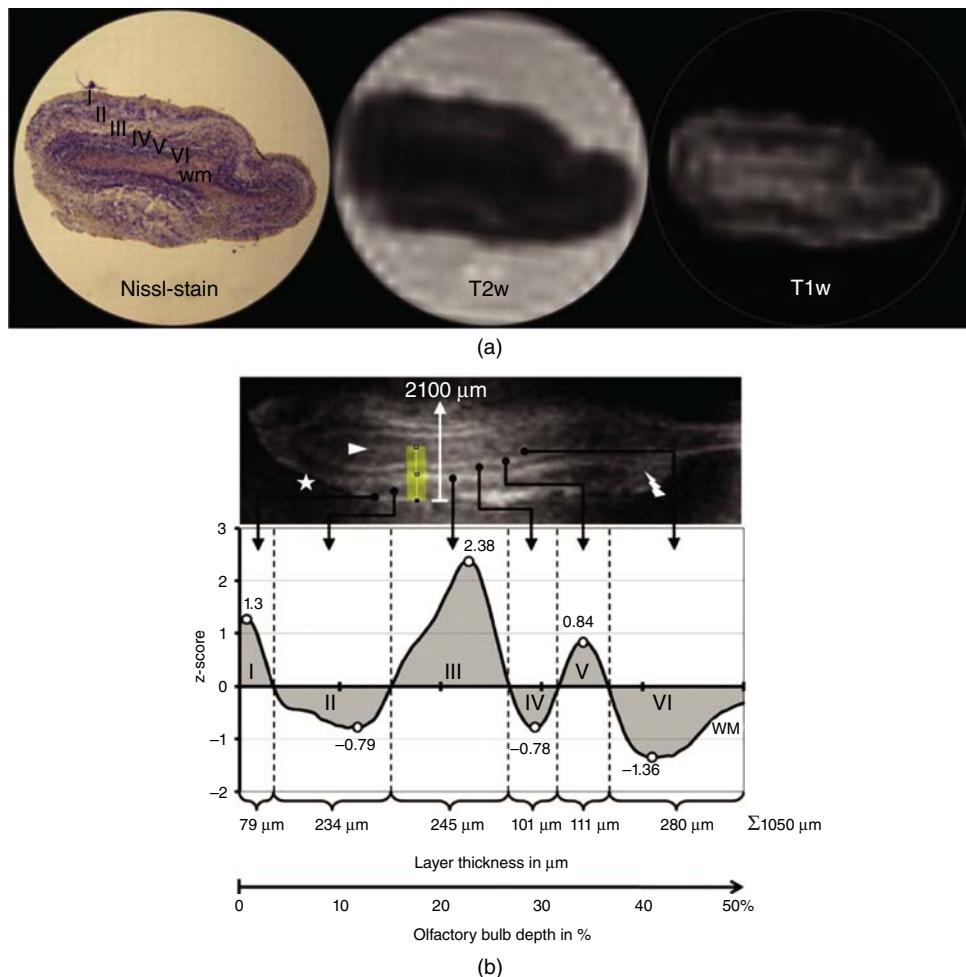

One technological development for imaging the olfactory bulb has been a shift from using T<sub>1</sub>-weighted sequences in favor of T<sub>2</sub>-weighted sequences. Although T<sub>1</sub>-weighted MRI strictly provides better anatomical resolution, T<sub>2</sub>-weighted MRI holds several advantages. Chief among these is the fact that CSF, which appears bright on T<sub>2</sub>, essentially encompasses the olfactory bulb and tract. As a result, these structures become sharply delineated by an outer bright ring, making it easier to trace their full extent. With improved contrast between

the olfactory bulb, the CSF, and nearby blood vessels, another impressive benefit is that penetration of the olfactory nerves through the bony cribriform plate en route to the bulb can be visualized (Duprez and Rombaux, 2010) (Figure 13.3c,d). These specialized T<sub>2</sub>-weighted MR scans rely on an imaging protocol known as a fast-spin-echo two-dimensional sequence, collected in the coronal plane, with 0.5 mm<sup>2</sup> in-plane (within-slice) resolution and 2 mm thick slices (Gudziol et al., 2009; Duprez and Rombaux, 2010). Notably, the recent introduction of a “constructive interference in steady state” (CISS) three-dimensional sequence, with an isotropic voxel resolution of 0.5 mm<sup>3</sup>, promises even greater signal resolution and reproducibility for olfactory bulb volumetry (Burmeister et al., 2011).

In exciting new work, Burmeister and collaborators (Burmeister et al., 2012) had an opportunity to obtain MR structural data of the human olfactory bulbs and tracts at high-resolution (0.2 mm<sup>3</sup> voxels at 3-Tesla and 0.1 mm<sup>3</sup> voxels at 9.4-Tesla) from embalmed post-mortem material that had been fixed in ethanol-formaldehyde (Figure 13.4). These MRI scans were compared to Nissl-stained 20-μm tissue sections from the same patient donors. Cross-sectional analysis of MR intensity through the olfactory bulb revealed four discrete intensity bands when imaged at 3-Tesla, appearing to correspond to major cortical lamina of the bulb on the histological sections,

**Figure 13.3** Structural MRI of the human olfactory bulb. (a,b) These T<sub>1</sub>-weighted coronal MRI scans show the olfactory bulbs (A, arrows) lying beneath the gyrus rectus bilaterally, and the olfactory tracts (b, arrows) lying at the base of the olfactory sulcus (arrowheads) bilaterally. Note that on these T<sub>1</sub>-weighted images, the olfactory bulb signal is brighter than the adjacent cerebrospinal fluid (CSF). (c) A T<sub>2</sub>-weighted coronal section from a 3-T MRI scan shows that the MR signal in the olfactory bulbs (white arrows) is darker than surrounding CSF and in fact encircles the bulbs, making it easy to identify the structure. Black arrow points to the dural sheath surrounding the optic nerve. (d) A sagittal T<sub>2</sub>-weighted image (where anterior is left and dorsal is up) highlights thin streaks of dark MR signal (small dotted arrows), which represent bony perforations in the cribriform plate through which the olfactory nerve filia pass on their way to the bulb. Arrowheads depict the CSF space between the ethmoid bone and the basal frontal lobe. a and b from Yousem et al., 1998; c and d from Duprez and Rombaux, 2010.

**Figure 13.4** High-resolution MRI of the human olfactory bulb. (a) A histological section of the human olfactory bulb (Nissl-stained; 20  $\mu\text{m}$  coronal sections) is compared to T2-weighted (T2w) and T1-weighted (T2w) MRI scans acquired at high-resolution (3-T MRI; 200  $\mu\text{m}$  sections). Both the histological and MRI images were obtained from human post-mortem samples. Six discrete layers can be identified in the Nissl-stained section of the bulb, including the olfactory nerve layer (I), glomerular layer (II), external plexiform layer (III), mitral cell layer (IV), internal plexiform layer (V), and granule cell layer (VI), as well as central white matter (wm). At least three layers can be discerned in the MR images, with alternating bands of hypointense (dark) and hyperintense (bright) signal. (b) Structural MRI scans at even higher resolution (9.4 T MRI; 100  $\mu\text{m}$ ) reveals identification of all six lamina in the olfactory bulb (upper half of panel). MRI intensity profile analysis was conducted in serial coronal sections across an area of the bulb delimited by the white asterisk and lightning bolt symbols. White arrow indicates diameter of the olfactory bulb; white arrowhead indicates central white matter. Intensity quantification was conducted from the inferior surface (i.e., 0% depth) to the mid-white matter (i.e., 50% depth). Normalized signal profiles are shown in the lower half of the panel. Modified from Burmeister et al., 2012.

including (from the outside in) the olfactory nerve layer, the glomerular layer, the external plexiform layer, and a portion spanning the mitral and granule cell layers. Intensity profiles were even more impressive at 9-Tesla, with intensity profile analysis capturing all cytoarchitectonic layers of the bulb. Additional 3-Tesla high-resolution image analyses indicated that the olfactory tracts could adopt four unique morphological configurations, including a tripartite shape (akin to a Mexican hat) in which a dorsal zone of MR signal hypointensity was suggested to represent the anterior olfactory nucleus. These new data

accentuate the remarkable potential of MRI to characterize microstructural details of the human brain. That being said, the imaging techniques described here would be extremely difficult to implement in living humans, if for no other reason that subjects would need to lie perfectly immobile during the 75–100 minutes of high-resolution 3-Tesla scanning, and that most subjects’ heads would not fit within the dedicated rat head coil (inner diameter, 3.8 cm) used to transmit and receive the radiofrequency signals. Thus, at the present time, laminar characterization of the olfactory bulb is out of reach of conventional 3-Tesla

MRI, but this situation will hopefully change as technology continues to move forward.

### 13.3.2 Olfactory Structural Imaging in Clinical Diagnostics

Perceptual deficits in the sense of smell occur in a wide number of neurological and psychiatric conditions, likely reflecting the fact that the neuropathology in many of these disorders involves, or even arises in, olfactory-related limbic brain regions of the medial temporal lobe and orbitofrontal cortex (OFC). As a result, a main goal of structural imaging of the human olfactory system has been to develop potential biomarkers of disease, perhaps even for pre-clinical diagnosis prior to onset of overt symptoms.

Some of the original work along these lines examined patients with schizophrenia, identifying a 23% reduction in olfactory bulb volume compared to control subjects (Turetsky et al., 2000), as well as volumetric reductions in perirhinal cortices that correlated with odor detection deficits (Turetsky et al., 2003b). The same investigators went on to show that the volume of the olfactory bulb (on the right side only) was also reduced in first-degree relatives of patients with schizophrenia (Turetsky et al., 2003a), suggesting a genetic predisposition to structural derangements in the olfactory system, irrespective of health status. Volumetric changes in the amygdala and hippocampus have also been implicated in schizophrenia, with hippocampal volumes correlating with odor discrimination performance (Rupp et al., 2005). Olfactory bulb volumes have recently been found to be reduced in another psychiatric disorder, major depression (Negoias et al., 2010). Interestingly, olfactory bulb volume inversely correlated with the magnitude of depression, that is, the most depressed patients had the largest olfactory bulbs. This somewhat paradoxical finding raises the intriguing idea that individuals with a more acute sense of smell are more prone to developing depression.

Patients with Alzheimer's disease develop smell deficits early in the course of their illnesses (Doty et al., 1987; Koss et al., 1988; Murphy et al., 1990). Such observations have motivated studies coupling structural MRI with olfactory perceptual testing. Murphy and colleagues (Murphy et al., 2003) found a significant association in Alzheimer's disease patients between the size of the left hippocampus and performance on an olfactory identification task where patients had to match an odor stimulus to line drawings. To the extent that successful performance on this task required binding together information across olfactory and visual modalities, this finding suggested key involvement of the hippocampus in olfactory relational memory. Subsequent work has shown that patients in the early stages of Alzheimer's disease have reduced olfactory bulb volumes, which correlated with a measure of global

cognitive decline (Thomann et al., 2009b). Similar volumetric changes were seen in patients with "age-associated cognitive decline," presumably in a pre-clinical phase of Alzheimer's disease (Thomann et al., 2009a), though because these data were pooled alongside patients with clinically established Alzheimer's disease, these findings remain to be confirmed.

A variety of structural imaging techniques have been applied to patients with Parkinson's disease, for whom olfactory impairments are an early non-motor manifestation. Using an imaging software platform known as volumetric brain mapping (VBM) to detect alterations in gray matter, Wattendorf et al. (2009) evaluated structural brain changes in mild and moderately advanced Parkinson's disease. Compared to control participants, test scores combining olfactory threshold, discrimination, and identification tasks were significantly correlated with piriform cortex atrophy in mild-stage patients and with amygdala atrophy in moderate-advanced patients, in spite of preservation of total gray matter volume. These findings suggest that at least a portion of olfactory perceptual dysfunction in Parkinson's disease has a central basis.

An alternative MRI technique, diffusion tensor imaging (DTI), has also been used to characterize structural changes in Parkinson's disease. DTI is based on the idea that water molecules diffuse more quickly along the longitudinal axis of white matter tracts than perpendicular to those tracts (Mori and Zhang, 2006; Hagmann et al., 2007; Assaf and Pasternak, 2008). By measuring diffusion in multiple directions, DTI provides a way to quantify the difference between parallel and perpendicular diffusion, which comprises the DTI signal.

In a group of 12 Parkinson's patients, increased diffusivity was observed in the base of the frontal lobes, in the vicinity of the olfactory tracts, when compared to 12 age-matched controls (Scherfler et al., 2006). Moreover, these data correctly classified 16 of 17 independent subjects into the Parkinson's group (9/9 patients) and the control group (8/9 controls), attesting to the robustness of the group differences in this brain region. However, these results should be interpreted with caution. The volume of increased diffusivity was  $\sim 1300 \text{ mm}^3$ , which far exceeds the volumes reported in the literature (the very upper estimate of olfactory bulb volume, based on structural MRI, is  $\sim 100 \text{ mm}^3$ ; Buschhuter et al., 2008). Furthermore, the scanning protocols were not optimized for imaging of the olfactory tract or bulb, where susceptibility artifact can introduce signal distortions. A separate DTI study identified changes in fractional anisotropy (an index of water diffusivity in the brain) in the gyrus rectus and primary olfactory cortex (near entorhinal cortex) in Parkinson's patients with smell loss, but not in control subjects, and fractional anisotropy measures from olfactory cortex correlated with odor identification scores (Ibarretxe-Bilbao

et al., 2010). Given that the control subjects had an intact sense of smell, it remains unclear whether these DTI changes simply reflect group differences in olfactory perception, or something unique about olfactory processing in Parkinson's disease.

## 13.4 FUNCTIONAL IMAGING

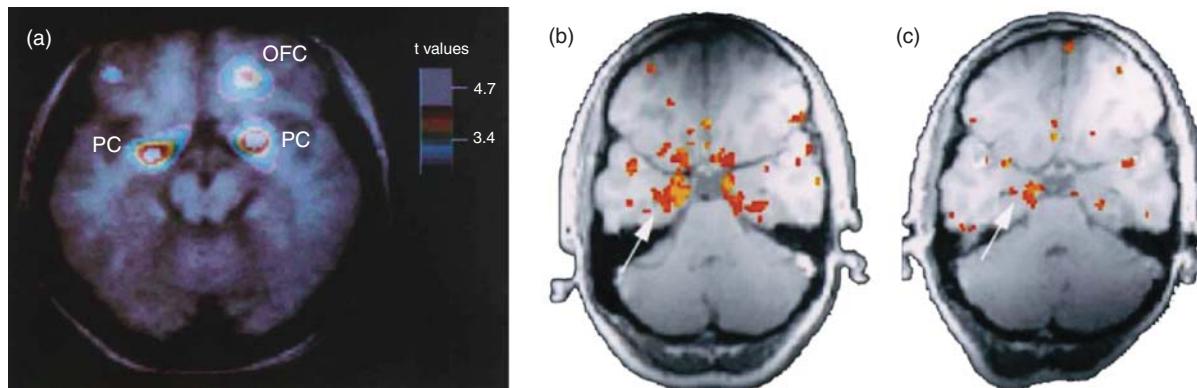

Functional imaging of the human brain is based on a simple principle: it takes work to think. It even takes work not to think (perhaps applicable to both resting brain states and certain neuroscientists). Neuronal activity is an energy-demanding process: for every ion-gated action potential and every ligand-gated post-synaptic potential, chemical concentration gradients between the extracellular and intracellular spaces need to be restored, and neurotransmitters need to be repackaged into vesicles. These cellular ‘housekeeping’ operations require energy, which for the brain equals glucose, along with oxygen to drive efficient conversion of glucose to ATP (this is known as aerobic respiration). It thus follows that a given brain region with increased activity will need more glucose and consume more oxygen. Depending on available local concentrations of glucose and oxygen, the brain may also need increased blood flow to deliver these substances and thereby sustain ongoing activity. The important concept is that all human functional imaging techniques provide only surrogate measures of brain activity.

### 13.4.1 The First Human Olfactory Functional Imaging Study

Initial approaches to identify odor-dependent activity in the human brain (Zatorre et al., 1992) used positron emission

tomography (PET). This modestly invasive imaging technique involves introduction of a radioactive tracer into the bloodstream, and was the leading functional imaging method through the late 1980s and early 1990s. The idea is that as the radioactive signal decays, it generates a positron, which quickly collides with an electron to generate two gamma rays that travel in opposite directions and are detected by an array of “coincidence detectors” positioned around the subject’s head. After sufficient time, the number of events accumulated at each detector can be transformed into a three-dimensional spatial map, with hot spots corresponding to brain areas of increased metabolism or uptake of the tracer. Note that PET scanning has nothing to do with MRI, though the PET images are aligned to a T1-weighted anatomical MRI scan for establishing which brain regions are activated.

In 1992 Zatorre and colleagues conducted the first olfactory imaging study, using PET with  $\text{H}_2\text{O}^{15}$  as the radioactive tracer (Zatorre et al., 1992), providing measures of oxygen consumption and regional cerebral blood flow (rCBF) in the human brain. (Another commonly used PET tracer is a fluorine isotope,  $^{18}\text{F}$ , conjugated to glucose, that is, fluoro-2-deoxy-D-glucose, or FDG, providing a measure of glucose uptake.) During scanning subjects were presented with either an odorless cotton wand (control condition) or a cotton wand saturated with one of eight different odorants. Comparison of these two conditions revealed odor-specific activations in the piriform cortex bilaterally and the OFC on the right side (Figure 13.5a). These findings nicely complemented data from patient lesion models of odor perception (Rausch et al., 1977; Potter and Butters, 1980; Eskenazi et al., 1983; Jones-Gotman and Zatorre, 1988) and suggested that imaging approaches could provide meaningful functional

**Figure 13.5** Functional imaging correlates of olfactory processing in the human brain. (a) Odor-evoked increases in PET regional cerebral blood flow (rCBF) are superimposed onto an axial section of an MRI scan (shown 17 mm below the intercommissural plane). Activations are depicted as a *t*-statistic image. PC, piriform cortex; OFC, orbitofrontal cortex. Modified from Zatorre et al., 1992. (b, c) Sniffing (in the absence of odor) evoked fMRI activity in the temporal piriform and entorhinal cortices (b, white arrow), but following topical anesthesia to the nasal cavity, fMRI was markedly reduced in this same participant (c, white arrow). Modified from Sobel et al., 1998. (See plate section for color version.)

information about the human olfactory system. By identifying some of the critical brain regions involved in human olfaction, this landmark work set the stage for the olfactory imaging work to follow.

Note that although PET imaging offers direct insights into cerebral metabolic states, there are several obstacles that have limited its research utility. First, the technique requires the costly availability of a cyclotron close at hand to generate the radioactive tracers in a timely way. Second, because PET involves the use of radioactive material, women of childbearing age are usually not enrolled in these studies. Third, while the radioactive half-life of the tracers is short, subjects can only receive a finite lifetime amount, restricting within-subject testing across multiple different conditions and/or days. Finally, due to the low signal-to-noise ratio of the PET signal, data for a given condition need to be collected over a 1–2 minute period (or longer). This poor temporal resolution is not compatible with many experimental designs involving rapid event-based stimulus presentations.

### 13.4.2 Initial Olfactory fMRI Studies

By the mid-1990s, cognitive neuroscience researchers were increasingly turning towards fMRI as the method of choice to elucidate human brain function. This technique takes advantage of the fact that deoxygenated (but not oxygenated) hemoglobin (Hb) is paramagnetic. Activity-dependent brain changes in the ratio of deoxygenated Hb to oxygenated Hb, arising from alterations in oxygen delivery, oxygen consumption, or cerebral blood flow per se, can be detected using specialized MRI sequences. The use of T2\*-weighted fMRI to measure this hemodynamic effect, referred to as blood-oxygen-level dependent (BOLD) contrast, has made it possible to study a wide range of perceptual and cognitive tasks. Formally speaking, the increased BOLD signal following cerebral activation is due to the delivery of oxygenated Hb that effectively displaces (washes out) the deoxygenated Hb, leading to reduced T2\* shortening and a brighter MR signal (Huettel et al., 2008). Based on combined neurophysiological and fMRI studies in both monkeys (Logothetis et al., 2001; Goense and Logothetis, 2008) and humans (Huettel et al., 2004; Mukamel et al., 2005), the BOLD signal appears to correlate best with the local field potential, reflecting integrated population activity and postsynaptic inputs, rather than single-unit or multi-unit spike firing reflecting the neuronal output of action potentials.

Interestingly, olfactory fMRI only lagged a few years behind fMRI of the visual, auditory, and somatosensory systems, hitting its stride in 1997 with publications from four different labs (Levy et al., 1997; Sobel et al., 1997; Yang et al., 1997; Yousem et al., 1997). Despite

differences in imaging protocol, subject number, odors, stimulus delivery method, and experimental paradigm, these studies variously demonstrated fMRI activations in olfactory-related areas such as the medial temporal lobes and OFC, as well as in non-olfactory areas such as the cingulate cortex and the superior temporal gyrus. In an important early experiment, Sobel et al. showed that regions of the human olfactory brain responded not only to odor, but also to sniffing in the absence of odor (Sobel et al., 1998). The ingenious use of a topical anesthetic applied to the inside of the nose was associated with a reduction of sniff-evoked fMRI activity, consistent with the idea that it is the physical sensation of airflow across the nasal mucosa that underlies the sniff-related imaging effect (Figure 13.5b). These findings were in close accord with animal models and suggested that the act of sniffing may serve to prime the olfactory system in advance of odor receipt.

One problematic issue in much of the early olfactory fMRI work was the inconsistent and weak activation of primary olfactory cortex (i.e., piriform cortex). This was attributed to two main causes. First, the inferior frontal lobes and medial temporal lobes happen to be situated near air-tissue interfaces, which are highly susceptible to fMRI signal artifact and dropout. This anatomical circumstance made it difficult to obtain reliable activity from piriform cortex and OFC, and in fact was cited by many researchers as a good reason to use PET techniques instead (which are not subject to this problem). Fortunately, the subsequent development of new imaging protocols (Deichmann et al., 2003; De Panfilis and Schwarzbauer, 2005; Hsu and Glover, 2005; Weiskopf et al., 2006) has led to substantial improvements in signal recovery from both piriform cortex and the OFC. As a simple first step, even just tilting the axial acquisition plane at a 30° angle to the intercommissural border (rostral edge higher than caudal edge) offers a fairly dramatic improvement over standard horizontal acquisition planes, though this can come at the expense of signal artifact in lateral temporal regions.

A second reason for the inconstancy of fMRI activity in the piriform cortex was based on the fact that many olfactory studies used “blocked” task designs, in which odor and no-odor periods were each presented in alternating blocks of 30–60 s. To be fair, these blocked designs were used in virtually all of the early fMRI studies, partly because the PET functional studies had established a precedent for condition blocks, and partly because the statistical algorithms for analyzing “event-related” designs (in which different conditions, or events, rapidly presented within the same block could be distinguished) were not yet available (e.g., Dale and Buckner, 1997; Josephs et al., 1997). All other things being equal, another relative advantage was that blocked designs, with long stimulus presentations,

conferred greater statistical power to identify main effects. However, in the case of odor stimuli, a longer presentation meant greater response habituation in piriform cortex, which had been shown to exhibit marked decline in animal single-unit studies (Wilson, 1998, 2000). Sobel and colleagues highlighted this issue by showing that with 40-s blocks of odor (vs. no odor), very little fMRI activity in piriform cortex could be visualized when averaging across the whole block, but by modeling the odor block with an exponential decay function, they were able to demonstrate a robust piriform response (Sobel et al., 2000); also see Poellinger et al., 2001 for related findings). This study brought new awareness to the importance of tailoring experimental designs to the unique constraints of the olfactory system.

### 13.4.3 The Event-Related Era of Olfactory fMRI

Recognizing the value of short stimulus presentations, researchers began utilizing event-related olfactory task designs. The use of brief presentations (~1–3 s) of multiple different odorants, with sufficient trial-to-trial spacing (~10–20 s), minimized the problem of sensory habituation, and also enhanced the flexibility and range of experimental designs. These technical innovations helped enhance the types of studies that could be conducted. An important element in this formula was the technology to deliver these odorants with a rapid on-off time, and MRI-compatible olfactometers (smell delivery machines) were introduced by Sobel et al. (1997) and by Lorig et al. (1999) to achieve fast computer-controlled presentation of odor in the absence of auditory, tactile, or thermal confounds. In addition, given that fMRI activity in the piriform cortex could be elicited by sniffing even in the absence of odor (Sobel et al., 1998), it became imperative to collect online measures of respiration during scanning, in order to ensure that condition-specific differences in sniffing did not confound the imaging data, or if so, to covary out this information from the analysis.

In a pair of studies, Gottfried and colleagues used event-related fMRI techniques to explore odor processing and olfactory Pavlovian conditioning in the human brain, with a focus on pleasant and unpleasant odors (Gottfried et al., 2002a; Gottfried et al., 2002b). During scanning, subjects participated in an olfactory version of classical conditioning in which a neutral item (the conditioned stimulus, or CS+) acquired behavioral significance by predicting the occurrence of an emotionally salient odor (the unconditioned stimulus, or UCS) after repeated pairings. In this study, three different neutral faces represented the CS+ stimuli, and three different odors varying in pleasantness were used as the UCS stimuli. Under a 50% partial reinforcement schedule, only one-half of all CS+

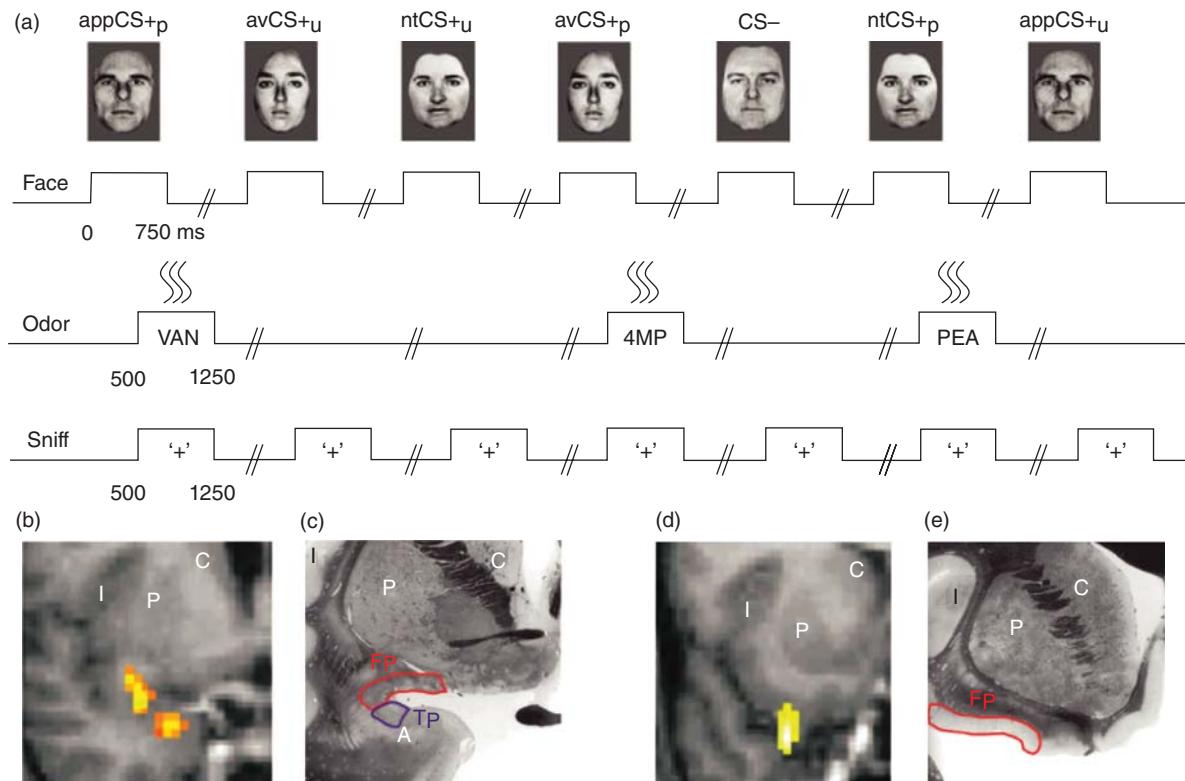

trials was paired with odor, providing a way to isolate olfactory sensory processing (by comparing paired vs. unpaired trials) as well as learning-related effects without interference from the UCS (Figure 13.6a).

A key finding in this work was that discrete piriform sub-regions showed differential sensitivity to odor: valence-independent responses were observed in the posterior piriform cortex (PPC), whereas valence-dependent responses were observed in the anterior piriform cortex (APC) (Gottfried et al., 2002a) (Figure 13.6b). These results provided evidence for the functional heterogeneity of human piriform cortex, in line with rodent models demonstrating anatomical and functional differences along the rostral-caudal axis of piriform cortex (Haberly, 1998). Interestingly, the amygdala and posterior OFC also responded to all three valence classes of odor, though fMRI representations of pleasant and unpleasant odor were identified in dissociable areas of OFC. Concurrent analysis of the learning data revealed that the OFC was activated in response to the conditioned cue (in the absence of odor), with selective involvement of the medial and lateral OFC in processing of the appetitive or aversive CS+ cue, respectively (Gottfried et al., 2002b). This and related fMRI studies (Gottfried et al., 2003; Gottfried and Dolan, 2004) have highlighted the capacity of emotionally salient odors to promote cross-modal associative learning, and support the idea that both piriform cortex and its projection sites in OFC should be considered as active participants in more complex aspects of odor information processing, rather than as mere sensory relays.

The following sections review some of the key functions and mechanisms of the human olfactory system that have been established using both fMRI and PET methods, with an emphasis on studies in which the neural data are closely linked to specific olfactory perceptual or cognitive states. Since the last version of this chapter appeared ten years ago, there has been tremendous growth in olfactory functional imaging. However, due to space limitations, it is not possible to include all of these studies. In addition, topics covered in detail in other chapters of the *Handbook*, including odor memory, multisensory integration, trigeminal processing, social behavior, and clinical investigations, will be discussed only briefly.

### 13.4.4 Encoding Odor Valence

Psychophysical research dating back to the 1970s indicates that valence (pleasantness) is a primary dimension by which humans categorize odors, particularly for smells that are unfamiliar or hard to name (Schiffman, 1974; Khan et al., 2007). Given the intimate anatomical overlap between the olfactory system and limbic brain regions mediating emotion and aversive learning, a plausible hypothesis was that the hedonic features of an odor might

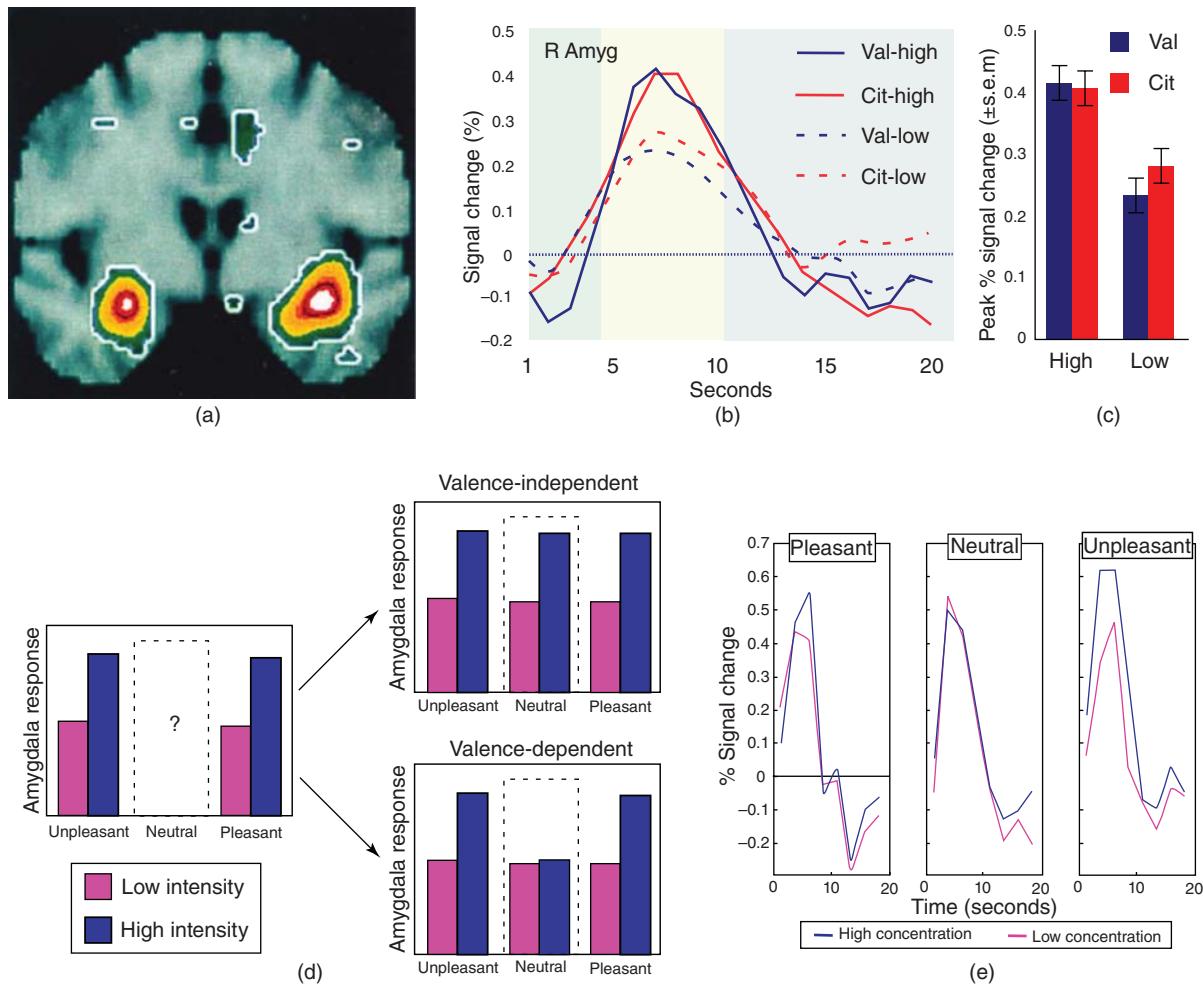

**Figure 13.6** An early example of an olfactory event-related fMRI study. (a) Task. During scanning, subjects viewed one of three neutral faces (the conditioned stimuli, or CS+). Each face was paired with a distinct odorant on 50% of trials (i.e., CS+p) and was unpaired on 50% of trials (i.e., CS+u). Another face was never paired with odorant (the control stimulus, CS−). Odorants served as the unconditioned stimuli (UCS), including vanillin (VAN) as an appetitive (app) reinforcer, 4-methyl-pentanoic acid (4MP) as an aversive (av) reinforcer, and phenethyl alcohol (PEA) as a neutral (nt) reinforcer. On each trial subjects were cued to sniff upon viewing a '+' crosshair on a computer monitor. Trials recurred every 7.5 sec, with each trial type evenly interspersed over the course of the 25-min experiment. (b-c) Valence-independent fMRI responses. The comparison of CS+p trials (odor present) vs. CS+u trials (odor absent) elicited odor-evoked activity in posterior piriform cortex (B), spanning frontal (Fp) and temporal (Tp) areas. (c) Activations are shown beside a high-resolution anatomical atlas image. (D-E) Valence-dependent fMRI responses. The direct contrast of aversive and appetitive odorants ([avCS+p—avCS+u]—[appCS+p—appCS+u]) revealed fMRI activity in anterior piriform cortex (d), shown next to a high-resolution image (e). Key: C, caudate; Fp, frontal portion of piriform cortex; I, insula; P, putamen; Tp, temporal portion of piriform cortex. Data from Gottfried et al., 2002a. Atlas images in C and E are modified from Mai et al., 1997, and used with permission of Academic Press and the author. (See plate section for color version.)

be encoded in the amygdala. To explore how the human brain processes unpleasant odor, Zald and Pardo (1997) used  $\text{H}_2\text{O}^{15}$  PET scanning to measure rCBF while subjects smelled highly aversive sulfides (rotten egg odor). Comparison of these unpleasant smells to less aversive odorants revealed activity in the amygdala bilaterally and in the left OFC (Figure 13.7a). Although these results were highly suggestive of a selective aversive response in these brain regions, differences in intensity between the odorants complicated the interpretation of the effects. In separate PET studies, increased rCBF in the amygdala, OFC, and hypothalamus were also observed when subjects made hedonic judgments of odors (Royet et al., 2000; Zald and Pardo, 2000; Royet et al., 2001).

Subsequent fMRI investigations arrived at somewhat different conclusions. As noted above, pleasant,

unpleasant, and neutral smells were each found to evoke similar magnitudes of fMRI activity in the amygdala (Gottfried et al., 2002a), arguing for a valence-independent coding scheme. In another study, one pleasant odor and one unpleasant odor were each presented at low and high intensity, providing an elegant way to dissociate these two perceptual features within the same experimental paradigm (Anderson et al., 2003). Interestingly, a main effect of intensity was found in the amygdala, with greater activity for pleasant and unpleasant odors at high (vs. low) intensity (Figure 13.7b,c). Valence-specific effects were only identified in the OFC. Finally, an fMRI study using a larger panel of odorants further complicated the story, showing that pleasantness ratings covaried with OFC activity, whereas intensity ratings covaried with activity in entorhinal cortex (Rolls et al., 2003). Together these

Activations superimposed on a T1-weighted MRI scan. From Zald and Pardo, 1997. (b, c) The fMRI time-series in right amygdala (B) for high- and low-intensity versions of pleasant (Citral, Cit) and unpleasant (Valeric acid, Val) odorants demonstrates an intensity effect in the absence of a valence effect. (c) Plots represent peak odor-evoked changes in fMRI signal. From Anderson et al., 2003. (D,E) Testing the hypothesis that odor-related amygdala activity reflects an integrated response to both valence and intensity. (d) The valence-independent model predicts greater activity for high-intensity odorants at all valence levels, whereas the valence-dependent model predicts greater activity for high-intensity odorants only at the extremes of valence. (e) Odor-evoked fMRI time-series are consistent with valence-dependent coding in the amygdala. Modified from Winston et al., 2005. (See plate section for color version.)

findings raised questions about the precise role of the amygdala in olfactory hedonic processing.

In an effort to clarify these discrepant results, Winston et al. (2005) built upon the Anderson et al. study by including high- and low-intensity versions of a neutral odorant, in addition to pleasant and unpleasant odorants. With this design, the dimensions of valence and intensity could be dissociated across a broader hedonic spectrum, enabling a test of two competing models of amygdala function: a valence-independent hypothesis in which the amygdala response to intensity is similar at all levels of valence; and a valence-dependent hypothesis in which the amygdala is sensitive to odor intensity only at the outer bounds of

valence (Figure 13.7d). Data were consistent with the latter prediction: intensity-based fMRI activity in the amygdala was observed only for the pleasant and unpleasant odors, but not for the neutral odor (Figure 13.7e). That the amygdala encodes an integrated representation of intensity and valence underscores the added importance of odor strength in appraising the behavioral saliency of valenced odors. Put differently, the more intense an emotionally salient odor, the more likely it is to be relevant for survival, which is not the case for emotionally neutral odors. These findings help bring some resolution to the mixed conclusions regarding the olfactory response profile of the human amygdala.

Across numerous functional imaging studies, odor valence-specific responses have been consistently observed in the OFC (Zald and Pardo, 1997; Gottfried et al., 2002a; Anderson et al., 2003; Rolls et al., 2003). Similar effects have been shown in an fMRI paradigm of olfactory sensory-specific satiety (O'Doherty et al., 2000). In this experiment, subjects were scanned while smelling two different food smells. Subsequently, the pleasantness of one of the two odors was reduced by having subjects eat a lunch of the corresponding food until they were sated. In parallel, the magnitude of OFC activity was reduced for the devalued odor but not for the control odor, suggesting that a representation of olfactory reward value is encoded in this region. Based on monkey single-unit studies showing that the OFC may encode the relative value of different stimulus options, Grabenhorst and Rolls (2009) showed that a given odorant was rated more pleasant when preceded by a less pleasant odorant, and was rated less pleasant when preceded by a more pleasant odorant. The degree of relative, or subjective, pleasantness between the first and second odorants on each trial was found to correlate with fMRI activity in the anterior lateral OFC (and relative unpleasantness correlated with activity in the insula). Interestingly, the absolute values of the pleasantness ratings were not associated with activity in these areas, though other regions of OFC were responsive to this measure. These findings suggest that the human brain has access to both relative and absolute representations of odor valence in order to guide olfactory-based decisions.

### 13.4.5 Encoding Odor Objects

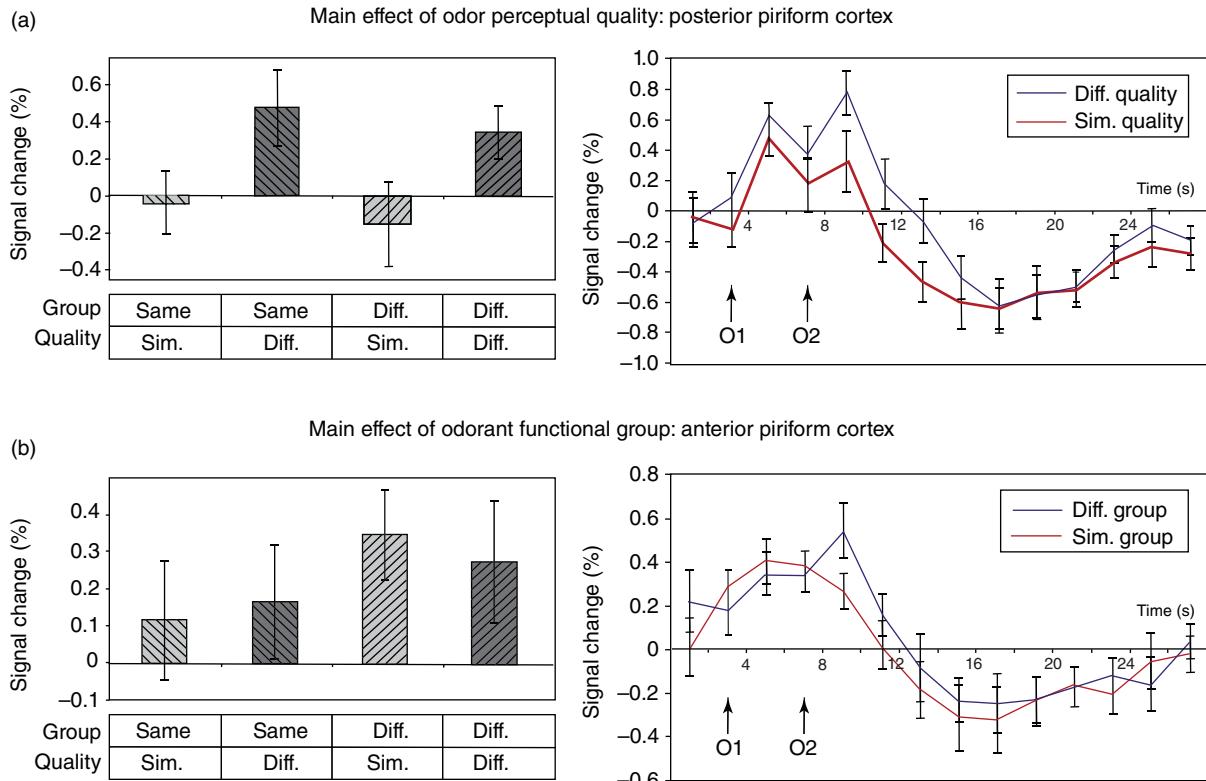

The term “odor object” refers to an olfactory source (such as a rose bush) or an olfactory event (such as the aroma of rose) that is presented to the senses. This is no different from conventional notions of objects in the visual domain, such as visual sources (rose bush) and visual events (the light reflecting off a rose bush). It is the distinctive physical and ecological form of sensory objects that shapes nervous system function (Gottfried, 2009, 2010). The fact that most smells naturally encountered in the environment are complex mixtures of dozens or even hundreds of different odorous molecules means that the olfactory system needs mechanisms to weave these odor elements into perceptual wholes. For many vertebrate and invertebrate species, efficient encoding and retrieval of behaviorally salient odor objects is critical for adaptive behavior, including but not limited to food search, mating choice, and territorial defense.

Anatomical, physiological, and computational studies in animal models suggest that odor object information may take the form of distributed ensemble patterns of activity in the piriform cortex (Haberly, 1985; Hasselmo et al., 1990; Illig and Haberly, 2003), but how odor objects are

represented in the human brain is unclear. PET imaging was initially used to address these questions by evaluating which brain regions were recruited during odor identification and discrimination tasks (Royet et al., 1999; Savic et al., 2000). To the extent that identifying an odor requires retrieving semantic object-based information about the stimulus, these studies showed widespread task-related activity in the inferior frontal gyrus, insula, caudate, and cerebellum. Although the use of PET techniques precluded the ability to assess odor object coding of specific stimuli, this is not a trivial goal even with fMRI. Assuming that different odor qualities (i.e., the perceptual character of a smell, such as its mintiness) evoke distributed but overlapping responses in piriform cortex, the use of standard fMRI analyses would be unable to discriminate unique representations of odor quality, because activity is averaged over all of the voxels within a region of interest, obscuring information that might be contained in individual voxels.

Recent methodological innovations have provided new ways to overcome these limitations. In one approach (Gottfried et al., 2006), an olfactory version of fMRI “cross-adaptation” was devised to dissociate the neural correlates of odor perceptual quality and molecular functional group (as a key attribute of odorant chemical structure). Cross-adaptation is based on the idea that sequential repetition of stimuli sharing a particular feature (such as object shape) causes adaptation of neural populations specifically sensitive to that feature, leading to local response decreases (Buckner et al., 1998; Kourtzi and Kanwisher, 2001; Winston et al., 2004). In this study, subjects made two successive sniffs to pairs of odors differing either in quality or functional group. The fMRI results indicated a double dissociation in piriform cortex, whereby *PPC encoded quality* (but not structure) and *APC encoded structure* (but not quality) (Figure 13.8). The identification of dual olfactory representations within discrete piriform areas accords with the known physiological organization of piriform cortex in animal models, suggesting a functional preservation across species. The presence of structure-based codes in APC would help ensure stimulus fidelity of the original sensory input, while quality-based codes in PPC suggests that more integrative mechanisms may underlie olfactory coding of odor objects in the human brain.

Taking these findings one step further, Howard et al. (2009) combined high-resolution fMRI with olfactory multivariate analysis techniques to investigate spatial ensemble coding of odor qualities and categories in human PPC. As noted above, multivariate fMRI methods differ from conventional (univariate) fMRI analyses, in which data are averaged over space (voxels), time (scans) and subjects, obscuring potentially important information that may be contained at the level of individual voxels, scans, and subjects. Pattern-based approaches provide a

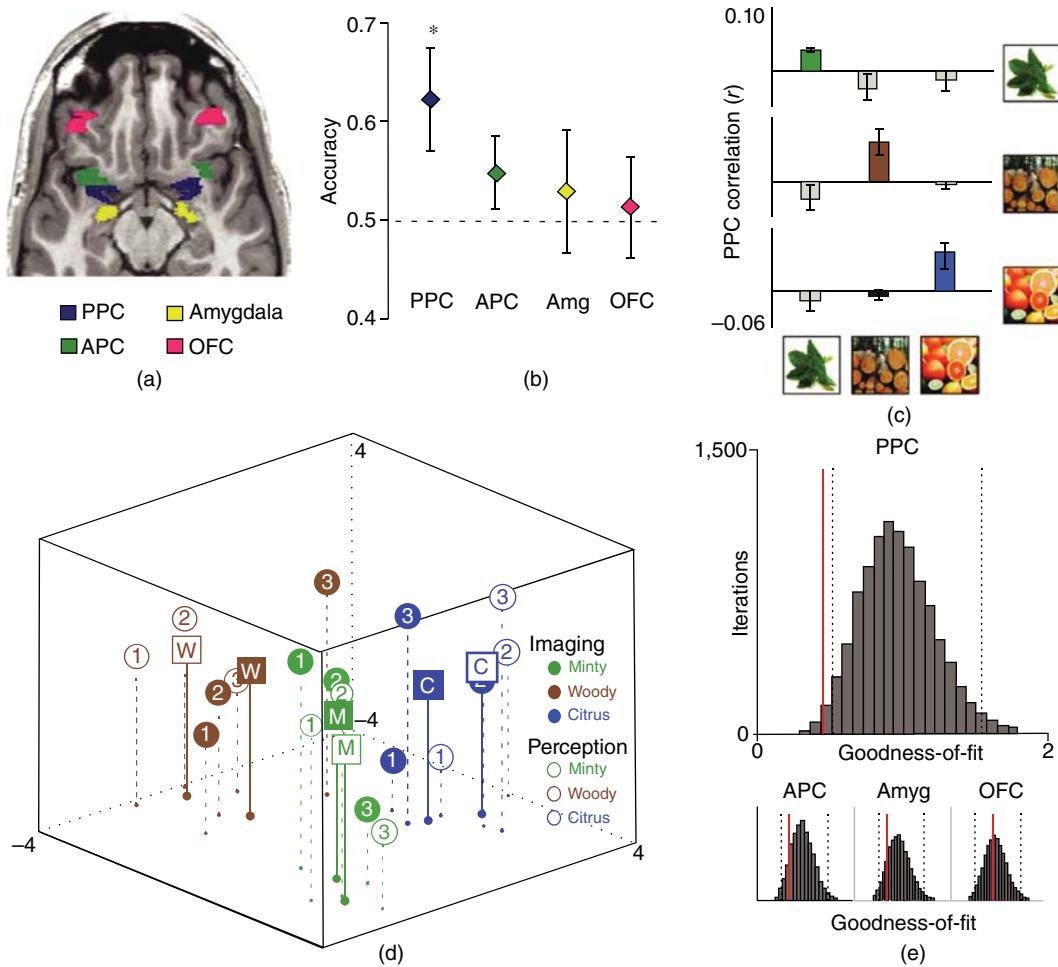

**Figure 13.8** Functional dissociation of odor quality and odorant molecular functional group in human piriform cortex. (a) Condition-specific plots of fMRI activity in posterior piriform cortex (PPC) show greater responses for odorants with different (diff.) perceptual qualities than similar (sim.) qualities, in the absence of an influence of functional group. (b) The fMRI time-course in PPC shows selective decrement (adaptation) when the second odorant (O2) is similar in quality to the first odorant (O1). (c) Plots of fMRI activity in anterior piriform cortex (APC) showed an opposite effect, with greater responses to odorants differing in functional group, with no influence of perceptual quality. (d) The fMRI time-course in APC shows response adaptation when O2 shares the same functional group as O1. Modified from Gottfried et al., 2006.

robust way to characterize how (rather than just where) perceptual information is represented in the human brain (Kriegeskorte and Bandettini, 2007). During the experiment, subjects smelled sets of odorants differing in odor quality categories (e.g., minty, floral, woody). Different odor qualities evoked overlapping but unique activity patterns in PPC, and these ensemble patterns coincided with perceptual ratings of odor quality, such that odorants with more (or less) similar fMRI patterns were perceived as more (or less) alike (Figure 13.9). Such effects were not observed in APC, amygdala or OFC, indicating that ensemble coding of odor categorical perception is regionally specific for PPC. These results demonstrate that the spatial arrangement of fMRI activity in PPC is distributed and overlapping for each odorant, without any obvious local clustering, consistent with the known anatomical organization of this region. Overall, these findings suggest that distributed olfactory codes of odor object categories are arranged in much the same way that visual object categories (for example, houses, cows, and chairs) are

organized in the inferotemporal cortex, highlighting the critical sensory-associative nature of PPC.

### 13.4.6 Odor Mixture Discrimination and Disambiguation

Several studies have begun examining odor mixture processing in the human brain. Because most naturalistic smells are complex mixtures of different odorous molecules, characterizing how the brain integrates odorant elements into perceptual wholes will be important for gaining a comprehensive understanding of olfactory perception. In mixtures containing both pleasant and unpleasant odor components, fMRI responses in discrete regions of the OFC and anterior cingulate cortex appeared to encode independent representations of positive and negative hedonic value (Grabenhorst et al., 2007). In another study, 100% citral (pleasant odor) and 100% pyridine (unpleasant odor) were mixed in proportions from 10/90 to 90/10. PET activity in the lateral OFC was associated with increasing odor impurity, whereas activity in the anterior

**Figure 13.9** Distributed odor object representations in posterior piriform cortex. Multivariate fMRI pattern analyses were used to characterize how, rather than simply where, odor object information is encoded in the human brain. (a) Regions of interest included PPC, APC, amygdala (amg), and OFC. (B,C) Subjects were presented with nine different odorants, including three stimuli within each of three perceptual categories (minty, woody, and citrus). (b) Classification accuracy, as indexed by the proportion of within-category correlations exceeding between-category correlations, was significant (\*,  $p < 0.05$ ) only in PPC. (c) This effect was observed for each odor category. (d) Perceptual ratings of odor quality similarity between all odorant pairs, and fMRI measures of odor pattern similarity between all odorant pairs, were projected onto a common 3-dimensional space. Perceptual maps and imaging maps closely overlapped, both for individual odorants and for odor categories. Squares labeled M (minty), W (woody), and C (citrus) represent centroids of each category for perceptual (empty squares) and imaging (solid squares) maps. (e) The 'goodness-of-fit', based on a comparison of the actual data to a distribution of 1,500 random permuted samples, was significant only in PPC ( $p < 0.05$ ). Modified from Howard et al., 2009. (See plate section for color version.)

OFC was higher for the binary mixtures than for the pure single odorants (Boyle et al., 2009). Finally, a more recent investigation combined fMRI, psychophysical techniques, and computational modeling to establish whether noisy sensory evidence is accumulated over time in the human brain to optimize olfactory perceptual decision-making (Bowman et al., 2012). In a two-alternative forced-choice task, subjects were presented with a series of odor mixture morphs ranging between 100% eugenol (clove odor) and 100% citral (lemon odor), and made as many sniffs as needed to determine whether the mixture smelled more like clove or lemon. A ramp-like increase of fMRI activity

was observed in OFC, peaking at the time of decision, whereas activity in PPC reached an early plateau after odor onset and was sustained up until the decision point. These data suggest that PPC provides an ongoing sensory report of odor input, while the OFC integrates this information over time to help resolve sensory noise and ambiguity.

### 13.4.7 Attending to Odors

Attending to an odor in advance of its receipt is important for optimizing olfactory perception. In general, the process by which the brain transforms sensory inputs into

perceptual events often begins before physical contact with the sensory stimulus. In the case of olfaction, the motor act of sniffing is an essential component of directing sensory attentional resources toward the olfactory milieu. Combining a clever psychophysical paradigm with fMRI, Zelano and colleagues (Zelano et al., 2005) asked subjects either to sniff and try to detect an odorant (which was absent on 50% of trials), or to sniff passively, knowing that no odorant was to be delivered (a less attentionally demanding task). Greater fMRI activity in frontal piriform cortex was observed in response to the no-odorant condition on the detection task, compared to the passive sniff task, suggesting a direct modulatory influence of attention on olfactory processing in the human brain. In a complementary experiment, subjects were simultaneously presented with an auditory tone and an odor stimulus, and informed either to attend to the odor and rate its intensity (ignoring the tone), or to attend to the tone and rate its pitch (ignoring the odor). Olfactory (vs. auditory) attention again revealed significant piriform activation. These findings demonstrated that the act of sniffing engages the olfactory system only when an odor is expected.

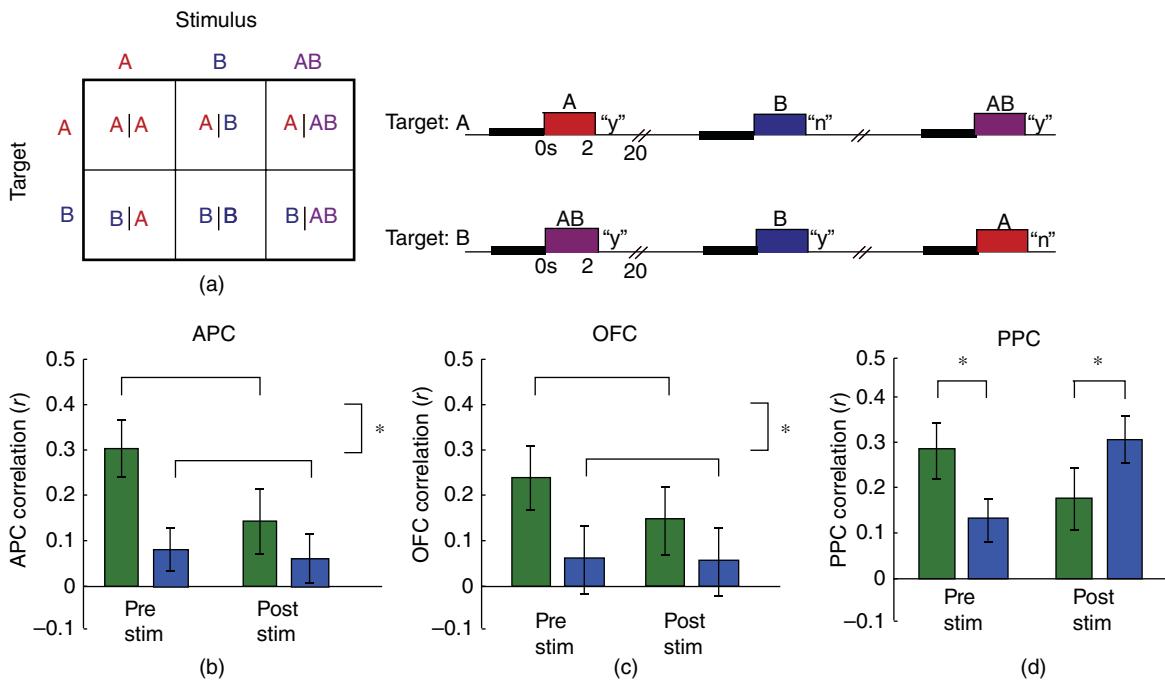

The modulatory role of attention on the human olfactory system has also been explored using fMRI effective connectivity. This analytical technique tests the influence that one neural population exerts over another, with the goal of defining how differences in brain states modulate the interactions between regions (Friston et al., 2003). In a study by Plailly and colleagues (Plailly et al., 2008), effective connectivity techniques were used to test the hypothesis that attention to smell augments functional interactions within thalamocortical networks. Prior animal studies suggest that odor information has direct access from piriform cortex to OFC without a thalamic intermediary, distinguishing olfaction from other sensory modalities. However, an indirect pathway from piriform cortex to OFC via the mediiodorsal thalamus (MDT) has also been described (Price and Slotnick, 1983; Russchen et al., 1987; Ray and Price, 1993). Results showed that odor attention significantly modulated fMRI coupling within the indirect pathway, strengthening connectivity between MDT and OFC (Plailly et al., 2008). Critically, these effects were modality specific (odor > tone attention), directionally sensitive (forward > backward connections), and selective to route (indirect > direct pathway). These findings suggest that the human transthalamic pathway is functionally active in humans and is a modulatory target of olfactory attentional processing.

The idea that attentional states can set up expectations for what is likely—but not yet—to be encountered is consistent with the concept of predictive coding (Rao and Ballard, 1999; Friston, 2005; Summerfield and Egner, 2009). By setting up predictive templates or “search images,” the brain can optimize perceptual processing at

the time of stimulus delivery. Early work in animal models (Freeman and Schneider, 1982; Freeman, 1983) provided theoretical and physiological support for predictive coding in the olfactory bulb, though whether such mechanisms are utilized in the humans has remained unclear. Recent work by Zelano, Mohanty, and Gottfried (Zelano et al., 2011) combined an olfactory attentional search task with multivariate pattern-based fMRI analyses to examine olfactory predictive coding in the human brain. In separate task blocks, subjects needed to decide whether a predetermined target smell (either “A” or “B”) was present on each trial, where odor stimuli consisted of A, B, or the mixture AB. This design enabled us to model the pre-stimulus and post-stimulus periods separately, and provided a way to examine target-related and stimulus-related activity patterns as they evolved from pre- to post-stimulus.

In APC and OFC, odor-specific ensemble patterns were formed prior to odor onset (Zelano et al., 2011). Notably, these patterns persisted even after odor stimulation, suggesting that APC and OFC encode what is being sought rather than what is being delivered. In contrast, fMRI patterns in PPC evolved from pre-stimulus target representations to post-stimulus odor representations, whereby activity patterns more closely resembled what was delivered rather than what was expected (Figure 13.10). Critically, the robustness of target-related patterns in PPC predicted subsequent identification accuracy on the odor search task. These findings were among the first to document feature-specific predictive codes in the human brain, and reinforce the idea that stimulus templates in PPC, with physical correspondence to odor-specific ensemble representations, play an instrumental role in guiding olfactory perceptual decisions. In identifying a distributed neural signature of odor templates in PPC, the results help validate longstanding models of piriform function (Freeman and Schneider, 1982; Haberly, 1985; Hasselmo et al., 1990; Wilson and Stevenson, 2003).

Interestingly, mean fMRI activity in MDT was significantly higher in response to unexpected trials (e.g., search for A, receive B) than expected trials (e.g., search for A, receive A). This profile is consistent with the idea that MDT may compare bottom-up odor input with top-down predictions to generate an error signal (Summerfield and Egner, 2009), and would be compatible with its known anatomical connectivity (Price and Slotnick, 1983; Russchen et al., 1987; Ray and Price, 1993). Additional support for this hypothesis comes from a recent patient-based MRI volumetric study (Olofsson et al., 2013), which showed that the cortical volume of MDT correlated with error rates on matching tasks between odors and pictures (and also between odors and words), with smaller thalamic volumes relating to a higher proportion of between-category errors. Together these findings highlight the putative role of MDT in coding of olfactory prediction error, and may help

**Figure 13.10** Olfactory predictive coding in the human brain. (a) Subjects participated in an olfactory attentional search task, in which stimuli consisted of odorants A, B, or AB, and the odor search target (A or B) varied across blocks. Subjects were informed at the beginning of a block whether the target odor would be A or B. On each trial, odor delivery was preceded by a 3-s pre-stimulus countdown cue. Subjects pressed a button indicating whether the target odor was present in the actual stimulus (“y” or “n”). (b-d) Target- and stimulus-related fMRI effects were computed by testing whether ensemble pattern correlations between same target/different stimulus conditions (green bars; e.g., A|A vs. A|B) differed from different target/same stimulus conditions (blue bars; e.g., A|A vs. B|A). In both APC (b) and OFC (c), target-related patterns emerged in the pre-stimulus period and persisted into the post-stimulus period. \*, p<0.05. In contrast, in PPC (d), target-related patterns in the pre-stimulus period gave way to stimulus-specific patterns in the post-stimulus period. In PPC the pre-stimulus target-specific patterns resembled the post-stimulus odor patterns, consistent with the formation of predictive odor templates in this region (data not shown). Modified from Zelano et al., 2011.

unify disparate observations of MDT olfactory function in both animal and human studies (Eichenbaum et al., 1980; Slotnick and Kaneko, 1981; Staubli et al., 1987; Plailly et al., 2008; Sela et al., 2009; Tham et al., 2009).

### 13.4.8 Odor Imagery

That stimulus-specific odor templates are encoded in the human brain raises an interesting implication: internal access to these perceptual representations should favor odor imagery. Indeed, behavioral studies have shown that odor imagery can enhance odor detection in a stimulus-specific way (Djordjevic et al., 2004), and that imagery of pleasant or unpleasant odors causes valence-appropriate modulation of sniff volume (Bensafi et al., 2003). Complementary imaging work demonstrates that odor imagery elicits activations in the same brain areas that are engaged during actual stimulus encounter (Djordjevic et al., 2005; Bensafi et al., 2007). In professional perfumers, the duration of olfactory training was found to correlate inversely with activity in PPC, OFC, and hippocampus (Plailly et al.,

2012), perhaps reflecting greater processing efficiency in odor experts.

### 13.4.9 Odor Memory

With Marcel Proust’s madeleine biscuit triggering nine volumes of turgid (for some, transcendent) prose, olfactory researchers have endeavored to find the Proust spot of the brain, that is, to understand at a neural level why odor stimuli seem to have such potency to evoke intense autobiographical memories. The short answer to this conundrum is that it awaits further study. However, in an interesting fMRI experiment, Herz et al. (2004) identified subjects for whom specific perfumes triggered remote personal memories. Presentation of these same perfume smells in the scanner evoked increased activation in the amygdala, compared to the activity levels evoked by pictures of the perfume bottles or by control odors. Although this study was based on relatively few subjects, it provided interesting insights into the involvement of the amygdala in reactivating olfactory memory.

PET and fMRI studies of olfactory memory have run the full gamut, including working memory (Dade et al., 2001; Zelano et al., 2009), recognition memory (Savic et al., 2000; Dade et al., 2002; Gottfried et al., 2004; Cerf-Ducastel and Murphy, 2006; Royet et al., 2011; Lehn et al., 2012), and free recall (Kjelvik et al., 2012). In most instances, successful odor retrieval is associated with neural activity in the same brain areas that are recruited in non-olfactory retrieval tasks (such as hippocampus and prefrontal cortex), suggesting that a dedicated memory network is engaged independently of sensory modality. In some of these studies, a retrieval cue in one modality (e.g., visual) elicited activity in olfactory cortical areas, either following encoding of new cross-modal odor-object associations (Gottfried et al., 2004), or as a result of previously learned associations (Cerf-Ducastel and Murphy, 2006; Lehn et al., 2012). These findings concur with the idea that odor-specific features of a multisensory memory may reside in the olfactory system and can be reactivated by non-olfactory components of the original event. In another cross-modal memory study, subjects learned to associate the same visual object with one, and then another, set of pleasant and unpleasant odors and tones (Yeshurun et al., 2009). At recall one week later, the first associations were remembered better than the second associations, for both unpleasant odors and tones, whereas fMRI scanning revealed preferential hippocampal activation only for first odor associations, regardless of valence. Finally, in a study examining sleep-related effects of odor context on episodic memory (Rasch et al., 2007), subjects were able to recall the locations of visual objects more effectively when an odor present at initial learning was re-presented during sleep, with odor-related fMRI activity in the hippocampus observed during the sleep period.

### 13.4.10 Olfactory Learning, Plasticity, and Experience

Odor perception is profoundly shaped by learning and experience. Olfactory psychophysical studies have robustly demonstrated the perceptual pliability of the human sense of smell (Rabin, 1988; Wysocki et al., 1989; Jehl et al., 1995; Herz and von Clef, 2001; Dalton et al., 2002; Mainland et al., 2002), and functional imaging studies have brought new insights into the mechanisms underlying this plasticity. Sensory context can alter odor processing at the behavioral and neural levels. Across several studies, it is apparent that presentation of an odor alongside a semantically congruent flavor, picture, or color facilitates odor perception and induces greater responses in the OFC, amygdala, and hippocampus, when compared to semantically incongruent pairings (Small et al., 1997; De Araujo et al., 2003; Gottfried and Dolan, 2003; Small et al., 2004; Osterbauer et al., 2005). Hedonic shifts in verbal context

are sufficient to modulate odor-evoked brain activity: an olfactory mixture containing isovaleric acid and cheddar cheese flavor evoked greater fMRI signal in medial OFC when it was paired with the label “cheddar cheese” than when it was paired with the label “body odor” (de Araujo et al., 2005).

The mere exposure to an odor can enhance perceptual processing. In one fMRI study, a single 3.5-minute presentation of one odorant enhanced perceptual differentiation for odorants belonging to the same odor quality category, an effect that persisted for up to 24 hours (Li et al., 2006). Thus, for example, subjects exposed to a minty odorant became mint “experts,” such that they were better able to tell apart different minty smells. This perceptual enhancement was paralleled by learning-induced response increases in PPC and OFC. Interestingly, the magnitude of change in OFC activation predicted subsequent improvement in perceptual differentiation on a subject-by-subject basis. These findings suggest that neural representations of odor quality can be rapidly updated through mere perceptual experience. This process of odor feature differentiation, via sensory exposure, may underlie much of the way that humans naturally learn to build up their “vocabulary” to recognize and discriminate odors.

Odor perceptual representations can also be updated through associative learning. Li et al. (2008) combined functional magnetic resonance imaging (fMRI) with multivariate analysis techniques to explore the impact of aversive Pavlovian conditioning on discrimination of predictive odor cues. The use of perceptually identical odor enantiomers (mirror-image molecules) provided a way to determine whether humans can acquire the ability to distinguish between odorous stimuli that initially smell the same. Subjects were presented with four odor enantiomers (two different pairs), one of which (the target CS+, “tgCS+”) was repetitively paired with an electric shock (US) during a conditioning phase, whereas its mirrored counterpart (“chCS+”) was not accompanied by shock. The second pair of odor enantiomers served as non-conditioned control stimuli. After conditioning, behavioral accuracy for distinguishing between tgCS+ and chCS+ was significantly enhanced, without any improvement in distinguishing between the control enantiomer pair. In parallel to these behavioral effects, ensemble activity patterns in PPC for the CS+ pair (tgCS+ and chCS+) became decorrelated after conditioning, particularly in comparison to the non-conditioned pair. These findings underscore the capacity of fear conditioning to update perceptual representation of predictive cues. That completely indiscriminable sensations can be transformed into discriminable percepts further accentuates the potency of associative learning to enhance sensory cue perception and support adaptive behavior.

Notably, the *lack* of experience can induce an opposite effect on odor discrimination. Following from animal models of odor deprivation to provoke changes in the olfactory system (Brunjes and Borror, 1983; Maruniak et al., 1989; Guthrie et al., 1990), Wu and colleagues developed a method to induce long-term odor deprivation in humans (Wu et al., 2012). Healthy subjects were admitted to the clinical research wing of a hospital for one week, during which time their nostrils were occluded with foam tape during waking odors. Perceptual tests and fMRI scanning were performed at baseline, immediately after deprivation, and one week later at recovery. Interestingly, olfactory perceptual performance was maintained despite a substantial reduction in odor afferent input. At the same time, the deprivation procedure elicited reversible fMRI changes in piriform and orbitofrontal cortices that may be instrumental in sustaining odor perception in the wake of disrupted input. The fact that odor perception was preserved across subjects suggests that the olfactory system possesses compensatory mechanisms that render it resistant to transient perturbations of afferent sensory input, as commonly occur during extended instances of rhinosinusitis or upper respiratory infections (Holbrook and Leopold, 2006).

### 13.4.11 Odors as Putative Chemosignals

The role of airborne odorants as putative human pheromones, or “chemosignals” (a less polarizing term), is hotly debated and the subject of entire chapters and books (Wysocki and Preti, 2004; Doty, 2010). Whether humans secrete odors that can be detected by the olfactory systems of other members of the same species in order to influence emotion, behavior, autonomic and hormonal states, and social judgments is an open question. Regardless of one’s scientific stance, it is clear that chemosignals have served as potent triggers of functional imaging investigations. Delivery of estra-1,3,5(10),16-tetraen-3-ol (EST), an estrogen derivative found in female urine, at sub-threshold concentration elicited fMRI responses in the anterior medial thalamus and inferior frontal gyrus (Sobel et al., 1999). Seminal PET work by Savic and colleagues showed that androstadienone (AND), a testosterone derivative found in male sweat, evoked activity in the hypothalamus in women, whereas EST evoked activity in a different hypothalamic region in men (Savic et al., 2001). Follow-up work by this same group confirmed and extended these sex-specific imaging effects in revealed similar effects in line with gender and sexual orientation (Savic et al., 2005; Berglund et al., 2006).

Other studies have utilized more naturalistic stimuli collected directly from human bodily secretions, including axillary sweat and tears. Smelling a friend’s body odor

activates a different network of brain regions than when smelling a stranger’s body odor (Lundstrom et al., 2008), including the precuneus, insula, and inferior frontal gyrus. Similarly, if women are asked to smell the body odor of their sister, compared to the body odor of a female friend, their PET rCBF responses show differential changes in the prefrontal cortex and intraparietal lobule (Lundstrom et al., 2009). These findings suggest that olfactory social-based cues can exert an impact on human brain function, lending credence to the idea of pheromonal control of kin recognition. The use of fear- or anxiety-inducing manipulations to induce production of emotionally laden chemosignals has also revealed interesting effects. Chemosensory “anxiety” signals, obtained from axillary secretions in students awaiting an important academic exam, were shown to evoke fMRI responses in numerous areas such as the precuneus, fusiform cortex, insula, and cingulate cortex (Prehn-Kristensen et al., 2009). “Fear” sweat obtained from individuals about to undergo their first skydive out of an airplane was associated with greater fMRI activity in the amygdala, cerebellum, inferior temporal gyrus, and precuneus, compared to a control exercise condition (Mujica-Parodi et al., 2009). “Sexual” sweat from the armpits of men watching erotic videos was presented in airborne form to female recipients, resulting in enhanced fMRI activation in the OFC, hypothalamus, and fusiform cortex (Zhou and Chen, 2008). Finally, sniffing “sad” tears from female donors reduced the sexual attraction of men to pictures of women’s faces, and also reduced fMRI activity in the hypothalamus and fusiform cortex while male subjects viewed erotic pictures and films, in comparison to control saline (Gelstein et al., 2011).

Whether the above chemosignaling effects are mediated by the olfactory system, the vomeronasal system (unlikely based on current evidence: Trotier et al., 2000; Meredith, 2001; Witt et al., 2002), or through direct stimulus absorption into the bloodstream, has not been clearly established. Interestingly, in men with smell loss arising from nasal polyposis, the EST stimulus failed to activate the hypothalamus (Savic et al., 2009), suggesting that the ability of these putative chemosignals to modulate hypothalamic brain activity is mediated by the main olfactory pathway. In an ambitious effort to test whether the human vomeronasal organ (VNO) might be involved in behavioral or neural processing of putative pheromones, Frasnelli et al. (2011) blocked the VNO using a latex patch that was placed under endoscopic guidance. This maneuver (compared to a non-occluded patch control) had no effect on perceptual responses to AND, nor did it alter AND-evoked PET activations in the hypothalamus and other areas. These findings provide additional negative evidence for the unlikely role of a separate VNO pathway in human olfactory function.

### 13.5 FINAL OBSERVATIONS

The introduction of noninvasive imaging techniques ushered in a highly tractable method to elucidate the structure and function of the human olfactory system. The relative rarity of patient lesion cases and postmortem material, and the coarse spatial resolution of CT scans and scalp EEG recordings, meant that prior to MRI, our understanding of human olfaction was mostly limited to behavioral observations. Although psychophysical studies provided (and continue to provide) keen insights into human olfactory perception, a neuroscientific perspective had been wanting. Combined with a wide range of experimental designs, psychological tasks, and imaging analyses, fMRI has offered unique insights into the mechanisms by which the human brain encodes information about odor objects and odor valence, and how learning, attention, context, and experience modulate this information.

That said, it is important to bear in mind that functional imaging, and also structural imaging of network connectivity (such as DTI), represent highly indirect measures of brain activity, and the physiological principles underlying neurovascular coupling—that is, the transformation of neuronal signals into hemodynamic responses—are vague at best. Moreover, fMRI activation within a single 1-mm<sup>3</sup> voxel represents the pooled activity of  $\sim 10^5\text{--}10^6$  neurons, with a time-to-peak of 4–6 seconds, long after fast synaptic transmission has concluded. My reason for highlighting these limitations is not to denigrate the field of human functional imaging, but rather to underscore the care one must take in designing and interpreting olfactory fMRI experiments. A few general guidelines are listed below.

1. Minimize MR signal dropout. A variety of methods is available to minimize MR signal dropout and distortion in basal frontal and medial temporal lobes. Using “out-of-the-box” MR acquisition protocols is unlikely to provide robust functional data from piriform cortex, amygdala, or OFC.
2. Limit odor exposure. The olfactory system is highly prone to sensory habituation, especially in the piriform cortex, comprising fMRI signal recovery. Unless a specific experimental design calls for prolonged odor exposure, it is best to limit stimulation to 2–3 seconds, including several different odorants as well as control (no odor) trials in the design. The start of one trial to the start of the next trial should be spaced 15–20 seconds ideally, but can be shorter depending on task needs.
3. Record respirations online. Because sniffing can induce activity irrespective of odor, it is critical to obtain a measure of sniffing during the imaging experiment. Sniff size, volume, and latency may vary by odorant, condition, or task, warranting acquisition of

event-related respiratory parameters. Breathing belts (respiratory effort bands), spirometers, and thermistors have all been used to collect these data.

4. Beware the lure of reverse inference. This problem is applicable to all imaging studies. The lure goes as follows: it is previously known that task A evokes activity in region X; in your new experiment, activity in region X is identified; therefore, you infer that region X is involved in task A.

As an example, one might design an odor detection paradigm in which odor-evoked activity is detected in the precuneus, an area adjacent to visual cortex that has been associated with visuospatial imagery. Therefore, it is concluded that the precuneus activity represents visual imagery that has taken place during the odor detection task. While theoretically plausible, the fact is that the original experiment was not designed to assess imagery. This is an example of reverse inference. The important point is that an imaging experiment should be designed to test specific hypotheses about specific cognitive/perceptual functions. In many instances it is also advisable to identify specific *a priori* brain regions of interest.

In conclusion, this chapter has surveyed human olfactory imaging from its historical beginnings up through 2012. The last decade has seen remarkable advances in both MRI technology and fMRI analytical approaches. Whether similar progress will occur over the next decade is less clear. The use of higher MRI field strengths will enhance signal-to-noise ratios as well as spatial resolution, but at the expense of greater susceptibility artifact that would further compromise fMRI signal in olfactory brain areas. This issue is particularly problematic for functional imaging of the human olfactory bulb, which to date has remained elusive. The development of new fMRI protocols not confounded by susceptibility artifacts may hold promise for imaging of this region. Future efforts are likely to utilize olfactory fMRI as one component of a multi-disciplinary enterprise, in which imaging is combined with other research modalities including EEG, “reversible lesion” techniques such as transcranial magnetic stimulation, and molecular genetics to generate a truly comprehensive scientific framework of human olfaction.

# Chapter 14

---

## Prenatal and Postnatal Human Olfactory Development: Influences on Cognition and Behavior

BENOIST SCHAAAL

### 14.1 INTRODUCTION

Our current understanding of the functions of human olfaction largely derives from research carried out in adults. Accordingly, knowledge of this sense during the first decade and a half of life remains largely fragmentary and contradictory, reflecting, in part, limited access to infant populations and difficulties in testing the perception of preverbal subjects (for reviews, see Crook, 1987; Beauchamp et al., 1991; Doty, 1992; Schaal, 1988, 1999, 2005; Schmidt and Beauchamp, 1992). An example of contradictory evidence is the paradox that children under the age of 10 are often credited with mediocre olfactory skills, even though memories for odors present during this early period may be vividly recalled in adulthood (Chu and Downes, 2000, 2002; Willander and Larsson, 2006).

This chapter focuses on the importance of ontogeny and early experience in understanding human olfaction. The first section examines the emergence of the anatomy and function of nasal chemosensation, including its development in young organisms as they gain sophistication in sensori-motor and cognitive skills. The second summarizes adaptive responses to odor exhibited by infants and young children, including newborns, in individual and social contexts. The final section assesses the long-term consequences of early exposure to odorants. Animal studies are mentioned throughout the chapter, taking advantage of the fact that they may provide insight into the specific psycho-biological mechanisms involved in the early

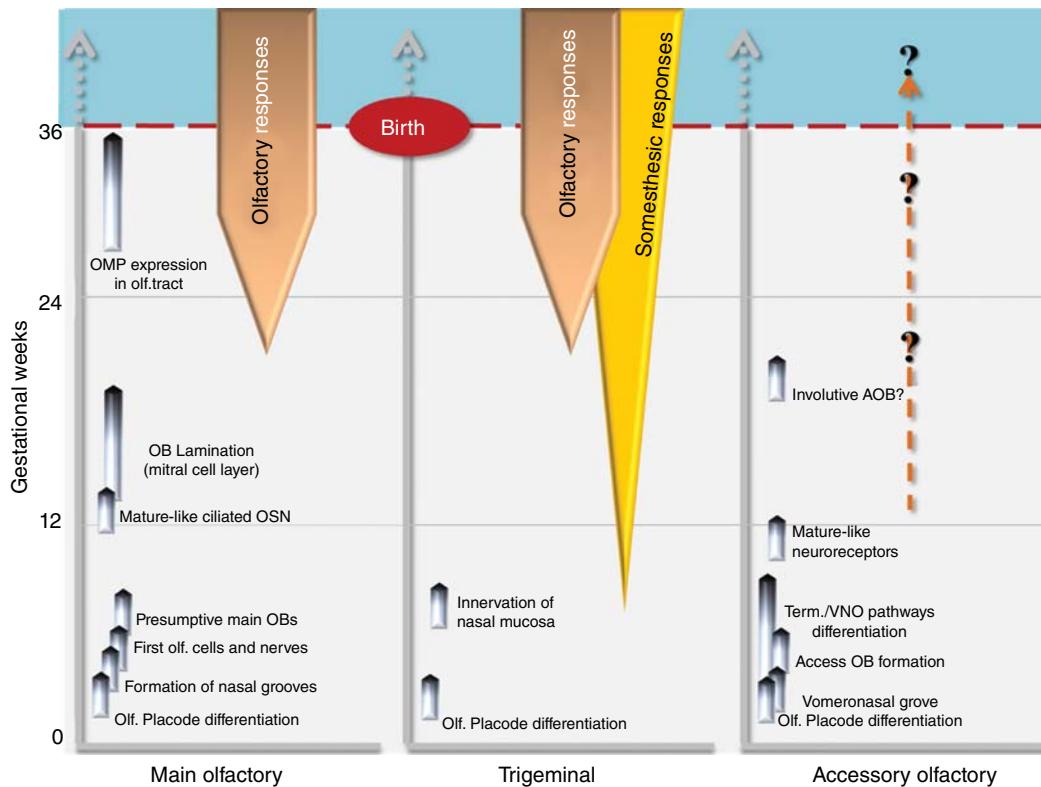

development of human olfactory abilities (e.g., Cheal, 1975; Alberts, 1976, 1987; Rosenblatt, 1983; Blass, 1986; Hepper, 1991a; Leon, 1992; Schaal, 2010).

### 14.2 DEVELOPMENT OF OLFACTORY STRUCTURES AND PERFORMANCE

#### 14.2.1 Nasal Chemoreceptive Structures

As shown in other chapters of the *Handbook*, chemoreception is based on multiple and anatomically distinct sensory structures associated with the assessment, intake, and utilization of volatile chemicals. Many mammals possess several distinct intranasal chemosensory systems, including the main olfactory and accessory (vomeronasal) olfactory subsystems, the trigeminal nerve, the terminal nerve (CN 0), and, in rodents, the septal organ of Masera and the Grueneberg ganglion (see Chapters 50–52). In humans, the only chemosensory systems that are functional in adulthood are those of the main olfactory (CN I) and trigeminal nerve (CN V) systems. Although a human vomeronasal system develops in utero, only non-functional remnants exist in adults. Nonetheless, it is theoretically possible that this system functions in utero in humans.

Milestones of the development of the olfactory, trigeminal, and vomeronasal systems of humans are depicted in Figure 14.1. The primordium of the *olfactory system*

**Figure 14.1** Timing of known steps of the prenatal development of nasal chemoreceptive structures and functions in humans. Data are presented for the main olfactory subsystem, the trigeminal subsystem, and the accessory (or vomeronasal) subsystem. Gestational age is given in post-ovulatory weeks. Based on Humphrey, 1978; Bossy, 1980; Chuah and Zheng, 1987; Schaal, 1988; Müller and O’Rahilly, 2004). Abbreviations: AOB: accessory olfactory bulb, Olf.: olfactory, OB: olfactory bulb, OMP: olfactory marker protein, OSN: olfactory sensory neuron, VNO: vomeronasal organ, Term.: terminal nerve.

can be seen during the first trimester, when the olfactory placodes differentiate during post-ovulatory weeks 3.5–5 and when the olfactory bulbs (OB) become visible during weeks 6–8 (Bossy, 1980). By weeks 4.5–7, the axons of the olfactory sensory neurons (OSN) develop first and define the olfactory nerves. During weeks 10 and 11, dendritic knobs of the OSN burgeon profusely into ciliary processes that express G-proteins involved in sensory transduction. Morphologically mature OSN can be seen from week 11, connecting with the OBs which are then visualized by MRI to be large relative to the entire brain (Azoulay et al. 2006). Histological analyses indicate that the OBs acquire their typical laminar appearance by week 19 (Bossy, 1980). Sensory like neurons are detected in the VNO between 5 and 13 weeks (Bossy, 1980; Ortmann, 1989; Boehm and Gasser, 1993), although the accessory olfactory bulbs to which they project undergo regression during the second trimester (Humphrey, 1940). Free endings of the *trigeminal nerve* become visible in the respiratory and olfactory mucosae in the 4-week-old embryo (Brown, 1974). They participate in tactile stimulus–response loops between

weeks 7.5 and 10, when they already mediate tactile reactivity (Humphrey, 1978).

The aforementioned studies accord well with the concept that some chemoreceptive structures are functional before birth, at least during the last trimester. Although early anatomists reported that epithelial plugs obstruct external nares until 16–24 gestational weeks (Schaffer, 1910), recent ultrasonographic studies show fluid movements through upper aerial passages during fetal pseudo-respiratory activity. Studies of premature neonates suggest chemosensory function may be restricted to the last two gestational months (Schaal et al., 2004). Given their stages of embryological development, information from several sensory systems, including taste, touch, and hearing, may be woven together during the later stages of pregnancy (Lecanuet and Schaal, 1996; Schaal and Durand, 2012).

## 14.2.2 Nasal Chemoreceptive Functioning

The functional onset of nasochemoreception has been studied in both animal and human infants (Smotherman

and Robinson, 1987, 1995; Schaal et al., 1995B). In the rat, olfactory sensory neurons (OSN) exhibit neural activity during the last five days of gestation with further maturation occurring postnatally (Gesteland et al., 1982). Although no such electrophysiological verification is feasible in human fetuses, indirect molecular markers of activity have been used, namely the ‘olfactory marker protein’ (OMP). The expression of OMP coincides with selective odor receptor cell reactivity and connectivity with mitral cells in the olfactory bulb of rats (Lee et al., 2011). Although the human olfactory system exhibits OSN of adult-like appearance by gestational week 11, OMP is not expressed before week 28. Between weeks 28 and 32, it is expressed in OSN cell bodies and dendrites, and, by week 32, in the entire OSN. Finally, by week 35, OMP is detected in the OBs (Chuah and Zheng, 1987) suggesting connections have been made with secondary neurons. The pattern of neural maturation indexed by OMP appears to parallel emerging odor reactivity in premature infants. Before week 28, they are rarely responsive to mint odor, whereas they react more and more consistently to it after 29 weeks. By 33–36 gestational weeks, premature infants respond as frequently to mint odor as do term newborns (Sarnat, 1978). But mint odor has a distinct somesthetic effect and trigeminal nerve endings may accordingly also contribute to early responses.

How central structures involved in adult odor processing develop in fetuses, infants, and children is poorly understood. Anatomical studies suggest that cerebral structures receiving primary afferents (i.e., anterior olfactory nucleus, olfactory tubercle, piriform cortex, and superficial parts of the amygdala, such as anterior cortical nucleus, nucleus of the lateral olfactory tract, and periamygdaloid cortex) and secondary or tertiary afferents (i.e., entorhinal cortex, hippocampus, orbitofrontal cortex, insula) reorganize during fetal development (Macchi, 1951; Humphrey, 1963, 1967, 1968). Several lines of evidence, albeit limited, suggest that the OBs connect with the limbic forebrain, olfactory paleocortex, and frontal neocortex during this early period of development. First, the OBs undergo anatomical changes discernible by MRI during the first decade, underlain by neuronal maturation (i.e., synaptic pruning, apoptosis, myelination) and internal reorganizations (Schneider and Floemer, 2009). Second, fetal and neonatal cortical processing competence of odor inputs is suggested by odor-induced variations in hemoglobin oxygenation (measured by Near Infrared Spectroscopy, NIRS) detected over the orbito-frontal regions in premature infants (Bartocci et al., 2000, 2001). Finally, the perceptual competence of fetuses, neonates, and infants (described in the following section) indicates that olfaction likely relies on processes that mobilize all levels of the olfactory system.

### 14.2.3 Olfactory Performance: Sensitivity, Reactivity, Discrimination, Recognition, Memory

**14.2.3.1 Fetuses.** Strong evidence for integrative processing of olfactory stimuli stems from studies on rat, mouse, and sheep fetuses tested *in utero* (Smotherman and Robinson, 1987; Schaal and Orgeur, 1992). Considerable progress was accomplished when extra-uterine live preparations of rodent fetuses were achieved by W. P. Smotherman and S. R. Robinson (e.g., Smotherman, 1982; Smotherman and Robinson, 1987, 1995). Subsequently, rat fetuses could be directly stimulated by infusing odors close to their snouts or into their mouths while their responses could be observed through the transparent amnion. These studies disclosed nasal detection of volatile compounds despite their being dissolved in fluid. In all species tested to date, fetuses exhibited acute autonomic and motor reactions when exposed to odorants. As these fetal responses differed with qualitatively and/or quantitatively distinct stimuli, discriminative abilities were demonstrated to emerge prenatally (e.g., Smotherman and Robinson, 1987; Ronca and Alberts, 1990; Schaal et al., 1991, Robinson et al., 1995).

In the human fetus, direct olfactory testing could only be run *ex utero* with infants born before gestational term (Peterson and Rayney, 1910–1911; Stirnimann, 1936; Sarnat, 1978; Pihet et al., 1996, 1997). Although the conditions of ligand-receptor interactions in such conditions do not match those prevailing *in utero*, it is assumed that, when tested as closely as possible to birth, preterm infants’ reactions reflect the operational properties of olfaction in same-age fetuses. Thus, prematurely born infants were shown to detect (Sarnat, 1978) and discriminate odorants. For example, Pihet et al. (1996) found that the odors of nonanoic acid or eucalyptol, selected for their respective low and high trigeminal potency (but matched in subjective odor intensity), released temporally different responses in infants born within 30–37 gestational weeks. A later study using vanilla and butyric acid odors at very weak concentrations showed that prematures aged on average 31.2 weeks discriminate both stimuli in terms of respiratory response, vanilla eliciting a fast accelerative response and butyric acid a slower, more persistent decelerative response (Marlier et al., 2001). The habituation paradigm further established discriminative abilities in prematures: after habituating infants (mean age: 31.8 weeks) to odorant A, the delivery of a novel odorant B prompted an increase in facial responses (Goubet et al., 2002). Finally, in preterm infants (mean age: 33.7 weeks) odorants with trigeminal side-effects decreased oxygenated hemoglobin over the parietal region (Bartocci et al., 2001). The fetal brain can

thus bear olfaction- and trigeminal-mediated sensation as early as the last months of gestation.

**14.2.3.2 Neonates<sup>1</sup>.** Since the first experimental attempts in the 1800s (e.g., Kussmaul, 1859; Preyer, 1884) up to the present time, infants have been nasally exposed to more than 80 different odorants and irritants. Over the first 3–4 days postbirth, their chemo-reactivity increases as measured by changes in motor/respiratory responses to constant stimuli (Self et al., 1972) or to dilution series intended to appraise detection thresholds. For example, Lipsitt et al. (1963) deduced rising odor sensitivity over the first four postnatal days by noting a decrease in the concentration of *Asafoetida*<sup>2</sup> necessary to elicit the response criterion. Alternative interpretations may, however, reside in neonatal response amelioration or in induced sensitivity by repeated exposure to the experimental odorant (as noted in adults; Rabin, 1988; Wysocki et al., 1989).

Several lines of evidence suggest that newborns can also discern odor qualities. First, different odor stimuli have been shown to induce different autonomic (heart and respiratory rates) and general motor reactions that vary in latency, duration, rate, and amplitude (Stirnimann, 1936; Engen et al., 1963; Self et al., 1972; Soussignan et al., 1997; Lipsitt and Rovee-Collier, 2012). Second, EEG responses to odorants (e.g., citral, coffee, lavender, pyridine, rosemary, and vanillin) have been demonstrated in neonates, although not before the age of six days (Fusari and Pardelli, 1962; Fernandez et al., 2003). Third, differential cortical reactivity has been inferred for vanillin, human milk, or axillary odors as early as the first hours after birth from variations of brain hemoglobin oxygenation measured using NIRS (Bartocci et al., 2000). Fourth, using habituation paradigms, infants 3 days to 1 month of age have been found to discriminate between pure odorants (Engen et al., 1963; Guillory et al., 1980; Goubet et al., 2002) or between mixtures and their components (Engen and Lipsitt, 1965). Fifth, “mere odor familiarization” can

<sup>1</sup>Developmental psychologists are in consensus in subdividing human development into several periods. First, the *neonatal period* lasts from the day of birth to one month of age. Then, *infancy* is defined from ages 1 to 24 months, *toddlerhood* being situated between 1 and 2 years. *Early childhood* lasts from the end of the 2nd to 5th year, *mid-childhood* from the end of the 5th to the 8th year, *late childhood* (prepubertal) from 9 to 11 years, and *adolescence* from 11 to 18 years, with prepubertal, pubertal and postpubertal stages being defined individually on the variable basis of developing primary and secondary sexual characteristics (e.g., Berk, 2007, 2008).

<sup>2</sup>Asafoetida was often used in early studies on infant olfaction. It derives from a powder obtained from the dried sap of the plant *Ferula assa-foetida* (*Apiaceae*). Its smell is very unpleasant due to sulfur compounds (hence its name *devils dung*), but in small amounts it is used as a spice (becoming garlicky during cooking) and as a remedy (hence, its other name *food of gods*) (Teuscher et al., 2005).

establish discrimination from a novel odorant diffused in the air around infants (Balogh and Porter, 1986; Davis and Porter, 1991). Finally, associations have been conditioned between the presence of an odorant and behavioral responses made to that odorant. Such learning procedures have been carried out using a range of rewards, including breast or bottle-fed milk (Irzhanskaia and Felberbaum, 1954; Schleidt and Genzel, 1990; Delaunay-El Allam et al., 2006) or tactile stimulation (Sullivan et al., 1991). Using such procedures, very early (i.e., first postnatal day), quick (i.e., minute-wise), and more or less stable (i.e., > 1, 5 year) discrimination abilities have been demonstrated (see below).

**14.2.3.3 Infancy and Early Childhood.** Olfactory development is poorly understood beyond the neonatal period, largely reflecting difficulties in devising age-adapted tests and in gaining preverbal children’s compliance. Nevertheless, several lines of evidence indicate that toddlers and young children react to, and discriminate among, odorants. First, as in neonates, behavioral measures indicate that preverbal children are affected by odorants, whether presented on objects, that is, as *features of objects*, or as contextual cues. For example, Schmidt and Beauchamp (1990) videotaped 9-month-olds sequentially given three objects (rattles) scented either pleasantly, unpleasantly, or neutrally (to adults); at first sight, the responses failed to yield conclusive data in terms of hedonic reactions, but the systematic coding of the videotapes revealed better-than-chance level responses to the hedonic quality of the odor of the object being handled. The same authors showed that female infants explored the odorized object more than a non-odorized object, while boys behaved indiscriminately (Schmidt and Beauchamp, 1989). Later, Mennella and Beauchamp (1998b) and Delaunay-El Allam et al. (2010) coded infants’ behavior (aged 6–13 and 5–23 months, respectively) while handling identical objects bearing different scents, one scent having been associated with the mother. The infants exhibited more positive reactions of the face/body toward the objects that smelled congruently with early odor experience. Finally, Durand et al. (2008) introduced olfactory novelty to assess odor detection in 7–15-month-olds who were videotaped while playing with scented and unscented versions of similar objects in consecutive sessions. The infants manipulated and mouthed less, and for shorter duration, the scented objects. But these responses, interpreted as indexing withdrawal, appeared only after a 2-minute delay, suggesting that it may take some time for infants to react to odor novelty and to separate odor cues from other attractive features of objects.

Infants and young children also react to the *odor quality of the background environment*. For example, Bloom

(1975; cited in Engen, 1982) diffused odorants (lavender, amyl acetate, butyric acid, dimethyl disulfide) unknowingly to 1–2-year-olds who played at a table while their facial reactions were evaluated by observers. Although 48 to 63% of the odor presentations did not elicit any detectable facial reactions, presumably due to the infant's attentional focus on playing, the remaining responses indicated nonrandom responsiveness to the odors in a way predictable from adult perception. More recently, 3-month-olds were subjected to an operant conditioning task in which they had to realize that their leg movements activate a colorful mobile, and this association was established in presence of an odor. When tested for retention of the contingency between kicking and the moving mobile 1, 3, and 5 days later, those infants re-exposed to the same odor remembered the association well. In contrast, those exposed to no odor exhibited only partial recall, whereas those exposed to a novel odor displayed no signs of remembrance (Rubin et al., 1998; Schroers et al., 2007; Suss et al., 2012). Thus, as early as 3 months of age, and probably earlier, contextual odors can facilitate subsequent memory retrieval.

Research assessing odor-induced brain activation in 3–4-month-old infants remains inconsistent. While some studies have reported undifferentiated EEG responses to food odors in waking infants (Kendal-Reed and Van Toller, 1992), others have noted differential cerebral responses to odorants in sleeping infants. For example, maternal milk odor reduced, bilaterally,  $\beta$  and  $\theta$  band waves recorded from frontal and central electrodes, whereas orange odor increased  $\delta$  wave activity from the central and right parietal positions (Yasumatsu et al., 1994), a difference attributable to qualitative and/or intensity (and trigeminal) stimulus differences. Another study recorded olfactory evoked response potentials (OERPs) to odorants administered intranasally through an olfactometer in 3.5–5-year-old children. The late positive peak of the OERP increased in latency with age, which was interpreted as reflecting deeper perceptual and semantic processing in older children (Hummel et al., 2007).

**14.2.3.4 Mid-childhood to Adolescence.** Psychophysical methods with children were initiated in the late 19th century, when Toulouse and Vaschide (1899a) studied detection and recognition thresholds for camphor in 3–12-year-olds. Older children (6 and 12 years) were reported to be more sensitive than 3–5-year-olds. An additional 10-odor recognition task indicated that accurate answers improved with age. In a related study that compared children to adults, 3–5-year-olds had detection thresholds for camphor equivalent to those of adults, but older children were more sensitive and adults were better in suprathreshold odor recognition (Toulouse and Vaschide, 1899a,b). At all ages, females outperformed males in terms

of sensitivity, discrimination, and identification. Although they bear the methodological limitations of their time, these early studies nonetheless set the stage for issues on age and gender differences in human olfactory sensitivity, discrimination, recognition, naming, and memory that still remain mostly unresolved.

Since these pioneering studies, much effort has been devoted to apply psychophysical approaches to children, mostly over 4–5 years of age. Although designed for adult participants, several tests have been used to quantitatively assess children's olfaction, usually for clinical purposes [e.g., University of Pennsylvania Smell Identification Test (UPSIT; Doty et al., 1984), a match-to-sample odor identification test (Richman et al., 1995), the Alcohol Sniff test (Davidson et al., 1998), the Sniff Magnitude test (Frank et al., 2004), the Biolfra test (Chalouhi et al., 2005), the San Diego Odor Identification test (Sandford et al., 2006), the Sydney Children's Hospital Odor Identification Test (Armstrong et al., 2008), the 'Sniffin' Sticks' test (Hummel et al., 2007), the Lyon Clinical Olfactory Test (Patris et al., 2009), the NIH Toolbox Pediatric Odor Identification Test (Dalton et al., 2011), and the Wheel Smell Identification Test (Cameron and Doty, 2013)]. Each of these tests has advantages and limitations in terms of validation with substantial sample sizes, practicality, and duration of administration, cultural ubiquity of odorants, dependence on memory and verbal abilities (see review in Laing and Schaal, 2012). Some of them have been used to characterize the development of olfaction over wide age-spans. For example, the UPSIT, which comprises 40 suprathreshold odorants each cued by four response alternatives as words or icons to lessen age/individual variations in mnemonic proficiency, was applied cross-sectionally over the life span. The smell identification performance followed an n-shaped curve, the average recognition score of 5–9-year-olds matching those of adults in the 7–8th decades of life, when olfactory abilities sharply decline. But by age 10–19, children's UPSIT scores reached as high a level as those observed in non-elderly adults (Doty et al., 1984). Across the 6–21-year age-range, females had better UPSIT recognition scores than males (Doty et al., 1985), suggesting female advantages in either sensitivity, cognitive abilities relevant to language, or familiarization with odorants.

More basic research in child samples has been applied in various tasks, involving detection threshold, suprathreshold identification and naming ability, and/or memory. But their focus was more on child-adult comparisons (clumping early ages indiscriminately into a "children" category) than on phenomenological and mechanistic analyses of *olfactory development* (e.g., Cain et al., 1995; De Wijk and Cain, 1994; Lehrner et al. 1999a, b). First, they reported that children (>8 years) were at least as sensitive as young adults for certain odorants [e.g., 1-butanol, but also pyridine

(Dorries et al., 1989), amył acetate (Koelega and Köster, 1974), trimethylamine (Solbu et al., 1990), R-(+)-carvone (Patris et al. 2009)], although other odorants resulted in lower thresholds in younger than in older children or adults [e.g., isovaleric acid (Koelega, 1994), tetrahydrothiophene (Patris et al., 2009)]. Second, when simple discriminative tasks were required, children nearly equaled or were only slightly below adults (5–8 years, similarity judgments; Thomas and Murray, 1980; 6 years, oddity test; Stevenson et al., 2007). Further, children (from 6 years) appeared as accurate as adults in expressing quantitative judgments when required to display simple motor actions commensurate with subjective intensity ratings (Rovee-Collier et al., 1975). Thirdly, when recognition was requested, children were clearly disadvantaged relative to adults, but the magnitude of this disadvantage depended on the task, the child's age, and familiarity with the odor stimuli. Tasks dependent on lexical, semantic, or symbolic processes show increments in performance as a function of age and training. Therefore, numerous studies have sought to assess odor identification and naming in children of various ages (Larjola and Wright, 1976: 5/10/15 years; Doty et al., 1984: 5–9/10–19 years; de Wijk and Cain, 1994: 8–14 years; Richman et al., 1992: 3.5–5 years; Cain et al., 1995; Rouby et al., 1997: 5–6 years; Jehl and Murphy, 1998: 5–7/8–11/12–16 years; Stevenson et al., 2007: 6/11 years; Patris et al., 2009: 5/6/8/10.5 years; Frank et al., 2011: 4–7/8–11 years). Odor identification tasks were variable across this set of studies, generally based on free remembrance of an accurate name or on a choice among four or five words or images. In these conditions, younger children had generally lower identification performances than older children and adults. Differences with adults tended to fade when children were semantically primed by a name or picture to the identity of the odor (e.g., Cain et al., 1995), highlighting that early limitations in odor recognition may depend on producing or remembering verbal associations. The general effect of age further interacted with gender, girls being generally better than boys in odor identification and naming. This age by gender interaction is often interpreted as resulting from superior verbal fluency or broader odor-related semantic knowledge in females, even from early ages (Ferdenzi et al., 2008a; Patris et al., 2009). Developmental differences in odor distinction are certainly causally multiple, presumably encompassing sensory factors, such as changes in odor sampling ability (changing nasal aerodynamics, poor sniffing before 2.5–3 years; e.g., Schaal, 1988; Mennella and Beauchamp, 1992) or in odor detection due to changing properties of the olfactory mucosa and range of expressed olfactory receptors (e.g., Apfelbach et al., 1991). It may also depend on general or olfaction-specific cognitive factors, such as more limited experience with odors leading to reduced related semantic stores, lower ability to verbally label odor stimuli (Engen

and Engen, 1997; Frank et al., 2011; Lumeng et al., 2005; Rinck et al., 2011; Bensafi et al., 2007), shorter spans in working memory (Larjola and Wright, 1976), or poorer recognition memory (Hvastja and Zanuttini, 1989; Frank et al., 2011). The latter psychological factors are also often evoked to explain early gender differences in olfaction. A challenge for future research will be to integrate longitudinally in a single multidisciplinary study biological, psychological and environmental determinants of chemosensory performance during human ontogeny.

Younger children are clearly disadvantaged in odor identification tests requiring naming of the veridical source. But identification of higher-order categories reveals their already elaborate odor cognition, even in cultural conditions that do not favor training and teaching of olfaction. For example, when 8–14-year-old American children had to tell the identity of 17 odorants and whether they belong to edible/non-edible categories, they were less accurate than young adults in naming of odor sources, but were equal to them by the edibility criterion (de Wijk and Cain, 1994). A related study asked French 5–6-year-olds to categorize 12 common odorants along different criteria such as origin (in/outdoor, natural/artificial, vegetable/animal) and functionality (edibility, wearability) (Rouby et al., 1997). While these children categorized the odorants accurately for edibility, and partly accurately for wearability, they could not classify them using the other, more abstract, criteria. Another study required 4–11-year-old French children and adults to rate six fruity and six floral odors in terms of typicality, familiarity, liking, and edibility, and to order them as members of binary fruit or flower categories (Valentin and Chanquoy, 2012). Results indicated a relatively high classificatory agreement from age 5 for some odorants in the series, but interestingly without a necessary overlap with hedonic categorization, suggesting that young children can separate emotional from more cognitive operations while processing odors. But from age 8, most odorants were classified into the expected category, as well as given a name in the correct semantic category. The ability to assign an odor an egocentric functional meaning may thus prevail on the ability to accurately name it, although naming certainly crystallizes conceptualization. Thus, children's odor categorization abilities depend strongly on the breadth and depth of prior experience with odors, and hence can only improve with exposure (Rouby et al., 1997; Prescott et al., 2008). Exposure creates familiarity with object features, increasing their perceptual salience and differentiation, and facilitating the learning of category types and borders and the articulation of semantic relationships (e.g., Folstein et al., 2010).

The effect of unsupervised training in the acquisition of the meaning of odors is best supported by studies on olfactory recognition of items that prevail in the environment. For example, children aged 2.5–6 (Noll et al.,

1990) or 5.5–10.5 years (Fossey, 1993) recognize and identify different types of alcoholic beverages, and these differences increase with age and rate of exposure. Thus, even if (Euro-American) children do not spontaneously talk about their odor experience in the early stages of language development (Engen and Engen, 1997), they are nevertheless aware of odors in their environment and behave accordingly. A survey study conducted on Finnish and French 6–12-year-olds confirmed early attention to the odor attributes of objects, persons, and domestic and outdoor settings (Ferdenzi et al., 2008a,b). Although these children ranked olfaction after sight, touch, and hearing in importance in their everyday experience, they also highlighted the unique significance of olfaction in their attention to the environment, especially in food selection and appreciation, self-grooming, interpersonal relationships, and environmental enjoyment. In line with the psychophysical data mentioned above, this survey confirmed that age obviously influences the ability of children to scrutinize the odor facets of their environment, although the most affectively-laden items or situations went unaffected by age. Lastly, girls (between 6 and 12 years) reported higher attention and reactivity to odors in daily settings than did boys. Beyond gender differences, this study also pointed to individual differences in the power of olfaction to control attitudes and overt behavior of children. When the participants' sample surveyed above was split as a function of their odor attention score, children who scored high on 'olfactory attention in everyday settings' were more aware of implicitly-presented real odors and more extreme in hedonic judgments of real odors than subjects who scored low on olfactory attention (Ferdenzi, 2007). The children's reported attention to environmental odor cues may directly influence the way they sense objects or contexts. For example, 4–7-year-olds sniffed at odor containers more distally and cautiously when they were classified as food neophobic (Bunce and Gibson, 2012), indicating either greater sensitivity and/or higher emotional reactivity to odors. This whole area of individual differences in olfaction is especially promising to probe how sensory phenotypes emerge and fluctuate during typical and atypical development, and which early life conditions do stabilize or alter the processing of odors from the molecular to the behavioral levels (e.g., Lane et al., 2010; Schecklmann et al., 2013).

A turning point in the development of odor perception is adolescence. A puberty-related shift in olfaction was first reported by Le Magnen (1952) who noted prepubertal children and adult men found the steroid exaltolide to be less intense than did women. This age by sex interaction in the detection of certain odorants was subsequently confirmed in cross-sectional studies for other steroid compounds, including artificial musk, androstenone, and androstadienone (Koelega and Köster, 1974; Koelega,

1994; Dorries et al., 1989; Hummel et al., 2005; Chopra et al., 2008). Typically, male sensitivity to these compounds decreased across the pubertal years, while female sensitivity remained constant. The rate of anosmia to the odor of androstenone between pubertal (9–14 years) and postpubertal (15–20 years) groups tripled (to reach 30%) in boys, while it remained low (around 10%) in girls (Dorries et al., 1989). Some studies indicated that this age by sex interaction concerned musky odorants (Koelega and Köster, 1974; Koelega, 1994; Dorries et al., 1989), but a wider range of odorants was affected by puberty-related changes in olfaction: strongly unpleasant odorants (sulfur compounds; Chopra et al., 2008) and even fruity or floral notes of strawberry or lavender (Moncrieff, 1965) were also involved, although food odors appeared generally excluded from such effects (at least in boys; Laing and Clark, 1983). The proximal causes of these peripubertal variations in olfactory processing remain little investigated and empirical attention from biological, psychological, and biosocial perspectives is needed. Related fluctuations in reproductive physiology are certainly involved in altered peripheral reception and perceptual processes, as are changes in brain maturation (e.g., Brewer et al., 2006) and related psychological processes (e.g., increased disgust sensitivity, novelty seeking and risk taking, and changing social roles and status, as suggested by variations in the valuation of certain foods, perfumes, or addictive agents).

#### 14.2.4 Developmental Odor Hedonics

Research on adults show that nasal chemoreception can mediate a wealth of informative "dimensions" inherent either to the stimulus (i.e. identity, quality, perceived intensity, complexity, position in space, variety) or to properties derived from an individual's prior interactions with it [i.e., familiarity/novelty, hedonic valence (pleasantness/unpleasantness), utility knowledge or affordances (e.g., eatability, toxicity, stress buffering value)]. These properties are not independent, however, as quality is often linked with intensity and hedonic valence with intensity or familiarity (Engen, 1974; Cain and Johnson, 1978; Delplanque et al., 2008). The extent to which these "dimensions" are relevant in the development of the ability to segregate odors into categories is poorly understood. Most studies have sought to understand when and how the affective impact of odorants develops, often confounded in intensity or familiarity/novelty "dimensions" (Delplanque et al., 2008). Some of these studies suggested that humans of all ages and genetic/ethnic backgrounds use similar hedonic criteria in dividing up the odor space. From the first hours after birth, odors considered pleasant for adults (e.g., orange, geranium) were reported to evoke positive oral activation, whilst unpleasant-to-adult odors

(e.g., asafoetida) caused facial/oral expressions of disgust and negative head turning in infants aged 15 minutes to 6 hours (Peterson and Rayney, 1910–1911). Also, Stirnemann (1936) established orofacial expressions emitted by newborns, including a premature infant born at 6 G months, in response to odorants that are pleasant or unpleasant to adults. These pioneering studies were confirmed and expanded by Steiner (1977, 1979) who showed that newborns under 12 hours of age, before any postnatal ingestion, display differential responses to various intense odorants chosen to represent pleasant and unpleasant extremes for adults (banana, vanilla, milky vs. fishy and rotten egg, respectively). Steiner presented these stimuli orthonasally while neonatal faces were photographed. These photos were then seen by a panel of “blind” adult judges who had to tell whether the facial response was caused by a pleasant, unpleasant, or neutral stimulus. Generally, odorants considered pleasant by adults induced facial responses rated as expressing contentment and acceptance (relaxed facial muscles, raising of mouth corners, licking and sucking), whilst unpleasant odorants elicited expressions interpreted as reflecting dislike and disgust (lowering of mouth corners, lip and tongue protrusion, gaping). Assuming that a commonality of facial expressions between neonates and adults implies analogous emotional states, Steiner postulated that certain odors were more acceptable than others for the newborn and that the perceptual attributes infants use to differentiate odors is hedonic valence. Accordingly, Steiner (1979) postulated that neonatal facial reactivity to odors depends on a hard-wired ‘hedonic monitor’ that activates an olfacto-facial reflex. After testing an anencephalic infant who responded to fishy, rotten egg, and banana odors by facial expressions similar to those of normal infants, he concluded that this early stimulus–response link was mediated by brainstem structures (Steiner, 1979).

Using a more quantitative and dynamic means to code infant responses, Soussignan et al. (1997) presented 3-day-old newborns (in different arousal stages) with 12 odorants [including four unfamiliar biological odorants (amniotic fluid, human milk, and two formula milks having different qualities), vanillin and butyric acid diluted to match the perceived intensity of previous odorants, and odorless controls]. Facial responses to odors were videotaped and then systematically decoded using Ekman and Friesen’s (1982) Facial Action Coding System.<sup>3</sup> In such conditions, neonatal facial actions to the different odorants were highly variable between neonates and could accordingly not be considered to be ‘automatic,’ as predicted

by Steiner’s olfacto-facial reflex model. However, facial responses were differentiable according to the hedonic value of the odorants, but more clearly so for odorants that were unpleasant to adults. Thus, while unpleasant butyric acid odor elicited more negatively-valenced responses than vanilla odor, the pleasant vanilla did not elicit any more positive facial response than did butyric acid. As both odorants were intensity-matched, the negative response could only be based on the neonates’ aptitude to differentiate odors in qualitative and/or hedonic terms, thus confirming only partially Steiner’s results. However, the odors of unfamiliar formula milks, although clearly unpleasant to adults, did not elicit negative facial responses in newborns. Therefore, the hedonic facets that newborns and adults detect in odorants are not completely superimposable.

Beyond the neonatal period, differences between infants, children, and adults in hedonic reactivity to odors have been, and still are, a source of long-standing debate (e.g., Schaal, 2012). Early studies reported young children’s relative tolerance to odorants that are unanimously rejected by adults. Based on behavioral or declarative responses of (hospitalized) Hungarian participants aged 1 month to 16 years to the offensive odors of oil of *Chenopodium*, trimethylamine or asafoetida, Peto (1936) pinpointed age 5 years as a turning point in the hedonic appraisal of odor: before that age, negative responses occurred only in 3% of the subjects, whereas beyond that age 72% expressed dissatisfaction. A convergent pattern was also noted among American children sampled between 3 and 14 years (Stein et al., 1958) with fruity (amyl acetate), sweaty and fecal odorants: 3–4-year-olds found all stimuli equally likeable, whereas older children discerned fruity from sweaty and fecal odorants, and clearly rejected the latter. Engen and Katz (1968) later found that the liking response for the unpleasant odor of butyric acid drops sharply between ages 4 and 5–6 years while those for pleasant odorants remain steady. But, in an effort to explain this apparent 5-year shift in the hedonic appraisal of odors, Engen (1974) suggested the involvement of a non-specific age-related response bias in a test situation where an infant is questioned by an unfamiliar experimenter. At age 4, children exposed to butyric acid odor were more inclined to answer “yes” than “no” to the queries “Tell me if it smells pretty?” as well as “Tell me if it smells ugly?”. This tendency fell sharply in 5–6-year-olds who were increasingly negative to this odor, answering “no” and “yes” to the former questions, respectively. Thus, a variation in the ‘yes man bias’ (Guilford, 1954) may best explain why younger children report positive responses to odorants regardless of their hedonic valence. Studies asking American or British children over the age of 6 years to rank-order sets of odorants in terms of their pleasantness resulted in responses roughly similar to those of adults (Kniep et al., 1931; Moncrieff, 1966). However, children ranked some odorants (fecal notes)

<sup>3</sup>Ekman and Friesen’s (1982) Facial Action Coding System is an anatomically-based system that itemizes the movements of each of the 44 facial muscles. It is a valid and reliable tool which has been used extensively for coding adult facial movements, but has been adapted for coding neonate and infant faces.

lower in unpleasantness than adults did (Moncrieff, 1966), suggesting either that rating scales are used in different ways at different ages or that preferences assessed through relative judgments (rank ordering or pair comparisons) are prone to age-related variations (Guinard, 2001). Finally, comparing 6–12-year-old children from different cultural backgrounds (i.e., Québec, Syria, Indonesia) for their hedonic rating of a set of 14 odorants, responses were consensual across cultural groups for the stimuli classified as the most negative, while the most preferred odors were variable between cultural groups, reflecting odor sources that are locally appreciated (Schaal et al., 1996). Thus, verbal responses to pleasant and unpleasant odorants appear asymmetrical in infants and children, the latter generally eliciting more consensual verbal responses than the former (see below).

Do measurements based exclusively on behavioral variables (i.e. independent of verbal response) provide more reliable results on the developmental trends of odor preferences? In the study by Bloom (1975; cited in Engen, 1982) mentioned above, pleasant (lavender, amyl acetate) and unpleasant smells (butyric acid, dimethyl disulfide) were unobtrusively sprayed in front of 1–2-year-olds who were playing at a table. Their facial reactions to the odor stimuli, as observed from behind a one-way mirror, were rather rare as most odor puffs were inefficient to cause a visually-detectable reaction. But, when only the stimuli effective to elicit a facial response were analyzed, pleasant odorants triggered more positive than negative facial actions. The reverse was true for unpleasant odorants. The hedonic hierarchy derived from these data in 1- and 2-year-olds was consistent with that predicted by adult ratings, *viz.* lavender > amyl acetate > butyric acid > dimethydisulfide. When these same odorants were presented to 3-, 4- and 5-year-olds, their facial reactions led to the same hedonic ordering of them. Thus, at least for these four odorants, orderly preferences begin to develop in 1- and 2-year-olds and appear stable through age 5 years (Bloom, 1975; see also Barnham and Broughan, 2002). But even earlier, by 9 months, American infants act differentially on identical objects scented pleasantly (methyl salicylate), unpleasantly (butyric acid) or not at all (mineral oil) (Schmidt and Beauchamp, 1990), some expressing reliable hedonic facial actions, while others responded by seemingly disregarding the object. A similar test situation in 7- and 21-months-olds came out with more positive and less negative responses (as indexed by object mouthing and face actions, respectively) for chamomile odor to which they were familiarized in the context of breastfeeding (Delaunay-El Allam et al., 2010). But again, the facial readouts provoked by the affective odor appraisal appeared asymmetrical, negative responses being generally clearer in communicative value to observers than positive responses (e.g., Steiner, 1979; Soussignan et al., 1997;

Delaunay-El Allam et al., 2010; Mennella et al., 2001; Zeinstra et al., 2009; Booth et al., 2010).

In older children, the accuracy of facial cues in unveiling an individual's hedonic experience can be strongly mitigated by the social context (Soussignan and Schaal, 1996a, 1996b), indicating incorporation of odor-elicited facial responses into the communicative repertoire (exaggeration, inhibition). When odors were presented by an adult experimenter (as compared to when they were self-administered in social isolation), 5- to 12-year-olds' responses were more positive for pleasant odors and less negative for unpleasant odors (and girls were more sensitive to such experimenter's presence than boys). An alternative to measuring facial responses *in vivo* or from videotapes is electromyography (EMG), the recording of electrical activity of facial muscles even before visual detection of any actual response. EMG has been used successfully in 7-year-old children exposed to pleasant vs. unpleasant odorants (Armstrong et al., 2007). However, as with facial expressions, EMG responses are not immune of social constraints (Jäncke and Kaufmann, 1994).

Another approach to assess the development of hedonic processes in olfaction relies on the subject's ability to translate hedonic judgments from odors onto attributes of visual stimuli having a pronounced social or symbolic meaning. For example, Strickland et al. (1988) required 3–5 year-old children to inhale hedonically-contrasted odorants and make the dichotomous decision to place them on 'smiley faces.' In these conditions, the pleasant (to adults) benzaldehyde and the unpleasant dimethyl disulfide were assigned to the smiling and frowning face, respectively, with 3-year-olds' attribution decisions being less clear than those of 4–5-year-olds. In a further study, 3-year-olds and adults were asked to give nine odorants to one of two television characters famous to American children, Big Bird and Oskar the Grouch, considered positive and negative figures, respectively (Schmidt and Beauchamp, 1988). Both age groups showed overall agreement in their preference pattern, although they differed in their hedonic assignments of some odorants to the positive or negative figure. While these studies have been criticized on the basis of early semantic and linguistic skills (Engen and Engen, 1997), they corroborate the idea that young children at the fringe of language and schooling can consciously distinguish odor stimuli in hedonic terms and that they do so in relative consensus with adult judgments.

In conclusion, research summarized in Section 14.2 clearly establishes the capacities of newborns, infants, and children to detect, discriminate, and to a certain extent, categorize olfactory stimuli. On top of this is their aptitude to subdivide the odor stimuli into attractive, non-attractive,

and repulsive. The sensory and psychological dimensions at the root of these early preferences remain poorly explored in humans, but one can safely assert that any weak odor to which the infant has previously been exposed will subsequently have a higher reinforcing value than any novel odor (although sensory specific satiety or boredom effects may induce occasional preferences for olfactory novelty; e.g., Mennella and Beauchamp, 1999; Hausner et al., 2010). This hypothesis attributes a major role to experience in the acquisition of olfactory preferences, even prenatally, although chemoperceptual specializations may emerge uninfluenced (or minimally influenced) by experience, as we will see below. The next section will consider the functional implications of these early discriminative abilities.

### 14.3 EARLY BEHAVIORAL FUNCTIONS OF OLFACTION

Here, we will consider the adaptive roles of olfaction in the succession of transitions that are typical of mammals, emphasizing the human case. We will first describe the fetal period during which offspring are anticipatorily primed to their future environment and the birth transition when newborns need to mobilize their sensory abilities to contact the mother and successfully ingest milk. Next, we will outline neonates' and infants' responses to social odors in the nursing niche, and survey odor-based processes in self-regulation abilities and in coping with social diversification. Finally, the involvement of olfaction in infants' and children's behavior will be considered in affiliative networks within and outside the family.

#### 14.3.1 Fetal Chemoreception

Mammalian, including human, fetuses dwell in amniotic fluid that is transplacentally permeated by odorous (and sapid) compounds. Such compounds are dependent upon the genetic, immunogenetic, and physiological constitution of the mother, as well as upon her life style, including diet, stress, activity and, in the case of humans, smoking behavior, medicaments, cosmetics, and use of addictive drugs (Schaal, 2005; Schaal et al., 1995d). This has been shown in numerous mammals, including humans. For example, pregnant ewes' or women's ingestion of garlic alters the sensory properties of amniotic fluid for adult noses (Nolte et al., 1992; Mennella et al., 1995), and odorous metabolites can be chemically traced into amniotic fluid after ovine or human mothers ate cumin in late gestation (Schaal, 2005). The mother-to-fetus transfer of dietary aromatic compounds can sometimes be so effective that the newborn's initial body odor is "spiced" accordingly (Hauser et al., 1985).

The odorous properties of the prenatal environment organize the fetuses' olfactory neural networks and induce the first 'odor images.' Integrative odor responses in fetuses were first assessed *in utero* in animal models. For example, fetal rats conditioned aversively to mint odor on embryonic day 17 retain the aversion on embryonic day 19 (Smotherman and Robinson, 1987). Thus, the neural chain for encoding, retaining, and retrieving chemosensory cues are present in the fetus in the later days of gestation. The *in utero* odor experience can carry over to the postnatal period (Smotherman, 1982; Stickrod et al., 1982; Hepper, 1988; Schaal et al., 1995d). Thus, mammalian fetuses from many species can respond to odors extracted from the womb and can retain memory for them for days to months postpartum (e.g., rats: Smotherman and Robinson, 1995; Hepper, 1988; mice: Youngentob and Glendinning, 2009; Todrank et al., 2011; rabbits: Bilko et al., 1994; cats: Becques et al., 2010; Hepper et al., 2012a; sheep: Schaal et al., 1995b; Simitzis et al., 2008; pigs: Oostindjier et al., 2009, 2010; *see* Schaal, 2005, for a review). Similar abilities have been shown in humans. For example, infants born to mothers who had eaten garlic during pregnancy show less aversion to the odor of allyl sulphide on the first postnatal day (Hepper, 1995). Infants of women that ingest anise in the last 10 days of gestation display greater appetitive responses and less aversive responses to a diluted anise odor relative to infants whose mothers did not consume anise (Schaal et al., 2000; *see* Figure 14.2). Finally, infants born to non-alcoholic mothers categorized as frequent drinkers during pregnancy ( $\geq 4$  times/month) are more reactive to ethanol odor than those born to non-frequent drinkers (<4 times/month) in terms of cephalic and facial movements on postnatal day 2 (Faas et al., 2000).

The most parsimonious explanation of prenatal odor acquisition is that of simple familiarization with odorants present in the amniotic sac. Thus, stimuli merely experienced *in utero* generally cause less aversion or more attraction than any novel stimulus. But associative learning may also function *in utero* to launch appetitive or aversive processes. This has been empirically explored in the fetal rat, but remains hypothetical in the human fetus. For example, a rat fetus readily associates a negative meaning to an odor experienced when an illness state is inflicted to itself (Stickrod et al., 1982; Smotherman, 1982) or to its mother (Gruest et al., 2004). Rat fetuses can also associate odors with endogenous physiological variations. For example, they can link an odorant co-occurring with decreasing brain oxygenation or re-oxygenation by cord clamping or unclamping and this odorant later becomes laden with aversive or attractive value, respectively (Hepper, 1991b, 1993).

Otherwise, each maternal meal, especially in late gestation, provides optimal conditions for the fetus to associate

**Figure 14.2** Examples of facial responses elicited by the presentation of odor stimulations to awake newborns. These infants were exposed to 10-second stimulations of a diluted anise odor. Infant a (age at test: 3 hours at the test) was born to a mother who consumed anise-flavored foodstuffs or beverages during pregnancy, and accordingly displays facial actions reflecting appetence to anise odor. Infants b, c and d (aged 1.5, 8, and 0.5 hours, respectively) were born to non-anise consuming pregnant mothers and expressed facial actions reflecting rejection (i.e., brow lowering, cheek raising, nose wrinkling, gaping, negative head turning). From B. Schaal, L. Marlier, and R. Soussignan, Human fetuses learn odours from their pregnant mother's diet. *Chemical Senses*, 25: 729–737.

inputs from chemoreception, motor activation, and brain metabolic sensing and reward processes. Exposure to an odorant *in utero* may induce epigenetic changes in olfactory receptor expression that may be actualized in biased sensitivity in the newborn (Semke et al., 1995; Youngentob et al., 2007). Prenatal olfactory experience may further facilitate neurogenesis and the synaptic organization in the OBs (Leon, 1992; Wilson and Sullivan, 1994; Todrank et al., 2011), as well as later positive investment in the newborn, for example, by strengthening an odorant's reinforcing value through postnatal reconsolidation. Such a fetal preparation process was shown in rat pups: when sensitized to citral *in utero*, they engaged a preference for citral only when re-exposed to it postnatally in particular arousal conditions (Pedersen and Blass, 1982; Alberts and Ronca, 2012). Ordinarily it is the amniotic fluid that plays the role

of an olfactory “initiator” that provides a link between the prenatal and postnatal environments (see below).

### 14.3.2 Birth and the Rapid Learning of Odors

The birth process itself impacts the perceptual development of the ‘perinate’, viz. the fetus as it is becoming a newborn. Labor-related physical compression and internal (blood gases) and thermal upheavals alter the perinate’s physiology with rising brain catecholamines and correspondingly high arousal levels, and facilitate learning of the current odor environment. During labor, the fetal brain seems to update the latest chemosensory profile of its amniotic environment. This is suggested in fetal rats exposed sequentially to two odorants 10 or 40 minutes

before cesarean delivery. When tested with both odors as neonates, the pups exhibit more activation to the odorant experienced closer to birth (Molina et al., 1995). Physiological and sensory effects associated with the natal transition itself further promote olfactory learning (Alberts and Ronca, 2012). This was shown by having rat fetuses externalized from the uterus and exposing them to artificial compressions mimicking labor in the presence or absence of an odor. Those fetuses exposed to odor-contingent compressions acquired the odorant as a postnatal cue to nipple seizing. In contrast, those fetuses exposed to compressions without odor or to odor without compressions did not acquire the odor as a cue to nipple grasping.

Labor-related experience has also been suggested in human infants exposed to an odor for 30 min after a cesarean delivery that was preceded or not by contractions. When these two groups of newborns were tested 1–5 days later for their attraction to that odorant relative to a novel one, only those having been exposed to labor oriented more to the familiar odor (Vareni et al., 2002). The experience of labor seems to mediate high arousal states during the first hours postbirth and to facilitate learning. Thus, exposing human neonates to an odorant for 30 min either in the first hour or after 12 hours' postpartum led to a differential response for the exposure odor two to three days later in the early-exposed

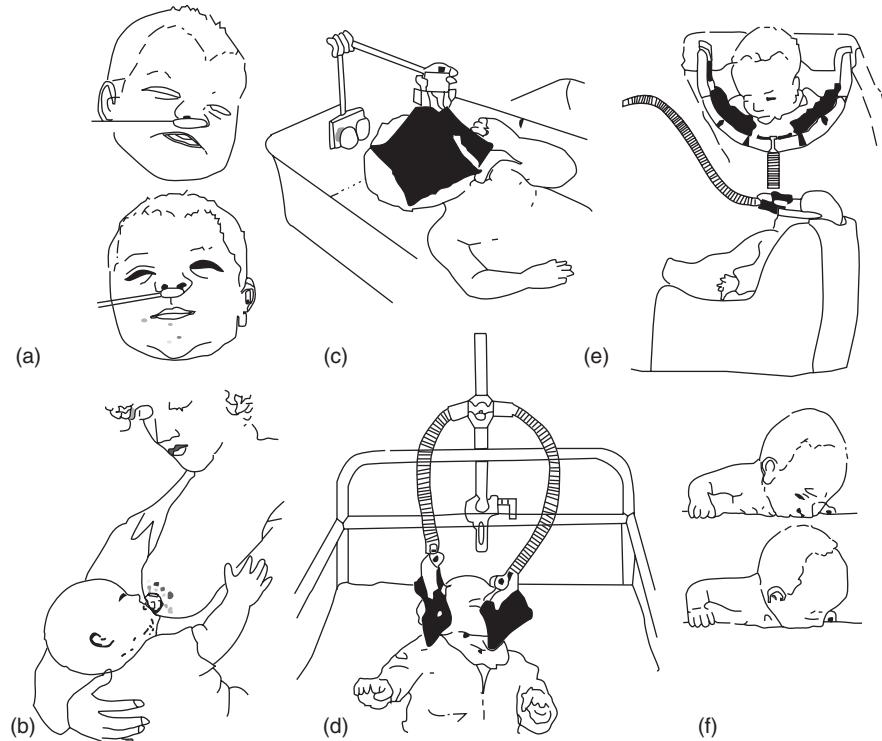

infants, but not in those exposed later (Romantshik et al., 2007).

### 14.3.3 Odor Communication in the Nursing Niche

As structures that provide milk to offspring, nipples or teats are the vital interface between lactating females and sucklings. These structures evolved to be sensorily conspicuous to offspring, mostly through their tactile and odor properties (Blass, 1990; Schaal, 2010). Empirical validations of this, however, are of recent vintage, despite the fact that this was recognized much earlier by such notables as Galen (AD 130–200) (Daremberg, 1856) and Darwin (1877).

#### 14.3.3.1 The Odor of the Lactating Breast.

In 1975, Macfarlane exposed supine-lying newborns to paired odor pads hung by their faces (Figure 14.3c). When exposed to a pad that had been in contact with the mother's nipple-areolar region and to a clean control pad, 17 of 20 breast-fed infants (aged 2–7 days) spent more time oriented towards their mother's pad, indicating not only detection but attraction. Such attraction was confirmed by others using variations of this test (Figure 14.3d). For example, 2-week-old bottle-fed infants spend more time oriented to an unfamiliar lactating mother's breast odor than to the odor of their familiar formula (Porter et al.,

**Figure 14.3** Contexts and devices used to investigate olfaction in human newborns. (a) Odorants are presented sequentially on cotton buds to assess differential oral-facial responses or reaction of the autonomous nervous system (e.g., Steiner, 1979; Soussignan et al., 1997; Mizuno et al., 2004; Doucet et al., 2009); (b) Infants are directly presented to their mother's breast after different treatments applied on the breast surface (e.g., Doucet et al., 2007). (c-d) Paired-choice devices to assess the general motor responses and relative head orientation of supine-lying infants (c: Macfarlane, 1975; d: e.g., Schaal et al., 1980). (e) Paired-odor choice test to assess differential head-turning and oral activation toward either stimulus in sitting awake infants (e.g., Schaal et al., 1995c; Delaunay-El Allam et al., 2006). (f) Differential rooting or crawling movements of the infant toward an odor source (e.g., Vareni and Porter, 2001) (Drawings: a-e: b Schaal; f: redrawn after Precht, 1958).

1991). One study presented 15-day-old bottle-fed infants with the breast odor of an unfamiliar lactating woman and the odors of either (A) the breast of a non-parturient woman or (B) the axilla of the same woman (Makin and Porter, 1989). Although they never directly contacted their mother's breast and were fed formula in highly reinforcing conditions, the infants oriented more to odor of the lactating breast, confirming that lactating women emit an attractive odor from the breast. Interestingly, newborns can crawl to an odor source 10–15 cm away (Figure 14.3f). When laid prone on their mother's chest, they can reach a breast within an hour from birth (Righard and Alade, 1990; Widström et al., 1987, 2011) presumably via the smell of the breast (Varendi et al., 1994). Similarly, when left bare in a warm incubator, infants creep more rapidly towards a pad odorized with their mother's breast odor than a scentless control pad (Varendi and Porter, 2001).

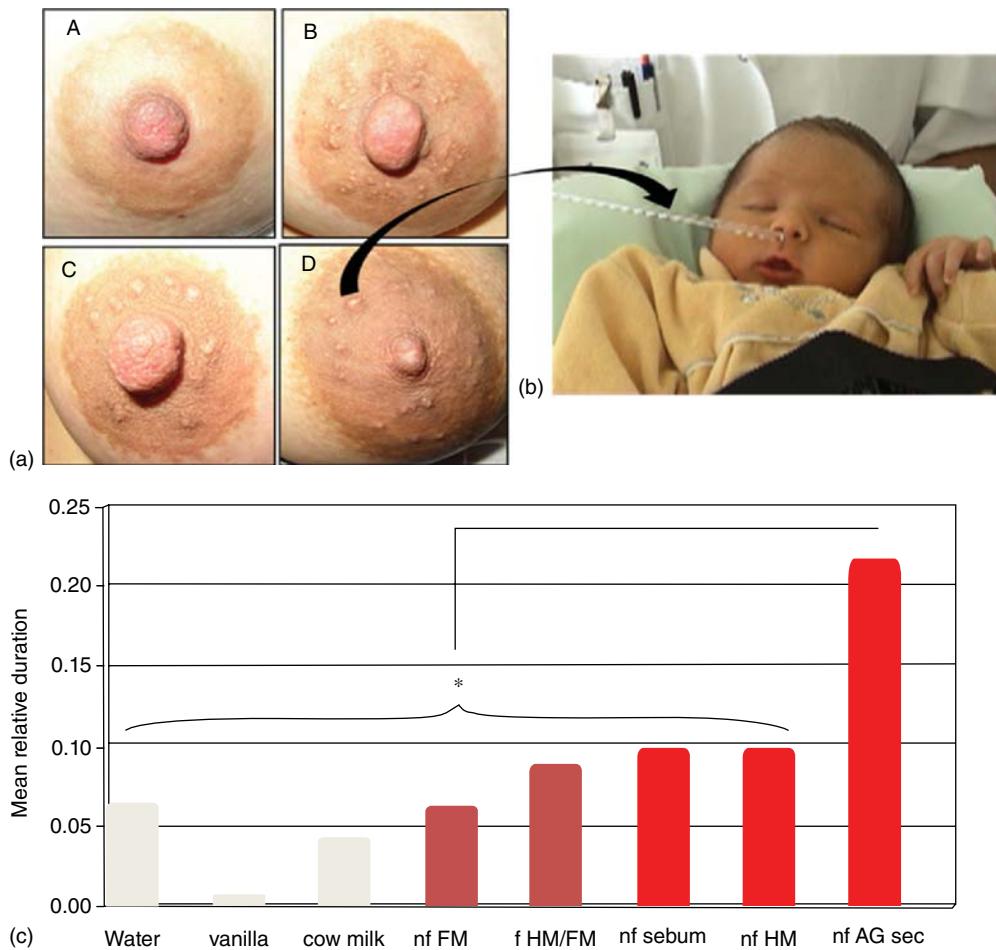

What are the sources of the attractive odor cues released by the breast? The human areolar-nipple area is complex in terms of multiplicity of secretions, making this difficult to determine. The breast is supplied with skin glands of eccrine, apocrine, and sebaceous types (Perkins and Miller, 1926; Montagna and MacPherson, 1974). The areolae are additionally dotted with small eminences that mark Montgomery's glands (MG) (Montgomery, 1837; Schaal et al., 2006), composed of sebaceous glands coalesced with miniature mammary acini (Montagna and Yun, 1972; Smith et al., 1982), and which can give off a latescent fluid (Schaal et al., 2006; Doucet et al., 2012). A recent study attempted to evaluate whether morphologically differentiable areas of the breast could induce distinct behavioral effects in newborns (Doucet et al., 2007). The 3-day-old infants responded (by rooting, mouth opening, or tongue protruding) similarly to whole breast vs. areola vs. nipple vs. milk odors, suggesting overlapping or equivalent attractive potencies in corresponding exocrine substrates. However, when presented separately from the other breast secretions, the Montgomerian secretion was more active in eliciting mouthing and in stimulating respiration than milk and sebum, as well as several other reference stimuli (e.g., cow's milk-based formula, fresh cow's milk, vanilla, water) (Doucet et al., 2009; Figure 14.4). Thus, Montgomerian secretions may play a special role in the infant's attraction to, and coordinated action on, the lactating breast (Schaal et al., 2008).

**14.3.3.2 The Odor of Milk.** Colostrum and milk add their intrinsic olfactory qualities to the nipple-areola. In both preterm and term newborns (Bingham et al., 2003a, 2007; Russell, 1976; Soussignan et al., 1997), these fluids elicit positive head-turning (Marlier et al., 1998; Marlier and Schaal, 2005) and activate facial/oral responses indicative of their appetitive value. For example, the odor

of mother's milk, as compared to the odor of a familiar formula, increases the efficiency of sucking during regular formulae feeding (Mizuno and Ueda, 2004) as well as non-nutritive sucking in premature infants (Meza et al., 1998; Bingham et al., 2003a, 2007). This milk odor-based stimulation of oral activity has been used to train the oral musculature of prematurely born infants and to accelerate the strengthening of their oral competence (Raimbault et al., 2006; Yildiz et al., 2011). Further, the odors of colostrum or milk elicit cortical activation (as assessed by EEG or NIRS; Yasumatsu et al., 1994; Bartocci et al., 2000), and the pattern of cortical activation induced by human milk in the orbito-frontal region differs from that of the odor of formula milk in infants consuming either milk (Aoyama et al., 2010).

The chemical nature of the active odorant(s) emitted in human milk or in any mammal's milk is largely unknown. Several analytic studies have found a variety of volatile compounds in human milk (Shimoda et al., 2000; Bingham et al., 2003b; Büttner, 2007), but these were so methodologically diverse (pooled vs. individual milk samples; fresh vs. frozen; solvent extracted vs. headspace) that no clear conclusion can be drawn. A similar approach in the European rabbit was more successful, certainly because of rabbit pups' non-ambiguous responses to odorants. Rabbit pups do indeed instantaneously orally grasp a glass rod dipped into fresh milk obtained from any female (Keil et al., 1990). In one study, gas-chromatography coupled with mass spectrometry and direct sniffing led to the identification in rabbit milk of a compound, 2-methyl-but-2-enal (2MB2), which was as efficient as whole rabbit milk in eliciting oral grasping motions in pups (Schaal et al., 2003). 2MB2 presumably is added to the milk in the final portion of the nipple (Moncomble et al., 2005). 2MB2 was detected in milk samples from females of different genetic and dietary backgrounds. Since its behavioral activity was highly selective and species-specific, prenatal or postnatal exposure was apparently not necessary for its function, Schaal et al. (2003) conclude that this agent functions as a pheromone and named it "mammary pheromone." The generalization of this mode of chemocommunication to other parenting and nursing strategies than the European rabbit awaits further investigation (Schaal, 2010).

**14.3.3.3 Transnatal Chemosensory Continuity.** By which mechanisms do secretions from the lactating breast or milk become attractive to neonates? Apart from mechanisms which apparently do not depend on sensory induction by prior direct exposure, such as the case with 2MB2, it seems that exposure effects and learning prevail in explaining this early attractiveness. As outlined previously, the perinatal brain is an efficient learning device, which is in age-adapted optimal operating

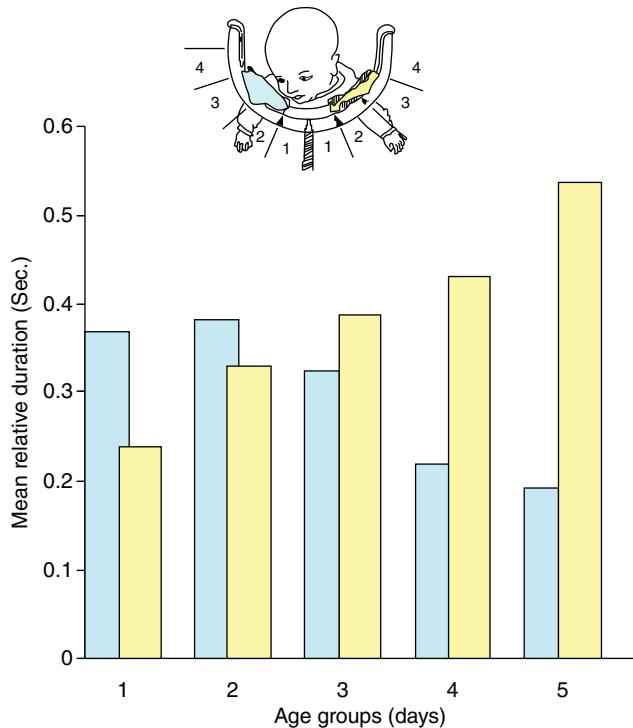

**Figure 14.4** The areolar glands of Montgomery and the behavioral effects of their secretion's odor in neonates. (a) Human areolae of lactating women (3 days postpartum) endowed with different amounts of areolar glands (a: absence of glands; b, c, d: variable number of glands). Photographs: S. Doucet. (b) Presentation of Montgomerian secretions to a newborn (age: 3 days) showing lip pursing and tongue protrusion. (c) Mean relative durations of oro-cephalic responses of 3-day-old newborns ( $n=19$ ) exposed (for a 10-second stimulus period) to nonhuman control stimuli [water, vanilla, non-pasteurized cow's milk, non-familiar formula milk (nfFM)] and to human odor substrates [familiar (F) milk (either human milk (HM) or formula milk (FM); non-familiar sebum (nf sebum); non-familiar human milk (nfHM); and non-familiar areolar gland secretion (nfAG sec)]. Areolar gland secretion releases more oro-cephalic responses than any other stimulus (From Doucet et al., 2009, *The secretion of areolar (Montgomery's) glands from lactating women elicits selective, unconditional responses in neonates. PLoS ONE*, 10: e7579).

conditions right before and after birth. Mammalian perinates do then face a sequence of odor substrates in highly reinforcing circumstances: amniotic fluid—secretions of the parturient mother's skin/breast—colostrum—milk. In human newborns, amniotic and lacteal fluids are attractive separately, but up to age 3 days they bear equivalent attractivity when presented concurrently as odors. However, beyond day 3, breast-fed infants turn more to the odor of their mother's milk than to the odor of their own amniotic fluid (Figure 14.5; Marlier et al., 1998). Undifferentiated responses between colostrum and amniotic fluid are also noted in other mammalian newborns that have been investigated (Figure 14.6; Schaal, 2005). This suggests a generalized chemosensory strategy among mammals

that raises the hypothesis of a *transnatal chemosensory continuity* between both vital fluids.

Such chemosensory continuity can be achieved by various means. First, the physiological transfer of odorant compounds into both fetal and lacteal compartments may create a *chemical matching* between amniotic fluid and colostrum. As already mentioned above, amniotic fluid is infiltrated with odorants from the mother's diet. Such odorants are also transferred into the colostrum and milk as shown by chemical analysis (Desage et al., 1996) or flavor preferences in weanling animals (e.g., Le Magnen and Tallon, 1968; Galef and Henderson, 1972; Capretta and Rawls, 1974; Wuensch, 1975; Mainardi et al., 1989; Bilko et al., 1994; Schaal et al., 2005; Langendijk et al., 2007). In humans, aromas from

**Figure 14.5** Mean relative duration of head (nose) orientation response of breastfeeding newborns within their first 5 days after birth when concurrently exposed to the odor of their prenatal environment (amniotic fluid; blue) and to the odor of the mother's milk of the day (yellow). From Marlier et al., 1997. (See plate section for color version.)

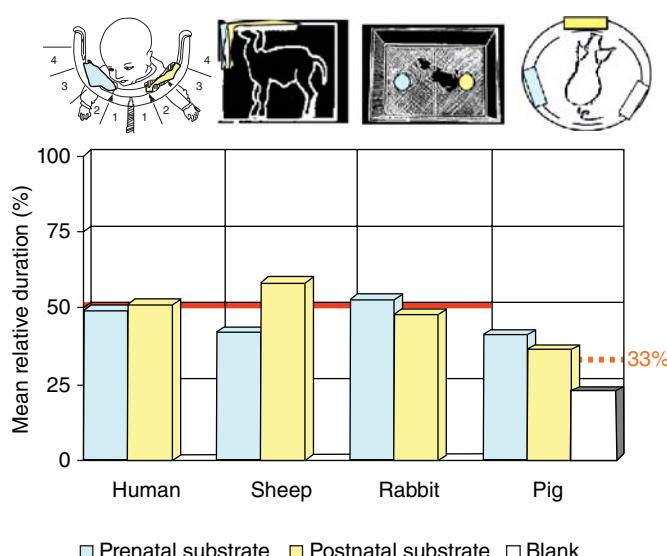

various foods (e.g., garlic, vanilla, alcohol, carrot) also easily pass into milk (Mennella and Beauchamp, 1991a; Hausner et al., 2008) and subsequent odor changes are detected by nurslings (Mennella and Beauchamp, 1991a, b, 1996, 1999). Maternally-inhaled odorants

(Dougherty et al., 1962), perfumes (Jirowetz et al., 1991), and burning tobacco odor (Lambers and Clark, 1996; Svensson, 1997; Karmowski et al., 1998; Mennella and Beauchamp, 1998a) also readily pass into the amniotic and mammary compartments. Finally, overlapping odor-active compounds deriving from normal metabolism were found in amniotic fluid, colostrum, and milk (e.g., androstenone: Doucet et al., 2010; fatty acids: Contreras et al., 2013; Hartmann et al., 2012).

A second mechanism of *perinatal chemosensory matching* is based on behavior. Females and their offspring deposit prenatal fluids on each other's bodies and, as already noted, these fluids are attractive to newborns of many mammals (i.e., rat: Teicher and Blass, 1977; Hepper, 1987; mouse: Al Aïn et al., 2013b; Logan et al., 2012; rabbit: Coureauaud et al., 2002; sheep: Schaal et al., 1995b; and pig: Parfet and Gonyou, 1991), including human infants (Schaal et al., 1995a, 1998; Soussignan et al., 1997; Varendi et al., 1996). Finally, a process of *motivational matching* between amniotic fluid and colostrum may operate in two ways. First, while nursing, females afford redundant rewards that boost the offspring's learning of any odor cue present on the nipple. Thus, for the newborn, the mere exercise of searching, rooting, and sucking in the presence of amniotic and colostrum odors assign them similar reinforcing value. Second, common bioactive compounds may similarly impinge on the brain of the fetus and of the neonate. Both fluids convey compounds, for example, opioids, that may promote learning of any contingent stimulus (Schaal, 2005; Robinson and Méndez-Gallardo, 2010).

#### 14.3.3.4 Olfaction and Energy Conservation.

After efficient suckling, it is essential that newborns conserve their energy. Early causes of energy loss are multiple, including separation-induced drops in body temperature,

**Figure 14.6** Mean relative duration of nose orientation of various neonate mammals when exposed to paired-choice tests opposing the odors of amniotic fluid and of colostrum or milk. (a) Cephalic orientation of 2-day-old breast-fed infants exposed to their own amniotic odor and to their mother's colostrum (Marlier et al., 1998). (b) search response of newborn lambs aged 2 hours post-birth to their amniotic odor and the odor of their dam's colostrum (Schaal and Orgeur, unpublished data). (c) Orientation response of newborn rabbits to the odors of placenta from their litter and of colostrum from their doe (Coureauaud et al., 2002). (d) Nosing response of pig neonates in a 3-choice test opposing the odors of their own birth fluids, of the sow's milk, and of a scentless control (Parfet and Gonyou, 1991).

restlessness, crying, and jeopardizing illnesses and pain. In human neonates, crying increases oxygen consumption by 10% (Blass, 1994). Energetic losses are attenuated or arrested by sensory features of the mother, including her warmth, movements, odors, and sounds (heartbeat and voice). As mentioned above, breast odor alone can prevent neonatal agitation (Schaal et al., 1980; Sullivan and Toubas, 1998). When distress and crying are caused by acute pain induced by heel lance or venipuncture, odor (or taste) cues from human milk reduce pain responses more than water or formula milk (e.g., Mellier et al., 1997; Örs et al., 1999; Upadhyay et al., 2004; Rattaz et al., 2005; Nishitani et al., 2009). Familiar odors can have similar effects (Field et al., 2008; Sadathosseini et al., 2011; but see Marom et al., 2011). Physiological responses (salivary cortisol level) to painful procedures can be attenuated by non-biological odors such as lavender or  $\gamma$ -dodecalactone thought to mimic milk odor (Field et al., 2008; Kawakami et al., 1997). In addition to its analgesic action mediated through opioidergic processes (Blass and Miller, 2001), milk also conveys bioactive compounds known to induce quiet states and sleep (Sánchez et al., 2009; Graf and Kastin, 1986). However, the efficacy of odors to induce and sustain sleep has been little investigated. Preliminary assessments on whether a t-shirt worn by the mother could prevent night awakening in 3, 6, 9, and 12 month-olds obtained mixed results due to poor control of maternal odor (i.e., one monthly sampling) and of infants' sleep parameters (Goodlin-Jones et al., 1997; Burnham et al., 2004).

#### 14.3.4 Olfaction in the Development of Social Cognition

Odor-based adaptive behavior persists well beyond the context of nursing and interactions with the mother. In fact, it participates in virtually all aspects of infant mammals' everyday lives, and the behavior of many mammalian infants cannot be fully understood without an in-depth understanding of olfaction (Alberts, 1981; Rosenblatt, 1983). Although most studies have employed altricial newborns whose perceptions are dominated by chemosensation, olfaction is also important in explaining the responses of precocial newborns of other species that also rely on vision and hearing (Olson, 1981).

**14.3.4.1 Social Diversification.** In most mammals, the nursing relationship favors more or less exclusive bonds between infants and their mothers. Postparturient females typically restrict their caregiving to their own offspring and reject unrelated young. Infants as well tend to respond preferentially to their own mothers and siblings (Hepper, 1991a). Such selective interactions

indicate that animals identify individuals or classes of conspecifics. However, when this occurs differs among species, being influenced by such factors as sensori-motor development at birth and the nature of the mother-infant bond, including the length of maternal dependence. For example, precocial neonates born in groups composed of several females (ungulates, pinnipeds) usually begin responding selectively to their own mother within several days after birth (Vince, 1993; Nowak, 1989; Charrier et al., 2001). In contrast, altricial neonates that remain confined in a nest may not develop individual recognition until weaning, the time when they become mobile and constrained to social selectivity (most rodents; Holmes and Mateo, 2007). The emergence of such discriminative social relationships in altricial neonates is generally based on the senses that develop earliest, that is, somesthesia and chemoreception.

#### FROM SOCIAL DISCRIMINATION TO SOCIAL RECOGNITION

Discrimination of the mother is rooted in the newborns' first experience with her as a sensory mosaic, composed of somesthetic, olfactory, auditory and visual cues, and their temporal arrangement. As noted above, odor cues carried in amniotic fluid, milk, and mammary secretions can convey several levels of meanings such as species, class of conspecifics, and specific individuals. An example of the first level is the rabbit pups' active nuzzling directed towards the belly or milk odor of any rabbit female, but not to such odors from rats or cats (Hudson, 1985; Schaal et al., 2003). Likewise, human infants orient more insistently to the odor of the breast/milk from an unfamiliar mother rather than to cow's milk or cow-based formula milk odors (Russell, 1976; Porter et al., 1991; Marlier and Schaal, 2005; Doucet et al., 2009). A second level, as alluded to earlier in this chapter, subdivides conspecifics into classes of individuals. Thus, mouse and rabbit newborns olfactorily differentiate males from females, and non-lactating from lactating females (Al Ain et al., 2013a; Coureaud and Schaal, 2000). Similarly, human infants discriminate body odors from unfamiliar lactating women as opposed to those of non-parturient women (Porter et al., 1991), indicating that lactation defines a class of especially attractive conspecifics. With regard to the third level, newborns appear to react discriminatively to odor cues that appear idiosyncratic to the mother. For example, while mammalian infants orient to any sample of amniotic fluid from their own species (Teicher and Blass, 1977; Schaal et al., 1995a, 1998), they selectively orient to their own amniotic fluid compared to the amniotic fluid from an unfamiliar conspecific neonate (rat: Hepper, 1987; rabbit: Coureaud et al., 2002; sheep: Vince, 1993; Schaal et al., 1995c; human: Schaal et al., 1998). Similarly, breast-fed infants aged 4 days display longer head-turning to their mother's milk odor when paired with milk odor from

another woman in the same lactation stage (Marlier and Schaal, 1997) and 4-day-old infants mouth more to their mother's milk odor than to another mother's odor when they were in contact with the mother right after birth (Mizuno et al., 2004).

Studies using cotton pads containing the *entire secretion* from the nipple-areola region provide convergent results. By timing the head-turning of 2, 6, or 8–10-day-old infants in tests pairing the mother's breast odor with that of another mother's breast, Macfarlane (1975) showed the gradual differentiation of mother's odor: 2-day-olds responded randomly, 6-day-olds turned more to their mother's breast odor, and 8–10-day-olds even more so. A subsequent experiment found that 3-day-old breast-fed infants can already discriminate their mother's breast odor, reducing their movements when oriented to their mother's breast pad relative to a pad that had been worn by an unfamiliar lactating mother or to a clean control pad (Schaal et al., 1980). Russell (1976) likewise observed differences in the mouthing responses of 6-week-olds when their nursing mother's breast pad was held under their nostrils, rather than a strange mother's pad. Even younger newborns, at about 24 hours of age, increased their rate of mouthing when exposed to the scent of their mother's hospital gown (especially the part that had been in contact with the mammary-axillary region) as compared with another mother's gown (Sullivan and Toubas, 1998). Finally, olfactory cues that enable infants to recognize their mother can be delivered redundantly by several other sources than the breast or milk, including those of the neck (Schaal et al., 1980) and axillae (Cernoch and Porter, 1985).

The above results indicate that volatile compounds from body secretions convey various levels of cues that newborns can use in their selective decisions, including identification of species, classes of conspecifics, and individual conspecifics. However, much remains to be learned about the nature and development of such processes. For example, it is not clear whether or to what extent a newborn orients to its mother's mammary scent because it is part of a recurring experience learned as safe and rewarding, because it carries attractive cues that are common to any lactating female, or because it evokes the mother as a unique individual. Indeed, social discrimination "is not an inevitable result of social recognition" (Mateo, 2004: 730). Contingency-based processes of recognition, that is, that an odor stimulus reliably recurs in a given context, may be a prelude to the elaboration of familiarity-based processes of recognition which precede the recognition of individuals as truly unique, which in human infants probably does not occur before several months of age (Olson, 1981). The need for several days of experience to establish maternal breast odor as attractive (Macfarlane, 1975; Schaal et al., 1980) and the failure of human

neonates to discriminate axillary odors from individuals with whom they have had little direct contact (i.e., fathers; Cernoch and Porter, 1985) underscore the prominence of repetitive exposure, familiarization, and reinforcement in the establishment of early social olfactory recognition. In general, concluding that human newborns can olfactorily recognize individuals seems equivocal as the experiments conducted so far involve odor stimuli stemming from individuals differing in familiarity and/or in genetic relatedness (Schaal, 1988). Thus, the critical experiment for *natural odor*-based recognition of individuals as unique (i.e. opposing individuals that are genetically and experientially equivalent for the tested subject) waits to be carried out in neonates.

The involvement of olfaction in early social discrimination is also attested by evidence that artificial odorants presented in the context of breastfeeding rapidly gain the ability to release approach and appetitive behaviors. Thus, painting an initially neutral odorant on the mother's breast in the first days of life converts it into an attractive one (Schleidt and Genzel, 1990; Delaunay-El Allam et al., 2010). In only three days of such association with nursing can chamomile odor become as (but not more) attractive as the natural odor of mother's milk (Delaunay-El Allam et al., 2006), and only a 5-minute exposure conjointly with tactile stimulation suffices to change a neutral odorant into an attractive one within the first day of life (Sullivan et al., 1991). If one assumes that the processes converting an artificial odorant into a meaningful cue are similar to the natural processes that assign significance to biologically-produced odorants, it is a suitable paradigm to use controllable artificial odorants in social contexts with human infants and children. Such experimental odor "probes" have greatly contributed to highlight how and when odor cues are behaviorally important in nonhuman infants (e.g., Alberts, 1976; Smotherman et al., 1987; Rosenblatt, 1983; see Section 14.4).

While individual recognition based on *natural odor* cues alone remains to be ascertained in human newborns, olfaction may participate in social learning via influences on other sensory modalities. For example, odors can influence the development of visual activity. When exposed to their mother's breast odor, 3-day-old infants (especially boys) display longer periods of eye opening as compared to a similar situation where the nipple-areolar odor is masked (Doucet et al., 2007). Such early intersensory influences reflect that, from the very onset of aerial life, olfaction can be engaged into wider perceptual activity. Thus, breast odor can be instrumental in an ordered searching sequence mobilizing touch and vision to boost nipple grasping; alternatively, breast odor may become rapidly linked with expectancies for postural, tactile, visual, and auditory reinforcements, hence instigating the search for corresponding cues (cf. Schaal and Durand, 2012).

**INDIVIDUAL RECOGNITION?** The importance of odors in early social cognition has been assessed in several ways. One, described above, is to demonstrate discriminative abilities among different social agents. Another is to measure the effects of changing previously encoded odor features of a given conspecific. In altricial rat pups, puppies, or kittens, perturbing maternal odor can induce distress as if the mother was not present or recognized (Rosenblatt, 1983; Blass, 1990). Similarly, applying strong artificial odorants on their mother's nipple releases aversion and crying in human neonates (Kroner, 1882; Preyer, 1884); masking the natural breast odor reduces their willingness to orally grasp the nipple (Doucet et al., 2007). But beyond the breast, altering the whole mother's body odor has been used to show how critical odor cues are shaping the global "representation" of the mother. When squirrel monkey mothers (genus *Saimiri*) were sprayed with an artificial odorant, their 1–5-month-old infants did not show the typical visual preference for their mother relative to a control female (Redican and Kaplan, 1978). A previous experiment had shown that such infants rely more on olfactory than visual properties of the (anaesthetized) mother (Kaplan et al., 1977). Thus, sensorily precocial *Saimiri* infants concurrently monitor the olfactory and visual features of conspecifics (or their substitutes).

Human infants also monitor odor cues in their multisensory environment (Schaal and Durand, 2012). For example, 4-month-old infants rapidly relate to an object with a distinctive odor (Fernandez and Bahrick, 1994). Such abilities may shape the recognition of social partners. A recent study in 4-month-olds showed that the mother's body odor influenced the infant's visual exploration of faces: in presence of their mother's odor, infants' preference for faces is enhanced and the eye region is fixated longer than other facial regions (Durand et al., 2013). Thus, a faint odor can make a difference in the way infants look at a face, presumably easing the encoding of individual-specific facial cues.

At later ages, when children can reliably point out or name their choices, evidence that body odors can be recognized as belonging to individuals should become clearer, although current data remain inconsistent. For example, using a two-choice procedure between t-shirts worn by their mother or an unfamiliar woman, 45 to 58-month-old children were each given 15 to 37 trials (Schaal et al., 1980). Among the 26 children tested, 18 chose the mother's t-shirt in >60% of the trials, but statistically significant differences were observed in only eight cases. It is not known whether such variability in toddlers' recognition of mothers' body odor pertains to maternal factors (quality or intensity of body odor), child factors (odor sensitivity, attention) or both (maternal proximity, quality of attachment). However, 3–8-year-olds of either gender are able to distinguish the t-shirts of their own

full siblings from those of unrelated age mates (Porter and Moore, 1981), indicating that they can determine familiarity and/or relatedness using odor cues produced by adults or prepubertal age mates. In a novel study, Weisfeld et al. (2003) tested the ability of 4–11-year-old children in remarried families to recognize the odor of siblings differing in coefficient of consanguinity [i.e. full (0.5), half- (0.25), and stepsiblings (0)]. The children were able to identify the odors of their full siblings, but not of their half- and stepsiblings, a result interpreted as reflecting a strong genetic influence on the production and perception of body odors. However, this differential response could reflect the generally less positive affective ties between half siblings and step siblings than between full siblings (Weisfeld et al., 2003), suggesting that the level of relatedness could be confounded by the frequency of exposure to body odors and, hence, with familiarity. A further test in that same study assessed whether 6–15-year-old children from stable families comprising at least two children could olfactorily recognize a t-shirt worn by their mother, father, or sibling(s) (relative to a t-shirt worn by an unrelated participant matched in gender and age). On average, (a) children chose their mother's odor at random [but in splitting the group in younger (6–8 years) and older (>9 years) participants, the older expressed correct mother recognition, without gender difference], (b) the father's odor was unambiguously recognized by daughters and sons alike, and (c) children identified their opposite-sex sibling, but not their same-sex sibling. To add complexity to the issue, a recent study investigating odor recognition between all members of stable 2-children families (opposing t-shirts of a person from the target family with t-shirts from matched person from an unfamiliar family) found that the children were inaccurate in identifying their mother, father, or siblings (Ferdenzi et al., 2010). Thus, evidence for true individual recognition does not appear fully conclusive. In two-choice paradigms, it is difficult to establish if an odor characterizes an individual rather than higher level meanings (e.g., familiarity, kin, gender, age, shared environment, etc.) (Weisfeld et al., 2003).

Another source of data germane to odor-based social recognition comes from studies of children who are genetically unrelated and who share only limited environmental circumstances (as in temporarily stable groups that form in schools or youth camps). For example, Verron and Gaultier (1976) asked 4–5-year-old blindfolded children to identify three to five classmates by smelling their neck. While boys were accurate in their recognition responses in 33% of the tests (21/62), girls succeeded in 69% of them (36/52). A similar study on same-age preschoolers showed that 8 out of 18 participants were able to name classmates whose neck they sniffed (Marlier and Schaal, 1989). Girls were more reliable in their odor-based recognition than boys, but in addition the girls *induced* better recognition than boys

from the odor cues of their necks. These studies highlight the fact that children's recognition performance of familiar peers is interindividually variable and doubly biased by the gender of the smeller and by the gender of the donor. In an additional study, 9-year-old children from a same school class were required to recognize the t-shirts of six target odor donors (self and five types of classmates delineated after ranking of socio-affective closeness within the class: same-sex and opposite-sex preferred peers, same-sex least liked peers, and mere acquaintances of same and opposite sex) (Mallet and Schaal, 1998). The tested personal odors reflected the habitual mix of natural and extraneous scents that impregnated t-shirts worn for three nights and one day, and to which classmates were normally exposed while interacting. Each of the six target odor donors was to be recognized among four distractor stimuli. On average, children were unable to accurately categorize their peers' body odors by gender, but the odor donors were individually recognized at a better-than-chance level. Same-sex peers were better identified than opposite-sex peers, with girls scoring higher for same-sex preferred and opposite-sex acquainted peers, and boys scoring lower for opposite-sex acquaintances. This study was confounded by the participants' cultural ecology, as their usual hygienic practices were not altered during the impregnation of the t-shirts. Personal odors are indeed the emergent result from mingling endogenous and extraneous compounds which create "culturalized" odor signatures that potentiate the communicative value of the natural odor signature (Milinski and Wedekind, 2001; Lenochova et al., 2012). Both natural and artificial "fractions" of olfactory signatures are accurately recognizable to children, as shown by the recognition of a t-shirt of an unrelated friend presented among four distractor t-shirts by adolescents (Olsson et al., 2006), gender assignation dependent on the "perfumedness" of body odor (Mallet and Schaal, 1998), and the ability of young children to identify their mother's perfume (Durand and Schaal, 2011).

**SOCIAL PREFERENCES** During development, odor-based preferences fluctuate until a time when they come to more or less overlap with those of adults of their community. This socialization of the hedonics of body odors may be achieved through various experiential processes involving (a) recurrent exposure to the natural odor signatures of conspecifics, as well as to added artificial odorants (perfumes), (b) passive reception of hygienic practices and learning to conform with local norms, (c) acquisition of contamination sensitivity (Rozin et al., 1986) and education of disgust for uncleanliness (Peto, 1936; Stein et al., 1958; Oaten et al., 2009), and (d) neophobia, which is best illustrated in the increased wariness for novel foodstuffs between 2 and 4 years (Cashdan, 1994), but could as well concern social odors (e.g., Stevenson and

Repacholi, 2005). Also, it is a general phenomenon that infants and children unknowingly perceive odors during emotionally-arousing events and label them as negative or positive. Such odors can subsequently re-evoke the affective states and emotional reactions in which they were acquired (Epple and Herz, 1999; Chu, 2008) and can subtly differ in relation to events concerning significant others. For example, in families where parents consume alcohol to cope with dysphoria, 5–10-year-old children dislike alcohol-related odors more than children whose parents usually drink for fun (Mennella and Garcia, 2000; Mennella and Forestell, 2008). Similarly, children whose mothers smoke to alleviate stress dislike the odor of tobacco smoke more than children of mothers who report smoking for other reasons (Forestell and Mennella, 2005). In sum, children can rely on odors not only to recognize individuals, but to differentially label the emotional context in which the individual odors are perceived.

Clearly, the developmental niche frames a child's perceptual abilities as well as normative expectations about self and others' olfactory appearance. When such expectations about personal odors are violated, faulty odor sources or odor-emitting individuals become rapidly consensual as targets of exclusion. For example, in a single case follow-up of a 13-year-old boy, violent stigmatization was reported to be induced by "bad body odors" (Todd, 1979); subsequently, this child was diagnosed defective in trimethylamine metabolism and treated with a choline-poor diet which alleviated the olfactory signature and resulted in satisfactory social integration a year later.

The most obvious way to develop selective responses to body odors would be through positive imprinting (as opposed to "negative imprinting" processes outlined below). That is, adolescents and young adults would be more attracted to odor profiles associated with the mother (caregiver) in early development or to individuals emitting elements of the parental odor phenotype. Numerous studies in nonhuman mammals have shown that infantile learning of odors in association with the mother can have long-term consequences in that they can positively influence mate choice and sexual performance. Although some studies indicate assortative mate preference and selection based on visual appearance of facial traits in humans (reviewed in Rantala and Marcinkowska, 2010), to our knowledge no such studies have been undertaken in the domain of olfaction (see below Section 14.4).

Such a framing of social odor preferences by the practices and values of local cultures was also suggested to be underlain by several kinds of more general mechanisms. First, parent-offspring interactions were conjectured to be influenced between two and five years by the oedipal process, which, according to Freud (1905–1962), is actualized by children's attraction to the opposite-sex parent and relative avoidance from the same-sex parent (Buss,

2008). Based on clinical material involving olfaction, Bieber (1959; Bieber et al., 1992) predicted an odor-based mechanism of avoidance and attraction in the family triad, between young children and their same-sex and opposite-sex parents, respectively. This point was followed up in a single case who displayed contrasting responses to each parent (Kalogerakis, 1972). Between 2.5 and 4 years of age, this boy reacted acutely to the body odors of both parents, with increasing differentiation in attraction to the mother and rejection of the father; when the mother induced occasional rejection by the child, it could be traced to the fact that her body or garments occasionally conveyed paternal odor cues. Although such casual observations have the rare merit of indicating that children as young as 2.5 years can detect and react to deviations from baseline body odor in adults, they all stem from Freudian proponents. When similar work was repeated in keeping on alternative theoretical options, it was concluded that the oedipal family situation has no empirical support (e.g., Goldman and Goldman, 1982; Daly and Wilson, 1990). A more parsimonious interpretation would be that children react more negatively to male body odors, just as adult raters who report male axillary or oral odors as clearly more intense and unpleasant than those of females (Doty, 1981; Schleidt and Hold, 1982).

Evolved odor-based processes have been proposed in a second domain of parent-offspring and between-sibling relations: the circumvention of incest. Mechanisms to prevent sexual interaction between offspring and parents operate in nonhuman primates, despite enduring affinitive bonds (Silverman and Bevc, 2005). In our own species, the primary way of incest avoidance appears to be “behavioral avoidance toward those with whom the individual has shared continuous early association” (Silverman and Bevc, 2005: 300), a mechanism of sexual uninterest triggered by physical proximity during the first five years of life and the so-called “Westermarck effect” (Westermarck, 1891). It has been repeatedly suggested that some olfactory mechanism might produce aversions during an early sensitive period. Some have predicted that such aversions, directed towards individuals rather their scent alone, will arise when adult-like sexual interests emerge and will be more potent among females (Schneider and Hendrix, 2000). Laboratory tests have sought to assess whether odor cues could mediate aversion for the opposite-sex parent and siblings in human children. Weisfeld et al. (2003) assessed preferences of each of 6–15-year-old children for the odors of t-shirts worn by their mother, father, and siblings. Each was paired with reference t-shirts from unrelated matched individuals. Overall, children expressed less preference for parents’ odor than for the reference odors (with mutual aversion between father and daughter) and sisters tended to avoid their brother’s odor. Mothers also expressed less preference for their children’s odor than for the reference

children’s odor. Interestingly, these responses raise the issue of whether or not the odor donor was recognized. Ferdenzi et al. (2010), adopting a procedure where the father’s and mother’s body odors were directly compared, showed that 7–18-year-old girls judged their father’s odor (without explicit recognition of him) as more intense, more masculine, and more unpleasant, than did boys. In contrast, no differential hedonic rating occurred for mothers and siblings. In addition, the younger, prepubertal children of either gender (aged 7–10 years) rated their father’s and sibling’s odor as less pleasant than did the pubertal and post-pubertal children. Thus, an indication of an odor-mediated aversion towards the opposite-sex parent is suggested in girls, corroborating one of Schneider and Hendrix’s predictions and Weisfeld et al.’s results above, but no clear pattern emerged in boys toward mothers’ odor.

These initial assessments of potential odor processes underlying the Westermarck effect need further documentation both in humans and nonhuman primates. The processes involved may be secondary to puberty-related perceptual changes co-occurring along with changes in chemo-emission. During the pubertal transition, children’s negative reactivity to androstenes in axillary sweat does indeed increase sharply, especially in girls (Dorries et al., 1989). At the same time, adolescents and adults express stronger aversion to the odor of t-shirts worn by unfamiliar young adults than do prepubertal (8-year-old) children (Stevenson and Repacholi, 2003). Otherwise, the negative valuation of male axillary odor by females fluctuates with the menstrual cycle, so that during the fertile phase they express less rejection (Moshkin et al., 2011). Thus, before and during adolescence, body odors from adult persons can come to evoke intense dislike, but intra-individual perceptual variations occurring after puberty may temporarily attenuate such repulsion. Clearly, the issue of olfactory influences on affectionate behavior and attitudes within families and among kin awaits more investigation.

#### **14.4 EARLY ODOR ACQUISITIONS PERSIST LATER IN THE CHILD AND ADULT**

Infantile olfactory memory has been examined in relation to (a) social and sexual preferences, (b) food preferences, and (c) fearful situations or stimuli. In dogs, for example, puppies learn the individual odor of the bitch, and after two years of total separation remain capable of recognizing it (Hepper, 1994). In Asian elephants, male calves that are separated from their mother for husbandry reasons can retain chemosensory information carried in maternal urine for 2 to 27 years (Rasmussen, 1995). Thus, early odor learning favors long-term recognition of individuals and kin.

Such an odor-based imprinting-like process has been analyzed in more detail in rodents. A pioneering

experiment consisted in treating rat dams and pups with cologne during the first postnatal month. In adult tests, the cologne-exposed rats were less sexually competent than the controls when exposed with a normal-odor partner (Marr and Gardner, 1965). A similar result was reached by Mainardi et al. (1965) who tested female mice whose nursing mothers were scented with violet odor. When sexually mature, these young females preferred males carrying this odor, while females nursed by olfactory-intact dams preferred normal-odor males (an effect not found in male mice). However, in rats, experiencing a given artificial odor in association with suckling modified the adult males' reactivity towards a receptive female carrying the same odor (in reducing ejaculation latency; Fillion and Blass, 1986). This effect was specific to the odor-nursing association, as an odor applied to the back of the nursing female did not alter adult sexual behavior. Further, when rodent pups were fostered to females of a different species, they showed more attraction to the odors of the foster species than do control animals, and such preferences continued into adulthood (Huck and Banks, 1980; Quadagno and Banks, 1970). Nursing-related odor learning also affects the behavior of females. For example, rat pups reared by a scented mother later, as adults, displayed increased body contact with, and licking of, pups carrying the same odor (although their latency to express maternal care was longer with the scented pups as compared with the control pups)(Shah et al., 2002). This phenomenon is not restricted to rodent species, as it occurs in ungulates as well (Müller-Schwarze and Müller-Schwarze 1971).

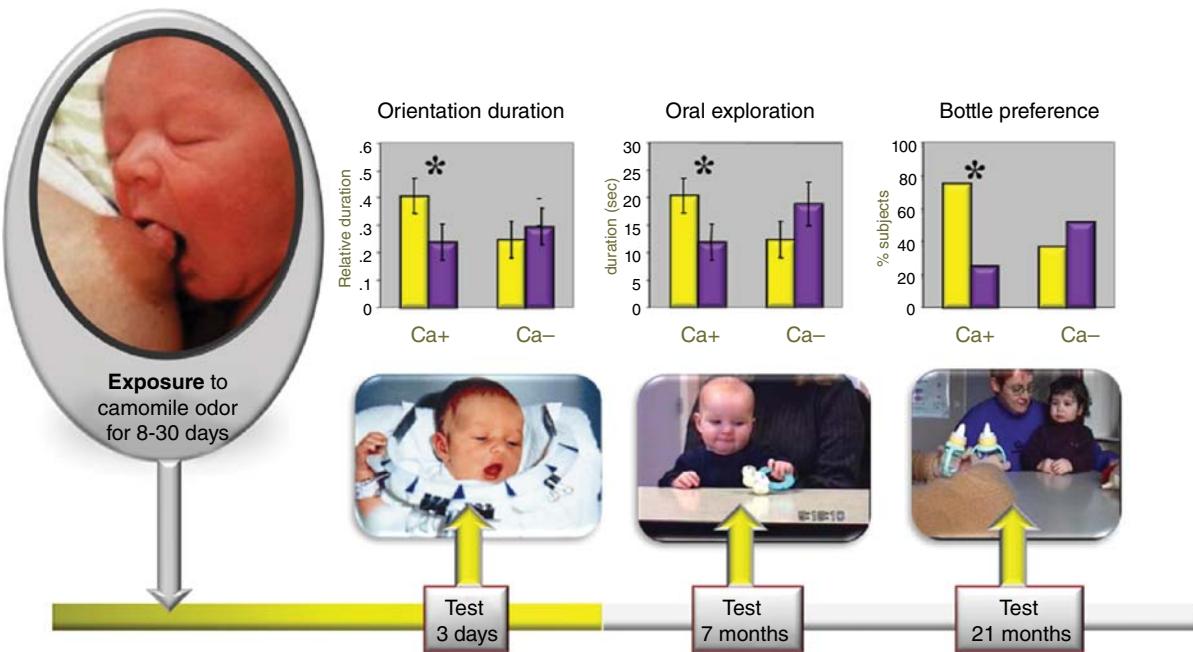

Clearly, early odor experience mediates adult recognition of individuality, familiarity, or kinship in various mammals, but the source and nature of the involved odorants and how information about kinship is olfactorily encoded are poorly understood. In rodents, relatedness assessment between individuals may depend on odor cues that are correlated with the major histocompatibility complex (MHC). Related individuals share similar MHC and similar odor properties, so that MHC-derived odor cues could function as an index of kinship. Mice and rats do indeed discriminate by odors among conspecifics whose genotypes only differ within MHC (Brown et al., 1987). Male mice of at least some inbred strains prefer females whose MHC differs from their own (Yamazaki et al., 1976). Such preferences for non-self MHC appear to result from early familial "imprinting." Males that had been raised until weaning by foster parents with a different MHC mated preferentially with females that shared their own MHC rather than that of their parents (Yamazaki et al., 1988, 2000; Penn and Potts, 1998). These males therefore avoided mating with females whose olfactory phenotype resembled the odor of the foster parent. In subsequent experiments with other inbred strains of mice, the effect of the rearing environment on MHC-based preferences was

greater for females than for males (Arcaro and Eklund, 1999). These results were generalized to semi-natural conditions in which early familial odor imprinting also appeared to account for the avoidance of males with wild-type females carrying the foster parent MHC genotype (Penn and Potts, 1998). Thus, in these rodents, an early olfactory imprint with MHC-based odorants can have long-term effects on choice of potential mates, either by avoiding inbreeding with mates sharing familial MHC chemosignals or by selecting mates bearing slightly different MHC genotypes.

Whether similar natural imprinting mechanisms operate in other species, including primates and humans, has begun to be addressed (Ruff et al., 2012). Humans also appear to be olfactorily sensitive to HLA<sup>4</sup>-correlated odor cues (Wedekind and Füri, 1997; Wedekind et al., 1995; reviewed in Havlicek and Roberts, 2009), but virtually nothing is known about the developmental course of this perceptual ability. In one experiment, Jacob et al. (2002) asked young women to rate the t-shirts of six male donors. The participating smellers, the donors and the smellers' parents were previously HLA-typed and characterized for the number of allelic matches. The participants expressed a preference for the odor of men bearing an intermediate level of dissimilarity (not those who had no or all alleles in common) and they preferred men who shared HLA alleles with their own fathers (but not with their mothers). A logical deduction would be, if fathers' HLA-type correlates with body odor cues, that adult females are more attracted to a male odor when it conveys some cues in common with their own father. But this possibility, which would run against the Westermarck effect outlined above, needs to be investigated properly before any conclusion can be made.

In both humans and nonhuman mammals long-term effects of early odor experience can further alter ingestive behaviors. Early breast or bottle feeding can affect subsequent odor or flavor preferences. Infants who have been nursed at a breast scented with chamomile during the first postnatal weeks are more attracted by a chamomile scented toy at 7 months of age, and, when re-tested 21 months later, choose to suck from a chamomile-scented bottle over a violet-scented bottle (Delaunay-El Allam et al., 2010; cf. Figure 14.7). Another element in favor of persistent effects of early experience in milk comes from a study showing that 6–13-month-old infants reacted differently to toys scented with ethanol or vanilla as compared to an unscented toy (Mennella and Beauchamp, 1998b). These authors hypothesized that the infants may have become familiar with these odors or flavors in the home, conceivably through mother's milk or breath odors. Such exposure effects appear heterogeneous during development, suggesting that early infancy constitutes a particularly sensitive

<sup>4</sup>The human MHC is named Human Leucocyte Antigen (HLA).

**Figure 14.7** Odor experience during breastfeeding and subsequent preferences for the exposed odorant in different contexts. Infants were first exposed to chamomile odor applied directly on the areola and nipple for 8 to 30 days after delivery. They were then tested for differential responses to the chamomile odor when they were aged 3 days, and 7 and 21 months. The chamomile-exposed participants (Ca+) were compared to same-age participants who were never exposed to chamomile (Ca-). The **3-day test** consisted in a double-choice test opposing chamomile odor and a scented control stimulus; it showed that infants of the Ca+ group, but not of the Ca- group, were attracted to the chamomile odor (Delaunay-El Allam et al., 2006). The **7-month test** consisted in presenting sequentially, in counterbalanced order, same objects odorized with chamomile or violet. The Ca+ group displayed longer mouthing of the object scented chamomile than of the object scented violet, while the Ca- infants did not express a differential response (Delaunay-El Allam et al., 2010). The **21-month test** consisted in presenting the infants two bottles scented chamomile or violet, in counterbalanced order, and asking them to choose the one they would like to suck. While the Ca+ group prevalently chose the chamomile-scented over the violet-scented bottle, the Ca- group did not respond differentially (Delaunay-El Allam et al., 2010). (\*p<0.05, \*\*p<0.01).

period for chemosensory learning in humans (Beauchamp and Mennella, 1998; Mennella and Castor, 2012).

Odors acquired *in utero* can be more, or at least equally, preferred postpartum than artificial odors subsequently associated with nursing. This effect has been demonstrated in the rat during the preweaning period (e.g., Hepper, 1988; Chotro and Molina, 1990) and even as adults (Smotherman, 1982). In the rabbit, a prenatally acquired odor can release as many appetitive and consummatory responses at weaning as odors present during suckling or first solid food ingestion (e.g., Bilko et al., 1994; Hudson et al., 1999). In humans, infants of mothers who consumed carrot flavor during the last weeks of gestation more easily accept carrot-flavored cereals five months later (Mennella et al., 2001). Further, 8–9-year-old offspring of mothers who ingested garlic during pregnancy ate more of a garlic-flavored meal than did children born to mothers who did not do so (Hepper et al., 2012b).

Odor aversions or preferences encoded during infancy and childhood can last until adulthood. For example, childhood food aversions can persist for over 50 years (Garb

and Stunkart, 1974). Among respondents aged 13–20, 12% traced their aversion to the 0–5 years' period, 58% to the 6–12 years' period, and 30% to the 13–20 years' period (see also Batsell et al., 2002). One study took advantage of a legal change in the flavoring of infant milk formula, which was prohibited in 1992 because of rising food allergies. Infants who were either breast- or bottle-fed before and after 1992 were considered massively or minimally exposed to vanilla, respectively. A determination was made of the relative preferences of subjects (mean age of 28, range 12–59 years) for a standard ketchup and a ketchup with slight vanilla flavor (Haller et al., 1999). While the early breast-fed participants preferred the normal ketchup to the vanilla-flavored ketchup (70.9 vs. 29.1%), those who were exposed to vanilla through formula-feeding responded the other way round (40 vs. 60%). Although this approach did not account for exposure to vanilla since weaning, it does underscore the fact that infantile memory for odors and flavors remains accessible and is sufficient to orient subsequent ingestive decisions in both juveniles and adults. A more recent study compared perceptual and

brain responses to the odors of mint and rose in adults who grew up either with parents who emigrated from Algeria to France (Algerian-French, AF) or with parents from French, German, British, or Spanish origins (European-French, EF) (Poncelet et al., 2010). On average, the AF group was exposed earlier and more often to mint odor/flavor in childhood than the EF group, expressed stronger preference for mint odor over rose odor (while the EF group showed no preference), and recollected more vivid childhood events after inhaling mint. These differences were linked with chemosensory evoked response potentials indicating differences in the brain processing speed presumably due to disparities in attention-evoking and emotional memory retrieval as a function early experience.

## Olfactory Memory

**THERESA L. WHITE, PER MØLLER, E. P. KÖSTER, HOWARD EICHENBAUM,  
and CHRISTIANE LINSTER**

### 15.1 INTRODUCTION

Olfactory memory plays an important role in the everyday lives of both animals and humans, even if people generally attend much less than animals to incoming olfactory information. Each of the three main functions of olfaction outlined by Stevenson (2010) would be impossible without odor memory: ingestive behaviors (e.g., food detection, flavor determination, breast finding), avoiding environmental hazards (e.g., fear related, disgust related), and social communication (e.g., reproductive behaviors, emotional contagion, territorial demarcation). Whether trying to remember whether the fruit of a tree is edible or toxic, or trying to determine friend from foe, the past experiences accessed through olfactory memory are critical in making the decision.

The phrase “odor memory” generally has two meanings. The first meaning reflects “odor-evoked memory”. Most of us are familiar with “Proustian effects” (Proust, 1928), or the ability of odor memory to evoke rich recollections of times and events gone by (Chu and Downes, 2000; 2002; Willander and Larsson, 2006; 2007; 2008; Herz and Schooler, 2002). Although these effects emphasize the episodic nature of olfactory memory, the memories in question are multi-sensorial, making them odor-evoked memories (Herz, 2012; Herz and Cupchik, 1992; 1995). This meaning of odor memory also illustrates the way that odors are associated with a variety of other stimuli through experiences and learning (Wilson and Stevenson, 2006). The second meaning of “odor memory” concerns the way that the odors themselves are remembered and recognized at a later time. Historically, the study of this

type of odor memory has been dominated by tasks that have their counterparts in the study of vision, such as discrimination, recognition and identification (e.g., Engen and Ross, 1973; Mozell, 1972; Goldman and Seaman, 1992; Jehl et al., 1994). These studies have led to some theories related to this meaning of odor memory that place odor semantics into prominence by invoking “odor objects” (Wilson and Stevenson, 2006), a form of internal representation that can be changed by such processes as odor-odor and odor-taste learning. Thus, from this theoretical viewpoint, recognition and identification of the “odor object” seem to be the most important tasks of olfactory learning and memory. Other theoretical views concerning the way that odors are remembered have emphasized the implicit and episodic nature of olfactory cognition (e.g., Zucco, 2003), and question the role of odor percept recollection in everyday memory use (Köster, 2005).

Rather than attempting to dissociate theoretical viewpoints, this chapter focuses on recognition memory and learning paradigms useful in characterizing the olfactory memory system. Since the basic anatomy and physiology of the olfactory system is well known and is described in great detail elsewhere in this volume (Chapters 1–10), only brief mention of anatomical structures critical for odor memory is made in the sections that follow. Among the brain regions most critical for odor memory are the hippocampus and the piriform, entorhinal, and orbitofrontal cortices, each of which seems to contribute to different memory-related functional properties (Eichenbaum, 1997; Petrus and Eichenbaum, 2003a; Gottfried, 2010).

## 15.2 RECOGNITION MEMORY

Adaptive behavior is characterized by the ability to remember information over both short and long time intervals. Although some memory systems (such as the verbal system) allow humans to reproduce a stimulus in order to indicate memory via recall (i.e., to repeat the to-be-remembered word out loud), demonstration of olfactory memory is generally restricted to recognition paradigms.

### 15.2.1 Short-term Memory

At intensities that are above threshold, a normal sense of smell enables many animals to easily distinguish the scent of two different odorants from one another, such as the odor of a strawberry from that of a lemon, even when the odorants are sniffed sequentially. This simple discrimination task requires the activation of a temporary internal representation of each odorant, and shifting attention toward different parts of each of the representations so that they can be compared, all the while keeping readily available the parts of the representations outside of the current attentional focus. Essentially this is a task that requires a short-term or working memory, a type of memory that is critical to the performance of any sort of olfactory comparison (White, 2012). Working memory is generally regarded as a type of memory that is responsible for the temporary maintenance and manipulation of information (e.g., Baddeley and Hitch, 1974). Such memory is possible because olfactory information, like visual or verbal information, can be maintained in a temporary memory state (White, 1998; White et al., 1998; Andrade and Donaldson, 2007; Zelano et al., 2009; Jönsson et al., 2011). Brain activation continues after the termination of the presentation of an odorant (Rolls et al., 2008), and the location of that activity seems to differ, depending on whether the odorant can be easily named. Odorants that are not easily named are most strongly associated with activity in primary olfactory (piriform) cortex, while odorants that have been verbally re-coded are more strongly associated with activity in other areas (Zelano et al., 2009).

**15.2.1.1 Habituation/Discrimination.** Habituation is one of the simplest forms of memory, seen in most animals and sensory systems (Castellucci et al., 1970; Ezzeddine and Glanzman, 2003; Kandel, 2001), including olfaction. Olfactory stimuli can elicit a variety of responses which decrease as a result of repeated stimulation over time. Such responses range from autonomic reflexes to behavioral arousal and investigation. Two primary behavioral paradigms have been used to study odor habituation in mammals: odor-evoked heart-rate reflex and active investigation of odorants.

The simplest, both in terms of underlying neural circuitry and interpretation, is the odor-evoked heart-rate orienting reflex. Novel sensory stimuli evoke a bradycardia reflex, which habituates with repeated stimulation (McDonald et al., 1964). The second major behavioral paradigm for investigating odor habituation in mammals is monitoring investigation of scented objects (Cleland et al., 2002; Hunter and Murray, 1989). An object scented with a novel odor is presented, and the duration of investigation is monitored and compared with investigation times on subsequent presentations of the same scent. Over repeated trials, investigation times decrease.

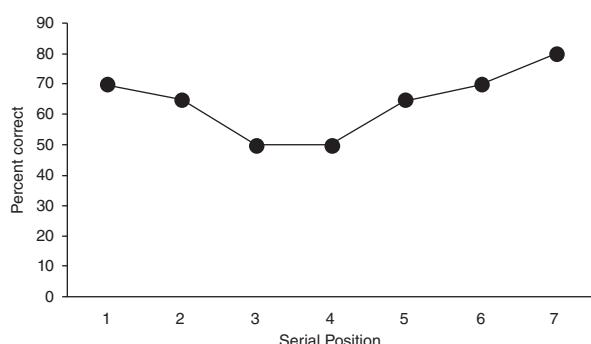

Habituation paradigms can be used to measure the formation of a simple memory, its duration, specificity, and neural correlates (Wilson and Linster, 2008). For example, after habituation to a specific stimulus, responses to novel stimuli can indicate how well an animal discriminates between the two stimuli (Cleland et al., 2002). Presentation of a habituated stimulus after varying time intervals also provides a means for testing the duration of memory. In rodents, habituation memory and specificity have been shown to be altered by such task demands as retention intervals (McNamara et al., 2008), as well as by such neuromodulators as acetylcholine and norepinephrine (Mandairon et al., 2006; Mandairon et al., 2008). Habituation paradigms are also commonly used to study species-specific communication such as recognition among males or females, discrimination between individuals, and scent marking (Petrulis, 2009; Petrulis et al., 2005).

Although olfactory sensory neurons can adapt to repeated or prolonged odor stimulation, behavioral odor habituation is a central phenomenon. As is the case in other sensory systems, central olfactory neurons show greater response decrement than peripheral receptors, with piriform cortical neurons showing rapid, nearly complete response adaptation within seconds or minutes of stimulation in both rodents (Wilson, 1998a; b) and humans (Sobel et al., 2000). Simultaneous recordings of second-order mitral cells and their target piriform cortical pyramidal cells have shown that the cortical neurons adapt to repeated or prolonged odor stimulation more rapidly and completely than their afferent mitral cells (Wilson, 1998a). Mitral cells do adapt to odors (Chaudhury et al., 2010); however, adaptation of their downstream targets is frequently fast and relatively complete. *In vivo* intracellular recordings have shown that the cortical adaptation is associated with depression of the glutamatergic mitral-pyramidal cell synapse and that this synaptic depression recovers with the same time course as the short-term adaptation of odor-evoked postsynaptic potentials (Wilson, 1998a). This short-term depression is mediated by group III metabotropic glutamate receptors. In addition to the short-term habituation described above, extended and/or spaced odor exposure

can lead to long-term habituation. In humans exposed daily to odors in the home or workplace, habituation to the exposed odor (elevated detection threshold) can last weeks (Dalton and Wysocki, 1996). Electrophysiological recordings in rats using the same stimulus paradigm used in behavioral studies showed that olfactory bulb mitral cells decrease their response to odor stimulation applied with 5-minute intertrial intervals and that this response decrease is dependent on functioning NMDA receptors in the OB (Chaudhury et al., 2010).

While the neural correlates of olfactory habituation in mice and rats are thought to be in olfactory bulb and cortex, habituation paradigms studying species-specific interactions in hamsters have located cellular correlates to higher structures such as entorinal cortex, frontal cortex, and amygdala (Maras and Petrusis, 2008; Petrusis et al., 2005; Petrusis et al., 1998; Petrusis and Eichenbaum, 2003b). It is most likely that, as in other memory functions, the formation of habituation memory is widely distributed across brain areas and depends on the types of olfactory stimuli used as well as on the behavioral relevance of these stimuli.

**15.2.1.2 Serial Memory.** As with many types of non-olfactory stimuli, memory for a series of odors is typically characterized in both humans and animals by a tendency to remember the beginning (primacy) and ending (recency) of the series better than the odorants in the middle (see Figure 15.1). Serial position effects offer an additional opportunity to examine olfactory working memory, as the recency portion of the curve is often associated with short-term memory (Jonides et al., 2008). However, in stark contrast to verbal and visual memory, the effects of serial position are not always observed in olfactory memory (Lawless and Cain, 1975; Gabassi and Zanuttini, 1983;

**Figure 15.1** Typical serial position curves, illustrating primacy and recency effects. Memory for the first few items constitutes the primacy portion of the curve, while memory for the last few items indicates effects of recency. The shape of the curve varies considerably for studies that require remembering odors in a series.

Johnson and Miles, 2009). When serial position effects are observed, reports of the shape of the curve vary considerably across experiments (e.g., White and Treisman, 1997; Reed, 2000; Miles and Hodder, 2005). For example, although primacy is occasionally observed (e.g., Reed, 2000), the more common finding is a curve characterized by recency only (Deacon and Rawlins, 1995; Miles and Hodder, 2005; Johnson and Miles, 2009; Fortin et al., 2002; Miles and Jenkins, 2000; White and Treisman, 1997). The memory for odorants in a series appears to be dependent on the hippocampal and medial prefrontal brain regions (Fortin et al., 2002; DeVito and Eichenbaum, 2011), although the ability to remember individual odors seems to be dependent on the parahippocampal region (Otto and Eichenbaum, 1992; Petrusis and Eichenbaum, 2000).

**15.2.1.3 Interference.** In other sensory systems, short-term memory stores are conceptualized as having limited capacity. If such were the case for olfaction, incoming information should interfere with information currently residing in the temporary storage center (thus producing the characteristic “recency” portion of the serial position curve). Such retroactive interference has been observed, in which the presentation of a new odor interferes with memory for a previously presented odorant (Walk and Johns, 1984; Miles and Jenkins, 2000; Thor and Holloway, 1982; Rochefort et al., 2002). Additionally, attempts by people to perform a concurrent olfactory task impair olfactory memory performance (Andrade and Donaldson, 2007), thus demonstrating retroactive interference. Although both proactive and retroactive interference have been demonstrated with olfactory stimuli, interference in olfactory memory is not a consistently observed phenomenon. Several studies have presented results that did not show any decrements in performance due to interference (Zucco, 2003; Schab and Crowder, 1995) and some show only proactive interference (Lawless and Engen, 1977) or interference only when explicit memory is tested (Stevenson et al., 2005).

**15.2.1.4 Delayed Match and Non-match to Sample Tasks.** The delayed non-match-to-sample task (DNMS) is a common and effective method of non-verbally evaluating olfactory recognition performance (Gaffan, 1974; Mishkin, 1978). This task consists of three phases: a sample phase where subjects are rewarded for investigating a novel object, a delay phase where the memory is retained, and a test phase, where the subject is rewarded for selecting a novel (non-matching) object over a familiar one (e.g., Eichenbaum et al., 2000). A variant of this task is the delayed match-to-sample which involves rewarding the animal for selecting the familiar object in both the sample and test phases (DMS; e.g., Yeshurun et al.,

2008). In both cases, the subject must remember the odor that has been previously presented over a delay interval that is sometimes brief (Otto and Eichenbaum, 1992) and sometimes extended (Ramus et al., 2007), thereby demonstrating declarative and episodic memory for that odorant (Suzuki and Eichenbaum, 2000).

The DNMS or DMS technique has been used to evaluate olfactory memory performance in a variety of animal models, including rats (e.g., Otto and Eichenbaum, 1992), monkeys (Gaffan, 1974), and humans (Kesslak et al., 1991; Yeshurun et al., 2008). Most species show increased forgetting when the size of the delay phase is increased (Koger and Mair, 1994; Otto and Eichenbaum, 1992), and when the same stimuli appear more frequently (Koger and Mair, 1994; Otto and Eichenbaum, 1992). Acquisition of this task is dependent upon an intact orbitofrontal cortex (Otto and Eichenbaum, 1992), but performance seems related to medial temporal lobe activity (Suzuki and Eichenbaum, 2000), particularly activity within the perirhinal and lateral entorhinal areas (Eichenbaum et al., 2007).

### 15.2.2 Long-term Memory

Long-term memory refers to representations of the past that have been stored for an extended period of time, and, in many models of memory, is theorized to be separate and distinct from working memory (e.g., Baddeley and Hitch, 1974). Some alternative theories of memory suggest a unitary memory store (e.g., Ranganath and Blumenfeld, 2005; Stevenson and Boakes, 2003) that is based entirely on activation of long-term processes. In these models, reliance on long-term processes suggests that the ability to perceive odors is dependent upon olfactory experience or knowledge (Rabin, 1988; Wilson and Stevenson, 2006).

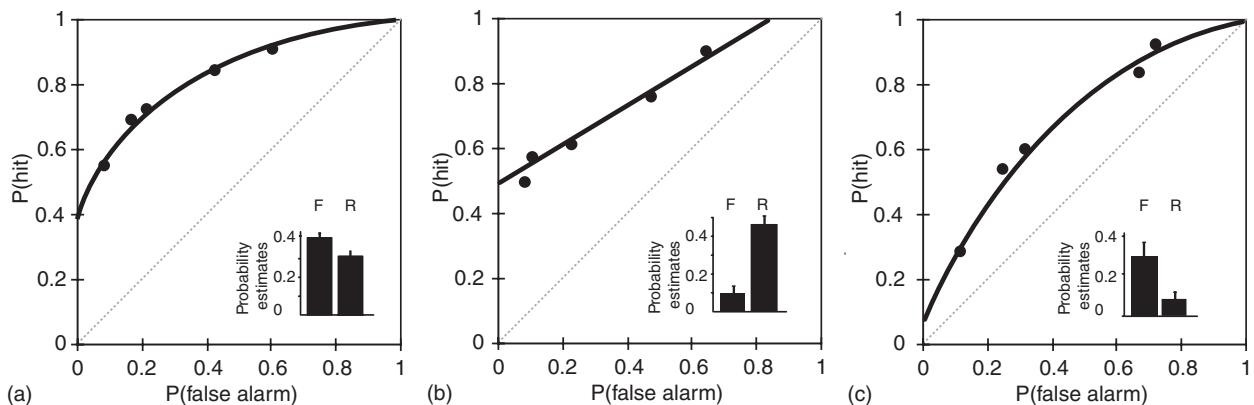

**15.2.2.1 Explicit Memory.** Explicit or declarative memory refers to consciously available memories. Explicit memory is a complex function, which relies on many areas of the brain. Imaging studies in humans, as well as lesion studies in animals, show activation in the prefrontal cortex and the amygdala, hippocampus, and rhinal cortices in the temporal lobe (Zola-Morgan and Squire, 1993; Kolb and Whishaw, 2003).

**FORMAL MEMORY TASKS** Formal long-term memory tasks differ across species, but each seems to test memory for the “odor object” over time. Humans are often tested using an item recognition paradigm, while animals are tested with a variety of techniques (Wood et al., 2000; Otto et al., 1991; Ramus et al., 2007), including novel-odor-recognition (White and Youngentob, 2004) and juvenile recognition (which is largely odor dependent) (Thor and Holloway, 1982; Petrusis and Eichenbaum,

2003a), both of which (like the human technique below) require the subject’s recognition of novelty. In both of these latter tasks, odors (or a juvenile) are presented for several minutes to a rodent, followed by a delay of varying length. The rodent is then presented with either the same odor (or juvenile) or a different one, and the amount of inspection time for each is measured. In both of these paradigms, mice are able to remember olfactory information over delays of a day or more (Kogan et al., 2000; White and Youngentob, 2004), though forgetting in rats is found at much shorter delays (on the order of 30 minutes) when juvenile conspecifics serve as the stimuli (Bluthe and Dantzer, 1990).

In the typical experiment on item recognition, human subjects smell a series of odorants and are subsequently tested with another series of odors that includes both the originally presented odors and an equal number of new ones. Participants must distinguish each odor as “old” or “new”. The number of odors in the initial series, as well as the length of delay prior to the recognition test, varies considerably between studies (e.g., Engen and Ross, 1973; Lawless, 1978), yet a reasonably similar overall picture emerges from such studies. Despite poor initial encoding, humans are able to remember a large number of smells over a long period of time. For example, in one study the subjects were able to accurately recognize an average of 70% of a 48 odor set when tested after a period of 30 days (Engen and Ross, 1973). Similarly, an array of 22 odors was recognized to 75% accuracy after 28 days (Lawless and Cain, 1975), and 24 odors were recognized at the 75% level after a 4-month delay (Lawless, 1978). The large number of odors in each set that is retained over long time periods is seemingly independent of set size, indicating a large capacity for olfactory long-term memory.

**FAMILIARITY VS. RECOLLECTION** Recent studies on odor recognition memory have exploited findings from cognitive science and neuroscience that employ signal detection analysis. This approach is based on the widely held view that recognition is supported by two processes: episodic recollection of previously presented stimuli and/or a sense of familiarity for recently experienced stimuli (Yonelinas, 2001). A typical human signal detection investigation of odor memory uses a recognition paradigm, in which people designate odors as “old” or “new”. Receiver operating characteristic (ROC) curves then relate the proportion of “hits” (correct identifications of old items) to that of false alarms (incorrect identifications of new items as “old”) across a range of response criteria, as described below. Performance is then plotted as two dimensional [P(hits) vs P(false alarms)] data points. Memory is reflected where P(hits) > P(false alarms), i.e., in data points that lie above the diagonal of the ROC curve,

**Figure 15.2** ROC analyses of odor recognition memory. Each panel shows ROC function indicating the strength of recollection as the asymmetry of the function and familiarity as the degree of curvilinearity. In addition, normalized probability estimates of recollection (R) and familiarity (F) are compared in insets. (a) item recognition. (b) associative recognition. (c) item recognition with response deadline.

which indicates chance accuracy at different response criteria levels (Figure 15.2).

An example study using an ROC approach to characterize odor recognition memory in rats is provided by Fortin et al. (2004). In this study, the memory cues were composed of a large pool of ordinary household odors (e.g., lemon, thyme) mixed in sand within small plastic cups. A series of 10 stimuli were presented during the study phase, with a bit of sweetened cereal buried in the sand of each cup (Fortin et al., 2004). On each successive stimulus presentation, animals were allowed to dig for that reward. After a 30 minute delay, a series of 20 “target cups” was presented, consisting of a random ordering of 10 old odors (those presented in the sample phase) and 10 new odors taken from the pool. The test phase involved a non-match contingency, such that rats could obtain rewards by digging only in target cups containing new odors. In addition, they could also obtain a reward in an alternate cup in the back of the cage if they refrained from digging in target cups that contained old odors. To manipulate the animal’s bias for responding (or not responding) to target cups, both the height of the target cup and the ratio of reward magnitude in the target cup versus that in the alternate cup were varied. Under these conditions, the rats were more likely to refrain from digging (i.e., identify this item as “old”) in a target cup containing a new odor if they could obtain only a small reward or had to apply more effort (corresponding to a liberal threshold for “old” responses in humans). Conversely, rats were more inclined to dig in a target cup (i.e., identify an odor as “new”) which contained a greater reward or required less effort to acquire (corresponding to a conservative threshold in humans). The possibility that rats can smell the rewards buried in target cups was controlled for by the use of probe trials in which the reward was not present in a cup with a new odor and instead was given only after digging commenced.

Using this protocol, the ROC curve of intact rats contained both an asymmetrical component (above-zero Y-intercept) and a strong curvilinear component (Figure 15.2a). This pattern is remarkably similar to the ROC of humans in verbal recognition performance, and consistent with a combination of recollection-like and familiarity-based components of recognition in animals (see Yonelinas, 2001). To examine whether the recollection (asymmetry) component of the olfactory ROC could be dissociated from the familiarity (curvilinearity) component, an associative recognition paradigm for rats was developed, using stimulus pairs composed of combinations of an odor mixed into one of several digging media (e.g., wood chips, beads, sand) contained in a cup (Sauvage et al., 2008). Each day the animals would initially sample a series of 10 odor-medium pairings, then following a 30 minute delay, had to distinguish re-presentations of the 10 original (old) pairs from 10 rearranged (new) pairings of the same odors and media, using the same non-matching rule and manipulations of bias as in our study on item recognition described above. The resulting ROC function was highly asymmetric, indicating the presence of a strong recollection component (Figure 15.2b). Furthermore, the shape of the ROC was linear, indicating the absence of a significant familiarity component. This pattern is similar to the ROC function of human subjects when they rely selectively on recollection in associative recognition and source memory studies (Yonelinas, 2001).

To examine whether the familiarity (curvilinearity) component of the olfactory ROC can be dissociated from the recollection (symmetry) component, another variant of the protocol was developed to exploit a distinction between the speed of recollection and familiarity as observed in humans (Sauvage et al., 2010). Familiarity was characterized as a perceptually driven, pattern matching process that is completed rapidly, whereas recollection

was characterized as a conceptually driven, organizational process that requires more time. A prediction from dual process theory was tested, that the addition of an early response deadline at the memory test phase would reduce the contribution of the slower recollection process while sparing that of the more rapid familiarity process. Animals were initially trained and tested using the same item recognition task without a response deadline that produces an ROC function that is both asymmetrical and curvilinear, replicating earlier results (Fortin et al., 2004). In this condition, the critical measure was the time to dig in the test cups containing new odors, or to turn away from test cups containing old odors, in order to determine normal response latencies. In subsequent testing, response deadlines that were half of the natural response latencies were invoked, using a cover to prevent digging in the test cup when the deadline arrived. Analysis of the ROC functions showed that, under the response deadline condition, performance was supported by familiarity as reflected by a curvilinear ROC function (Figure 15.2c). However, in striking contrast to the ROC function in the no-deadline condition, recollection did not contribute significantly to recognition performance such that the ROC function became fully symmetrical. Collectively, these findings support the view that familiarity-based responses can be accomplished rapidly whereas recollection based responses are slow, consistent with the dual process model.

### ROLE OF THE HIPPOCAMPUS AND AMYGDALA

The ROC studies described above provide a strong foundation for examining the role of the hippocampus in episodic recollection. In the following studies, the hypothesis was that the hippocampus is selectively involved in recollection and not familiarity, and is also not involved in learning the basic rules of the non-matching task or in sensitivity to manipulations that affect response biases. ROC analyses then should show that rats with isolated hippocampal damage are able to perform the non-matching task and their response biases should not be affected. Furthermore, animals with hippocampal damage should have an intact familiarity (curvilinearity) component of the ROC function but a loss of the recollective (asymmetry) component. These expectations were fully supported in a study showing that rats with localized hippocampal damage have a fully symmetrical and curvilinear ROC function, consistent with the loss of recollection and sparing of familiarity, respectively (Fortin et al., 2004). The conclusion that the hippocampus is selectively involved in episodic recollection but not in familiarity was further confirmed by observations that, in the associative recognition variant of the task, familiarity is enhanced in the absence of normal hippocampal function (Sauvage et al., 2008). As described above, the ROC function of normal rats in associative recognition was strongly asymmetrical

and linear, consistent with strong recollection and absence of familiarity, respectively. Animals with hippocampal damage suffered a significant decrease in the asymmetry of the ROC, indicating a deficit in recollection. Furthermore, after damage to the hippocampus, the shape of the ROC function became curvilinear, consistent with enhanced and compensatory use of familiarity. The double-dissociation between reduced recollection and enhanced familiarity is entirely consistent with the hypothesis that the hippocampus plays a selective role in recollection and in its absence performance is supported by familiarity.

An additional study examined the role of the amygdala in odor recognition memory using the signal detection approach. The amygdala is connected to the perirhinal cortex and hippocampus, so it might influence the role of either area in recognition memory. However, the connection to perirhinal cortex is exceptionally robust, suggesting that the amygdala might differentially contribute to perirhinal familiarity representations by supporting an increased attractiveness of the study stimuli associated with recent “mere exposure” and rewards. Consistent with these expectations, bilateral lesions of the amygdala resulted in a decrease in the curvilinearity of the ROC function, consistent with a loss of odor familiarity, without a significant change in the ROC symmetry, consistent with no effect on recollection (Farovik et al., 2011). Combined with the findings on hippocampal damage, these studies reveal a double-dissociation between critical contributions of the hippocampus in odor recollection and of the amygdala in odor familiarity.

**15.2.2.2 Implicit Memory.** Implicit memory is a form of memory in which previous experiences influence later behavior without awareness of these previous experiences. In everyday life, it may be the most important form of odor memory. We encounter smells of our surroundings on a daily basis. Each room, each part of the garden, and even each person, has a different smell. Yet we seldom notice smells consciously and, if we do so, it is either because we are surprised by a smell or because we intentionally sniff to verify the safety and/or the pleasantness of our surroundings. In everyday life, conscious olfactory perception seems to be a form of “perception by exception” that occurs spontaneously only when the inhaled air or odor does not fit expectations. This means that odor memory plays a very special role in olfactory perception: it helps people not to notice the well-known odors in the surroundings, thus increasing the likelihood that novel stimuli will be detected.

**NOVELTY AND CHANGE DETECTION RATHER THAN RECOLLECTION** One technique for studying implicit memory for odors in people is repetition priming

(Olsson and Cain, 1995; Olsson, 1999; Olsson and Friden, 2001), which compares the reaction time for the identification of previously presented odors to that of new odors. Response latencies of the previously presented odors that later were identified (or named) by the participant were longer than the latencies of previously presented odors by controls, while the reverse was true for the unidentified odors (Olsson, 1999). Thus, in this technique, semantic knowledge about the odor, such as its name, seemed to hamper implicit memory rather than help it, suggesting that olfactory memory may be more designed for change detection than labeling. This finding has also been demonstrated in studies that used a different technique for examining implicit memory in which incidentally learned associations were formed between odors and the rooms in which they were unconsciously perceived (Degel and Köster, 1999; Degel et al., 2001).

Additional support for the idea that, at least in olfaction, novelty or change detection is more important than recollection has also been obtained in experiments on olfactory same-different detection (Møller et al., 2012). In two experiments, it was shown that in olfaction “different” decisions were made more quickly than “same” decisions (Møller et al., 2012), while in vision, the reverse is true (Posner, 1986; Luce, 1986). In those experiments, people who claimed to have the ability to imagine odors were much faster in their same-different judgments than those who could not imagine odors, though their “different” judgments were still faster than “same” judgments. This suggests that the capability for an internal representation of the odor influences decision speed, but that novelty and change detection prevail over recollection even in those who seem to be able to recollect their odor memories willfully.

**SOCIALrecognition OF BODY ODORS** Long-term recognition memory for olfactory stimuli can be demonstrated via social recognition of body odors, such as kin recognition and pair-bonding. Each of these social activities requires the individual to have retained memory for the odor of another individual over an extended period of time following initial encoding of that individual’s scent.

Kin recognition is the ability of parents to recognize the scent of their offspring (and vice versa), and can be observed in a variety of species, including rodents (Todrank et al., 1998) and humans (Porter and Moore, 1981). This recognition of the odor of the offspring could be an evolutionary phenomenon possibly evolved to prevent inbreeding and appears to be achieved with very little conscious recognition (Lundström et al., 2009).

Shortly after mating, pair-bonding species that do not typically form long-term attachments (such as hamsters or rats) prefer the odor of a novel potential mate over the odor of the recent partner (e.g., Carr et al., 1970). This variant of

the “Coolidge effect”, in which sexual arousal is enhanced by exposure to new mating partners, is dependent on olfactory (as opposed to vomeronasal) perception (Johnson and Rasmussen, 1984), and does not seem to be hippocampally dependent (Petrulis and Eichenbaum, 2000). An intact perirhinal–entorhinal cortex is required for the effect, however, suggesting a strong role for that structure in the natural formation of social olfactory recognition (Petrulis and Eichenbaum, 2003b) and that the general familiarity/novelty detection process that is widely used for visual object and odor recognition tasks is involved in the effect (Petrulis, 2009). Olfactory-based recognition of mates also has been readily observed in a number of species that form long-term attachments, including prairie voles (Newman and Halpin, 1988) and humans (Hold and Schleidt, 1977).

**SEMANTICS-FREE ODOR MEMORY** In most explicit odor recognition experiments, the stimuli have been common odorants disconnected from the way that they are normally perceived. As a result, it is almost impossible to separate the roles of pure odor memory and verbal or semantic memory in people. In implicit memory tasks, semantic memory is avoided through the use of uncommon and unidentifiable odors presented at concentration levels that do not catch the conscious attention of the subject. Another technique is to use experimental paradigms in which the subject believes that they are participating for a different purpose than just odor exposure (Degel et al., 2001). Another way of securing semantics-free memory has been used in food-related experiments in which the subjects were exposed to target foods during a meal that was offered to them between other experiments without any reference to a possible later memory test (Mojet and Köster, 2002; 2005; Morin-Audebrand et al., 2011). When later unexpectedly tested they had to recognize the target foods they had eaten between distractors that were only slight variations of the target (differing only at just noticeable difference level in one aspect) and therefore had the same overall taste, appearance and, as a result, the same name as the target. In these experiments, the target odors were not recognized any better than chance guessing, but the distractors were significantly rejected and the subjects were more sure of these negative decisions.

**DIFFERENCES IN IMPLICIT AND EXPLICIT MEMORY** In one set of studies, elderly people with a still intact sense of smell performed at least as well, and in one case even slightly better, than young people in implicit memory tasks while this pattern was reversed when intentional learning was involved (Møller et al., 2004; Møller et al., 2007). This performance pattern was primarily due to a better rejection of the distractors in the intentional test phase by the young people, as their hit rate

was at roughly at chance level (Møller et al., 2004; Møller et al., 2007) and could not be attributed to self-developed verbal descriptors for the odorants (Møller et al., 2004). Whether this difference in ages reflects the fact that incidents of intentional learning become less frequent later in life, despite continued incidental learning, or whether there are real impediments of intentional olfactory encoding involved in the elderly, is not yet clear.

## 15.3 LEARNING

### 15.3.1 Appetitive Conditioning of Discrimination of Odor Cues

Novel odors can be paired with positive consequences (such as food) or negative consequences (such as illness or shock) in order to gain appetitive meaning (Galef and Giraldeau, 2001; Laska et al., 2003; Li et al., 2008). For both animals and humans, previously acquired meaning for odorants can be modified through subsequent experiences, such as sensory specific satiety (Rolls et al., 1981; Rolls et al., 1986).

**15.3.1.1 Discrimination Learning.** In discrimination learning, animals learn to differentiate between two stimuli, usually associated with different behavioral outcomes (Nigrosh et al., 1975; Slotnick and Katz, 1974). Most often these stimuli can readily be discriminated and what is learned is the expected response to each stimulus (Slotnick, 2001; Slotnick and Bodyak, 2002; Smith and Cobey, 1994). In some cases, stimuli that cannot be easily discriminated, such as the enantiomers of limonene, alcohols with similar numbers of carbons, highly overlapping odor mixtures, or two concentrations of a same odorant, can be learned to be discriminated in a situation in which an animal is motivated to do so (Cleland and Narla, 2003; Linster et al., 2002; Linster et al., 2001; Pelz et al., 1997). Because it is difficult to differentiate between the acquisition of a rule in discrimination learning and odor discrimination, it is not easy to know how well animals can discriminate between a pair of odorants. It has been shown that rodents can acquire a rule after which they can discriminate between further odor sets much faster and one may assume that these odors can readily be discriminated (Barkai and Saar, 2001; Slotnick, 2001; Slotnick and Katz, 1974). Instead of associating different behavioral outcomes with odorants, one can probe odor discrimination by associating a reward repeatedly with a single odorant and subsequently probing the animal's response to novel odorants (Cleland et al., 2002; Daly et al., 2001; Linster and Smith, 1997; Smith and Cobey, 1994). This paradigm, often referred to as generalization, makes it possible to determine how closely animals associate odors which each other and how this changes as a function of

learning parameters, stimulus parameters, and previous experience (Cleland et al., 2009). Previous experience with odorants strongly affects odor discrimination learning, as tested through latent inhibition (Meyer and Louilot, 2011; Sevelinges et al., 2009) or blocking type paradigms (Gerber and Smith, 1998; Pelz et al., 1997; Wiltrot et al., 2003).

Although odor discrimination learning can be strongly affected by manipulations in the olfactory bulb (reviewed by Mandairon and Linster in 2009), and bulbar neurons significantly modulate their activity in response to odor stimuli during and after discrimination training (Doucette and Restrepo, 2008; Kay and Laurent, 1999), neural correlates of odor discrimination can be found in many other structures. Neurons in olfactory bulb, piriform cortex, orbitofrontal cortex, and hippocampus change their response profiles to odorants as a result of discrimination learning (Calu et al., 2007; Roesch et al., 2007; Schoenbaum et al., 1998; 1999; Schoenbaum and Eichenbaum, 1995). In many cases, responses reflect the learning of odor discriminations, especially in the olfactory bulb. In addition to single cell responses, overall dynamics in olfactory structures are also strongly modulated by discrimination learning (Beshel et al., 2007; Kay and Beshel, 2010; Kay and Lazzara, 2010; Martin, et al., 2007). In invertebrates, neural correlates of olfactory discrimination learning have been reported in both the antennal lobe and mushroom body structures (Silbering and Galizia, 2007; Silbering et al., 2008; Szyszka et al., 2005). In summary, discrimination learning is a distributed process across many brain structures and is modulated by stimulus and task parameters, previous experience with odorants, and manipulations of specific neurotransmitter and neuromodulator systems.

**15.3.1.2 Odor Memory in Food Preference and Food Habit Formation.** Flavor is the integrated experiences of taste, smell, and texture (tactile) sensations, the latter of which are largely mediated via the trigeminal nerve. Since olfactory sensations are crucial in forming the flavor, odor memory plays a substantial role in food acceptance and in food preference formation through a number of mechanisms. For example, in mere exposure (Zajonc, 2001; 1968) the participant is exposed to the same stimulus (e.g., foods) a number of times, which often leads to a reduction of neophobia (Pliner, 1982) and an increase in liking for the stimulus, possibly due to 'the absence of ill effects' (Zajonc, 2001). Most flavor learning in food preference formation is incidental and the kind of memory involved in the changed preference responses to the stimulus is unconscious. This type of learning has been observed in fetuses (Schaal et al., 2000; Mennella et al., 2001; Mennella and Beauchamp, 2002) and pre-verbal

children (Hausner et al., 2010; Mennella and Beauchamp, 2002), as well as in rodents (Youngentob and Glendinning, 2009) and other animals (Schaal, 2012).

### 15.3.2 Stimulus-Stimulus Associations

In everyday life, odor memory not only helps us to feel at home in our world (McBurney et al., 2012), but plays an important role in the development of links to personal history via the strong associations between odors, other stimuli, and past places. Apart from the reactions to predator odors (e.g., Wallace and Rosen, 2000) and possibly “pheromonal” activity found in some animals (Keil et al., 1990; but see Doty, 2010), associations to most odors are not innate (Engen and Engen, 1997). Instead, these associations are learned through experience across the life-span (e.g., Schaal et al., 2000; Beauchamp and Mennella, 2009) and enhanced by emotional responses to the experiences (Engen, 1991; Herz, 2001; 1997). Hippocampal neurons across species respond generally to novelty or familiarity (Wood et al., 2000; Cahusac et al., 1993; Ekstrom et al., 2003), suggesting that hippocampal neurons encode associations between a specific odorant and its location or context (Eichenbaum et al., 2007). Thus coding in the hippocampus reflects the unique episodic combination of a stimulus, its importance to the perceiver, and the behavioral response it elicits, as well as the places and contexts in which the stimulus occurs (Eichenbaum, 2004; Goodrich-Hunsaker et al., 2009).

**15.3.2.1 Associations Between Odors and Visual Stimuli, Especially Places.** Cross-modal associations between visual and olfactory stimuli have been demonstrated in a variety of species, including honey bees (Srinivasan et al., 1998), Drosophila (Guo and Guo, 2005), primates (Rolls et al., 1996), and humans (Gottfried and Dolan, 2003; Lawless and Engen, 1977). These associations have indicated that odorants can influence preference for visual stimuli, such as faces or abstract paintings (Todrank et al., 1995; Van Reekum et al., 1999), and conversely that visual cues can affect aspects of olfactory perception, such as perceived intensity (Zellner and Kautz, 1990; Dematté et al., 2009). Combining information from both senses improves task performance (Steck et al., 2011), underscoring the episodic nature of olfactory memory.

Studies with animals have evaluated the association between odors and places using a variety of experimental techniques. Open field tests indicate that olfactory cues can be salient cues for rats in identifying location, by showing that the number of correct food site identifications is increased (Lavenex and Schenk, 1995; 1998). In another

technique involving a multi-armed maze, rats can be trained to sample an odor at a central location and respond as to the odor’s identity by entering a location associated with the smell (Youngentob et al., 1990; 1991). Each of these techniques suggests that rodents can easily associate a place with a particular odorant.

Humans can also associate places and odors, and the odorants that people incidentally encounter in specific places and situations become a part of the memory for the entire episode (Degel and Köster, 1999; Degel et al., 2001). When implicitly tested later, the unidentified odor seems to “fit” the place where it was previously encountered (Johns et al., 2012). An odorant that is highly specific to a particular location can strongly evoke memory for the location. For example, people who had been exposed to an unusual “viking” smell in the Jorvik Viking museum an average of six years prior, remembered many more details of the museum when they were given the specific odor again (Aggleton and Wasket, 1999). It is of interest to note that most odor names reflect the source of the odor, which in one sense is the odor’s location (e.g., lemon, lime, coffee, fish, flower, etc.).

**15.3.2.2 Odor-Tactile Associations.** Cross-modal associations between olfactory and tactile stimuli can be observed in a variety of species, including rats and humans (Tomie and Whishaw, 1990; Dematté et al., 2006). The associations have been taught explicitly in rats, most notably in a paradigm that associated strings of different textures and thicknesses with odorants, and then required particular combinations of strings and odors in order to obtain a food reward (Tomie and Whishaw, 1990). The acquisition and retention of this task was impaired by lesions of the orbitofrontal cortex (Whishaw et al., 1992), suggesting that an alternative pathway to the hippocampus for acquiring associations may exist.

During the course of everyday life, experiences of the combination of tactile sensations and odors (such as soft clothes and floral odor) occur often enough to form an implicit association between them, through associative learning, which is possibly facilitated through shared hedonic qualities of the stimuli (Dematté et al., 2007). In people, ratings of the texture of a cloth can be altered by the presence of an odorant, and the qualities of the specific odorant can determine whether the cloth is perceived as more rough or more soft (Dematté et al., 2006). This change in the human perception of texture due to fragrance also has been observed in the differences in the perception of hair washed with shampoos that differ only in fragrance (Churchill et al., 2009). These learned associations are stable enough to affect the latencies in an Implicit Association Test (Dematté et al., 2007), which indirectly measures the association between olfaction and touch.

**15.3.2.3 Odor-Odor Associations.** Memory for relationships between two odors has been used as a method of investigating declarative memory in animals and humans (Bunsey and Eichenbaum, 1996; Alvarez et al., 2001), as well as memory flexibility (Bunsey and Eichenbaum, 1993). In a typical task, subjects learn to associate two odors with each other, and then later learn additional transitive inferences (e.g., A and B are associated, B and C are associated, so A and C are associated). Acquisition of this task is disrupted by lesions to the perirhinal and entorhinal cortices (Bunsey and Eichenbaum, 1993) and prefrontal cortex (DeVito et al., 2010). In contrast, lesions of hippocampus do not disrupt formation of the initial association in this type of learning, but the associations are not transitive after that point (Bunsey and Eichenbaum, 1996; Li et al., 1999). Odor guided transitive interference tasks, which are hierarchical in nature, are also disrupted by disconnection of the hippocampus (Davis, 1992), as is a transverse patterning (A>B, B>C, C>A) task (Dusek and Eichenbaum, 1998). Thus relational memory between odors seems to be mediated by a network of connections between the hippocampus, surrounding cortical areas, and the prefrontal cortex (DeVito et al., 2010).

**15.3.2.4 Odor-Taste and Odor Toxicosis Association.** Both animals and humans will avoid a flavorant that has been associated with gastric illness (Garcia and Koelling, 1966; Bernstein, 1978). This special case of single-trial classical conditioning is called “taste potentiated odor aversion,” and is often mediated through the sense of smell (Bartoshuk, 1989), which can warn the individual of the potential of danger. Although both taste and smell are “near” senses, orthonasal olfactory information arrives prior to the ingestion of a flavor, and can give rise to expectations of a particular taste that accompanies the odor (White and Prescott, 2007). Aversion to ingestion of a substance that produced an illness is robust and can continue for more than 30 days after the initial gastric distress (e.g., Chapuis et al., 2007). The basolateral nucleus of the amygdala is involved in the acquisition, consolidation, and the retrieval of this type of memory (Shionoya and Datiche, 2009), but other structures, such as orbitofrontal cortex (Schoenbaum et al., 1999), hippocampus (Ferry et al., 1999), and olfactory bulb (Kay and Laurent, 1999) are also involved.

**15.3.2.5 Odor-Verbal Associations.** Humans are notoriously bad at associating a name with an odorant (e.g., Engen and Ross, 1973). Many studies have reported un-cued odor identification accuracy levels that are quite low, generally falling between 44% and 55% (Cain and Potts, 1996; Engen, 1987). Despite the difficulty in attaching a name to an odor, it is possible that verbal encoding

assists in olfactory memory accuracy (Paivio, 1991). Reports as to whether or not labeling assists in memory vary, with some studies observing no benefit from labeling (Engen and Ross, 1973; Møller et al., 2004) and others reporting memory improvement (Rabin and Cain, 1984; Lyman and McDaniel, 1986). Some of the differences in these reports seem related to the nature of the label, as being able to apply a label consistently (as opposed to accurately) seems to improve odor recognition memory accuracy considerably (Cain and Potts, 1996; Frank et al., 2011). The consistently applied label may seem to be incorrect, yet may simply reflect idiosyncratic odor knowledge that reflects the variability of the olfactory stimulus (Cain, 1979; Sulmont-Rosse et al., 2005).

## 15.4 CONCLUSIONS

Olfactory learning and memory result from brain activity in multiple memory pathways that contribute to different strategies of memory performance (McKenzie and Eichenbaum, 2012). The hippocampus is intimately involved in these pathways (DeVito et al., 2010), supporting the process of odor recollection (Fortin et al., 2004), as opposed to familiarity, which is mediated by the amygdala. The hippocampus also acts to integrate aspects of associative memory (Gottfried and Dolan, 2003; Eichenbaum et al., 2007) and is important in transitive inference. The medio-dorsal thalamus and the orbitofrontal cortex contribute to memory formation, particularly the acquisition of “rules” of learning associations with odors (Petrulis and Eichenbaum, 2003a), including the value changes that occur with reinforcers (Rolls, 2000). The olfactory bulb and piriform cortex are also integral to the olfactory memory process (Gottfried and Dolan, 2003; Zelano et al., 2009).

A well-known scent such as coffee evokes in people not only the memory for the characteristic smell of coffee, but also recall of the verbal label for “coffee” and a myriad of other associations with the hot beverage. In studies of human odor memory, this complicates the question of whether humans are endowed with memory systems for the odor per se or whether ‘odor memory’ is mostly based on verbal and other semantic labels, particularly when well-known odors and explicit memory paradigms are used. Implicit learning paradigms (e.g., Degel and Köster, 1998) seem to more closely model the types of episodic interactions with odors that are experienced in everyday life.

Because of the critical nature of odor memory in performing daily olfactory functions, continued examination of the parameters surrounding the learning and memory of odors is vital. Evaluation of the theoretical, behavioral, anatomical, and neurochemical substrates will continue to

be important in elucidating the mechanisms of memory that are integral to olfactory perception. A major issue to be resolved in that evaluation is the level to which odor memory processes are unique or independent of the memory processes associated with other sensory systems.

## Nasal Patency and the Aerodynamics of Nasal Airflow in Relation to Olfactory Function

KAI ZHAO and RICHARD E. FRYE

### 16.1 INTRODUCTION

#### 16.1.1 Recognition of the Nose in Respiratory Function: A Brief History

The Ebers Papyrus, the only complete Egyptian papyrus, mentions the nose as a respiratory organ: “As to the breath which enters into the nose, it enters the heart and lungs; these give to the whole belly” (Ebbell, 1937). The Egyptians knew that the nose secretes mucus, contains arteries and veins, and is responsible for olfaction, but Galen was the only Greek physician or philosopher on record to recognize the importance of the nose in respiration (Kimmelman, 1989). In 1844, Piorry espoused the importance of the nose in respiratory function (Williams et al., 1970), but it was not until Kayser (1895) that nasal airflow was quantitatively measured with the first anterior rhinomanometer.

#### 16.1.2 Functional Physiology of the Nasal Airway: A Brief Review

The nasal airway serves to optimize gas exchanged by conditioning the inspired air; incoming air is heated, humidified, and filtered of airborne pathogens and environmental pollutants. Even in extreme environmental conditions, inspired air can be heated and humidified to nearly 90% of the intra-alveolar air before reaching the nasopharynx (Rouadi et al., 1999). Thomson and Dudley-Buxton (1923) highlighted the functional

significance of nasal morphology by demonstrating that the anthropological cephalometric nasal index varies across races in relation to indigenous climate. Approximately two-thirds of the resistance of the entire airway tract occurs in the nasal airway (Ferris et al., 1964). Nasal airway patency is functionally coordinated with pulmonary function. By matching lower airway impedance, the nose assists in control of breathing frequency and expiration length and provides positive end-expiratory pressure. Turbinete swelling is increased by pulmonary stretch, lower airway irritation, normocapnic progressive hypoxia, and respiratory drive (Lung and Wang, 1991; Maltais et al., 1991; Nishihira and McCaffrey, 1987; Series et al., 1989).

Three sets of protrusions from the lateral wall form the inferior, middle, and superior turbinates in the human nose (see Chapter 2). These structures assist in efficient transfer of heat and moisture and diverge the inspiratory and expiratory nasal airflow into complex parallel channels. The resulting airflow can exhibit dramatic intra- and interindividual differences due to congenital anatomical features, inflammation arising from acute or chronic conditions, or the presence of polyps. These anatomical deviations may have additional functional consequences. Excessive high- or low-speed flows may also induce abnormal structural changes in the nasal cavity. For example, Ogawa (1986) reports that polyps and turbinate hypotrophy occur more often on the concave side of unilateral septal deviated noses, possibly because of higher flow rates.

### 16.1.3 Influence of Nasal Airflow on Olfactory and Trigeminal Senses

The nasal cavity is the initial site where airborne chemicals contact olfactory receptors and trigeminal nerve endings. The olfactory neuroepithelium is a small ( $\sim 2\text{--}5 \text{ cm}^2$ ) region of the nasal mucosa located below the cribriform plate, on the upper nasal septum, dorsal superior turbinate, and regions of the middle turbinate. The irregular contour of the nasal cavity, combined with high-velocity airflow, produces nonlinear aerodynamics that promote odorant mixing while producing a complicated odorant distribution. Only 15% of the incoming airstream passes near the olfactory epithelium. Subtle alternations in nasal geometry may deflect the airstream away from the olfactory epithelium; in many cases nasal resistance and patency perception are unaffected. Trigeminal nerve endings are distributed throughout the nasal mucosa; however, the anterior regions (vestibule and nasal valve) have been reported to be more sensitive to irritants and nasal airflow (Clarke and Jones, 1994; Eccles and Jones 1983; Meusel et al., 2010; Scheibe et al., 2006; Zhao et al., 2011).

## 16.2 BASIC CONCEPTS OF NASAL FLUID DYNAMICS

Nasal aerodynamics are influenced by nasal anatomy and serve as a basis for much of its physiological function.

### 16.2.1 Basic Equations

The Hagen–Poiseuille equation, which is derived from fully developed, steady, laminar flow in a circular, straight, and rigid duct, is often used to describe nasal airway resistance (NAR). This equation relates the driving pressure ( $p$ ) across a conduit to the volume airflow rate ( $q$ ) through the conduit. The equation can be rewritten in the form of Poiseuille resistance,  $R$ , an analog to electrical ohmic-type resistance, where  $l$  is conduit length,  $\eta$  is dynamic viscosity, and  $r_o$  is the radius of the tube:

$$\frac{p}{q} = R = \frac{8 \cdot \eta \cdot l}{\pi \cdot r_o^4}$$

Since the resistance of a conduit is inversely proportional to the fourth power of the radius, small changes in the diameter of the nasal cavity can greatly influence resistance. However, the Poiseuille equation assumptions are certainly violated by the complex shape of the nasal cavity; thus, the relationship between nasal pressure and flow is often nonlinearly related even in healthy airways. Although most studies attribute this nonlinearity to the airflow turbulence,

slow flow development due to the nasal cavity's irregular geometry also produces a nonlinear relationship.

### 16.2.2 Incompressible, Laminar, Turbulent, and Quasi-Steady Flow—What Do They Mean?

The discussion of laminar vs turbulent flow starts with the concept of viscosity, which describes the internal resistance of fluid to flow. Since air is only considered compressible at flow velocities near Mach 1 (340.3 m/s in air), nasal airflow, which is considerably below Mach 1, is considered “incompressible.” As flowing air comes into contact with a wall (or sinonasal mucosa), the velocity of the air in immediate contact with the mucosa is zero, owing to viscosity (the term “no-slip” is used to describe this situation), with flow velocity gradually increasing as distance from the wall increases. When this velocity gradient is low, laminar flow is maintained, characterized by concentric layers of well-organized flow, with the outermost layer close to the wall traveling at almost zero velocity and the centermost layer traveling at maximum velocity, resulting in a parabolic flow profile. If this velocity gradient continues to rise, by either reducing viscosity or increasing bulk stream flow, random vortexes or eddies occur between different layers of flow—hence, turbulence. When turbulence occurs, greater energy (pressure) is needed to push the flow. Turbulent flow results in a flow profile that is flat, with a quick velocity drop near the wall of the conduit. The ratio of a fluid’s momentum (velocity) force to inertial (viscosity) force is often described by a dimensionless number, called the Reynolds number (Re):

$$Re = \frac{\rho VD}{\mu}$$

where  $\rho$  is fluid density,  $V$  is fluid velocity,  $D$  is distance or diameter of the fluid containing cavity, and  $\mu$  is dynamic fluid viscosity. In general,  $Re < 1500$  usually indicates laminar flow,  $Re > 2000$  indicates turbulence, and  $1500 < Re < 2000$  is transition flow—a mixture of turbulent and laminar flow. Theoretical estimates of the Re of nasal airflow range from 600 (resting breathing) to 2000 (strong sniffing) (Keyhani et al., 1995). However, the occurrence of turbulence also depends on geometry. Flow through a smooth tube can be carefully maintained in a laminar state at Re values as high 10,000, whereas turbulence may occur at Re values as low as 1000 when a conduit has irregular walls, bifurcations, bends, or abrupt changes in a cross-sectional area (CSA). The accurate characterization of nasal airflow turbulence has to come from empirical measurement. It is generally agreed that nasal airflow at a restful breathing rate  $<200 \text{ mL/sec}$  is likely predominantly laminar, while strong sniffing would result in transitional or turbulent flow.

Once turbulence develops, the previously orderly forward fluid motion disperses in random eddies, thus increasing air mixing and odorant diffusivity. The turbulent diffusivity, which may facilitate the delivery of odorants to the olfactory epithelium, is often hundreds of times higher than that of laminar flow. One computational study surprisingly suggested that turbulence mixing may have a negligible effect on odorant sorption in the olfactory mucosa (Zhao et al., 2006a). Their results suggested that nasal airflow, during sniffing, is far from fully turbulent, with a ratio of turbulent viscosity to molecular viscosity <5 (in full turbulence this ratio is >100). Thus, the increase of eddy diffusivity due to turbulence in the main airstream is limited. Nevertheless, even without the effect of turbulence, the mere increase in flow rate to the olfactory region during sniffing can have a strong functional effect and can potentially differentiate odorants based on their sorptive properties (Sobel et al., 1999, 2000).

Another rather confusing term depicts the flow phase, that is, steady or quasi-steady flow. During both inspiration and expiration, incoming nasal airflow starts with acceleration, which is followed by stagnation, deceleration, and then flow reversing. Quasi-steady flow assumes that these transitional phases are relatively insignificant and assumes that the transient cycle at a given time point can be captured by the steady state of the same total flow rate. This assumption is adopted by most nasal airflow studies since it greatly eases both computational and experimental setups. Strouhal and Womersley number analyses are frequently the theoretical basis for this assumption; however, studies have increasingly suggested that even if the nasal airflow is quasi steady, the underlying transport events can be unsteady (Shi et al., 2008, Jiang and Zhao, 2010). Nevertheless, steady-state analysis remains important because one can estimate the unsteady effect averaging over a breathing cycle (Shi et al., 2008) which seems to provide sufficient functional information. However, recent advances in animal studies that focus on temporal coding of the olfactory system within or between sniffing cycles (see Section 16.5) may move future nasal airflow study in humans toward full-blown transient-state analysis, once the findings in animal models are translated to humans.

### 16.2.3 The Collapsible Nasal Valve

The pressure drop across a tube due to airflow is determined by the smallest cross-sectional area (CSA), also known as the minimal cross-sectional area (MCA) (Williams et al., 1970). In the normal nasal airway, this occurs at the nasal valve which accounts for 90% of the pressure drop (Jones et al., 1988), and is located approximately 2 cm posterior to the entrance of the nares. Part of the nasal valve is composed of compliant tissue, allowing it to partly collapse when the differential pressure reaches a critical value. Collapsible tubes are known as flow regulators, which prevent flow

from exceeding an upper limit (Conrad, 1969; Holt, 1969). Nasal alar muscle activity reduces nasal valve elasticity, thereby increasing the critical pressure (Cole et al., 1985). Many factors influence the onset and magnitude of alar muscle activity, including breathing rate, maximum flow rate, acceleration of airflow, sleep state, CO<sub>2</sub> concentration, resistive loading, and negative airway pressure (Mezzanotte et al., 1992; Strohl et al., 1980, 1982). Sagging or depression of the upper lateral nasal cartilage, anterior nasal septum buckling, or inferior turbinate inflammation can narrow the nasal valve area, leading to a lower critical pressure (Adamson, 1987; Goode, 1985; Kasperbauer and Kern, 1987). Critical pressure also depends on both upstream and downstream resistance; thus, the dynamics of the nasal valve may depend on nasal airflow resistance changes in other regions. Except in rare conditions, the nasal valve normally does not collapse during expiration.

The collapsible nasal valve and the elastic or dynamic properties of the mucosa are not considered in most experimental and computational models when studying nasal airflow. Their implications for olfactory or trigeminal function are presently unclear.

## 16.3 MEASURING NASAL AIRFLOW AND AIRWAY PROPERTIES

### 16.3.1 Rhinometry

Rhinomanometry is a technique that measures differential pressure across, and volume flow through, the nasal cavity. It was first described by Kayser (1895) and further improved upon by Spoor (1965), who incorporated electronic pressure transducers (Nakano, 1967; Randall, 1962). Rhinomanometry measures NAR, which is best measured by anterior rhinomanometry. In this procedure, nasal airflow is measured on one side of the nose while pressure is measured on the other side of the nose. However, this method is technically difficult. Thus, NAR varies significantly among subjects; within subjects, alterations in NAR can result from the nasal cycle, body position, and nasal decongestion (Eccles, 2000).

Acoustic rhinometry introduces sound pulses into the nose, and analyzes the reflections to determine nasal cross-sectional area as a function of distance from the nares. Primary reportable measurements include unilateral or total nose MCA and nasal cavity volume (NCV). This technique requires minimal cooperation from the subject and does not require breathing effort, making it particularly useful in evaluating children, even infants, or patients with severe nasal obstruction.

Both rhinomanometry and acoustic rhinometry are reliable over several weeks if performed by an experienced operator under controlled circumstances (Silkoff, 1999). Both methods are also easy to perform on large samples,

objective, and can reflect changes in nasal cavity anatomy resulting from various clinical abnormalities (e.g., septal deviations and surgery induced alterations) and pharmacological treatments [e.g., decongestants (Hummel et al., 1998b; Masieri et al., 1997); steroids (Lund et al., 1998)]. Acoustic rhinometry and anterior rhinomanometry are most sensitive in revealing severe deviations in the anterior nasal cavity and are less sensitive in demonstrating middle and posterior deviations (Szucs and Clement, 1998). The accuracy of acoustic rhinometric measurements is greatly reduced beyond the nasal valve, due to sound wave scattering by the turbinates and sinus. Thus, NCV measured by coronal high-resolution CT correlates well with acoustic rhinometry measurements in the anterior but not posterior nasal cavity (Dastidar et al., 1999a,b). Alternatively, information from both rhinomanometry and acoustic rhinometry can be combined into a unique index. However, both methods do not provide details on airflow patterns, potential turbulence, or the dynamics of the nasal valve, and may be less sensitive in populations with less severe symptoms (Andre et al., 2009).

### 16.3.2 Experimental Models

**16.3.2.1 Early Nasal Models.** Early *in vitro* models were constructed using plastic casts from cadaver noses in which the septum was replaced with a flat glass to aid visualization. Airflow measurements of these models were generally crude or descriptive, accomplished by visualizing dye (Masing, 1967) or aluminum tracer (Stuiver, 1958) in water flow, or smoke in airflow (Proetz, 1951), or by using miniature Pitot tubes (Swift and Proctor, 1977), laser Doppler velocimetry (Girardin et al., 1983), or radioactive tracers (Hornung et al., 1987a). However, many of the insights that these early studies provided are still relevant today. For example, airflow to the olfactory region increased as total nasal flow rate increased (Stuiver, 1958). Various abnormalities in the nasal cavity may have differential impact on nasal airflow (Proetz, 1951). Visual comparison of nasal airflow between F344 rat and rhesus monkey revealed that a common distribution mechanism of nasal airflow does not exist across species (Morgan et al., 1991). However, the anterior portion of the nose is important for directing the incoming airstream, regardless of the species. Some early reports differed on nasal airflow being laminar (Masing, 1967; Hornung et al., 1987a) or “turbulent-like” (Swift and Proctor, 1977), which historically created some confusion. It is now clear that these different flow regimens can be attributed to individual differences. Nevertheless, how to generalize the results across potential individual differences has been a consistent problem facing nasal airflow studies, even today.

**16.3.2.2 Quantitative Nasal Models.** In attempts to increase the spatial resolution and accuracy of measures of nasal airflow patterns, enlarged anatomically accurate models of the nasal cavity were constructed based on coronal MRI or CT scans [Schreck et al., 1993 (3 times larger); Hahn et al., 1993 (20 times larger)]. Using a hot wire anemometer, Scherer et al. (1989) and Hahn (1993) quantified nasal air currents at physiological inspiratory flow rates ranging from restful breathing (15 L/min) to strong sniffing (120 L/min). Air velocity was found to be relatively high through the inferior and middle meatuses and lower in the olfactory cleft. At least 50% of the airflow passed through the inferior and middle meatuses, while 15% passed through the olfactory region. Turbulence intensity was also first measured in these studies. For restful breathing with Reynolds numbers roughly 400, laminar-like flow was present throughout most of the nasal cavity, with some regional transitional flow. However, at higher flow rates, moderate turbulence (turbulence intensity <5%) occurred, although full turbulence was never reached even at the highest nasal flow rate.

Particle image velocimetry (PIV) is a recently developed technique in experimental fluid dynamics research. It uses suspended particles in the flow as tracers, which is in principle similar to earlier smoke or dye methods. However, PIV uses shutters and sheets of laser light to shine in one or more planes within the flow field and digitally track the movement of particles within the planes. This provides far more quantitative data and higher spatial resolution than visually tracking particles (Adrian, 1991). Park et al. (1997) and Kelly et al. (2000) were among the first to apply PIV to investigate nasal airflow, with the latter employing a model with better anatomical accuracy.

In earlier PIV investigations, the light sheet was pulsed twice, one plane at time; thus, only those particles that moved within the plane were recorded, and velocity across the plane was lost. Since most of the nasal airflow movement is in one direction (from nostril to pharynx during inspiration, and the reverse during expiration), this limitation is acceptable with careful selection of the study plane. Recent advances (e.g., stereoscopic PIV, defocusing PIV, tomographic PIV, and holographic PIV) allow three-dimensional spatial measurement of all three velocity components, although as yet there has been no application of three-dimensional PIV in nasal airflow studies. Creating an accurate transparent three-dimensional nasal model is another essential element in the PIV approach. Here, rapid prototyping and three-dimensional printing techniques, first used by Kelley (2000), represent another technological advancement. The approach first creates a computational nasal model from CT scans, which is then printed out in solid three-dimension with water-soluble starch and molded in transparent silicone. Once cured and the starch dissolved, what remains is a transparent replica of the nasal

cavity. PIV also uses much more sophisticated particles as tracers (e.g., hollow glass spheres) that are a better match for the density of the fluid, which is often a mixture of glycerin and water in order to match the light refractive index of silicon. A tidal water pump (Chung et al., 2006) can be used to simulate breathing. Kim and Chung (2004) have also shown that rapid prototyping can be used to study the effect of various turbinectomies. The results from these PIV studies showed similar levels of intersubject (model) variabilities. For example, the main flow was found in the inferior airway in Kelly's (2000) experiments but in the middle airway in those of Chung et al. (2006).

Despite the advances in in vitro models, the limitations of the approaches include greater cost, time, human effort, and in some cases specialized equipment. In addition, suspended particles may not simulate molecular dynamics accurately, and insertion of Pitot tubes or anemometers into a model may alter aerodynamics. Given that PIV and computational models have shown generally good agreement (Hörschler et al., 2006; Weinhold and Mlynški, 2004), the latter has become more common in the study of nasal airflow due to its lower cost and ease of performance. Nevertheless, validation with experimental results is still needed.

### 16.3.3 With Computational Fluid Dynamics (CFD) Models

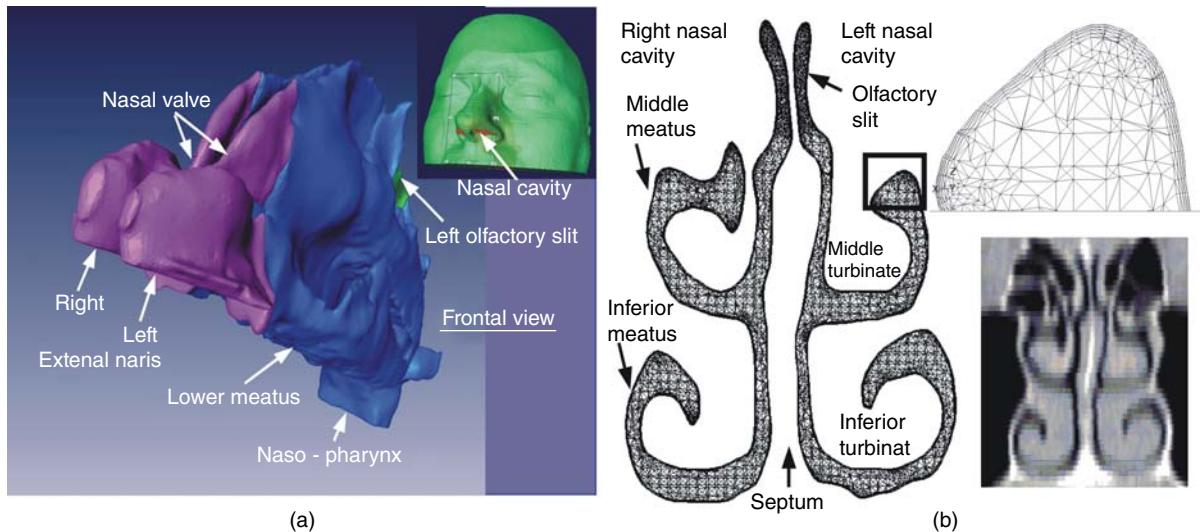

Although the set of equations that govern all fluid motions—the Navier–Stokes equation—are unsolvable analytically, advances in computer technology have made it possible to simulate nasal airflow numerically. The methods work in principle by dividing the air space geometry, obtained through imaging or casting, into many small and simple volumes (mesh), for example, tetrahedrals, polyhedrons, prisms. The first attempt was made by Elad et al. (1993), who used a crude nasal cavity represented by a trapezoid outline and two curved plates as the inferior and middle turbinates. Later, Keyhani et al. (1995) and Subramaniam et al. (1999) developed anatomically accurate models constructed from CT and MRI scans, respectively. A typical CFD model for the nasal cavity contains a few hundred thousand to a few million elements (mesh). Within each element volume, the nonlinear and higher-order Navier–Stokes equations can then be approximated linearly, which leads to approximation of the solution through iterations. Obviously, the more numerous and finer the elements, the closer the approximation is to the real solution. Thus, a mesh convergence check is often necessary by comparing simulation results in models with increasing mesh size. The quality of the elements, often reported as aspect ratios (between the shortest and the longest edge), also affects the accuracy of the simulation.

Turbulence presents another mathematical challenge, and various additional numerical schemes must be used, often involving the averaging of the randomness of turbulent flow (Reynolds averaging) (Zhao et al., 2006a) or the filtering out of small eddies (Large Eddies Simulations). For these common CFD schemes, once the mesh is created, the computation afterward is rather straightforward, although incorrect settings to the software can produce distorted findings.

A few other CFD schemes, such as direct numerical solutions and Lattice Boltzmann simulations (Eitel et al., 2010), may also be applied to nasal airflow simulation. While Boltzmann simulation is a nonorthodox CFD approach and has some advantage in grid/mesh generation, direct numerical simulation is often considered the gold standard in CFD. However, both methods require significantly greater computational cost and often require in-house coding. Validation between CFD simulation and experimental models is sparse; however, good agreement has been shown when tested (Keyhani et al., 1995; Elad et al., 1993).

With the advances in computational power, the bottleneck in the CFD approach lies in the meshing process, which, to date, still cannot be fully automated. Early CFD nasal models took a few months to a few years to generate manually, element by element. Major advances occurred around the turn of twenty-first century. For example, Zhao et al. (2004) rapidly semiautomatically generated eight versions of models (>1 million meshes for each requiring only days for the generation of each model) (see Figure 16.1). However, the technique has not advanced much since that time. Without a fully automated scheme, considerable effort is required to correct and oversee the meshing process. Most studies, even the most recent ones, still involve models of one or just a few subjects.

Earlier CFD simulation results indicated that most air flows along the nasal cavity floor, while the turbinate structures confine flow into parallel channels in an anterior-posterior direction, with about 10% of the airflow passing into the olfactory cleft (Keyhani et al., 1995; Keyhani et al., 1997). However, later CFD analysis showed, in accord with other methods, that nasal airflow distribution may have significant individual variations. For example, Keyhani et al. (1995) and Ishikawa et al. (2006) both reported the peak velocity in the nasal valve, but the specific location of the valve differed. Many studies differ regarding where most of the flow occurs. [e.g., along the middle meatus (Simmen, 1999); lateral to the nasal septum at the level of the either middle or inferior turbinate (Grant et al., 2004; Hahn et al., 1993; Lee et al., 2009)]. Zhao et al. (2004) demonstrated this anatomical effect using a three-dimensional anatomically accurate nasal cavity model based on a normal subject's CT scan. These investigators varied the nasal anatomy in two critical regions (the

**Figure 16.1** (a) an anatomically accurate computational nasal model constructed from nasal CT scans (b, lower right) of a normal adult human female. (b) A coronal cross section of the same model, which is filled with 1.7 million tetrahedral elements suitable for numerical airflow simulation. In a close-up view (b, top right), layers of small and fine elements can be seen along the wall that can capture the rapid near wall changes of air velocity and chemical concentration. Figure is adapted from Zhao et al., 2004. (See plate section for color version.)

nasal valve and the olfactory cleft) and showed that the overall nasal airflow pattern was highly sensitive to local nasal geometric configurations (Figure 16.2). Fractional airflow to the olfactory region was found to increase up to 50 times. This explains previously reported airflow pattern discrepancies based on different cast models. Such variant airflow patterns, independent of total nasal resistance or total nasal airflow rate, are likely to have enormous implications for the sensory function of the nose—pungency, patency, and olfaction.

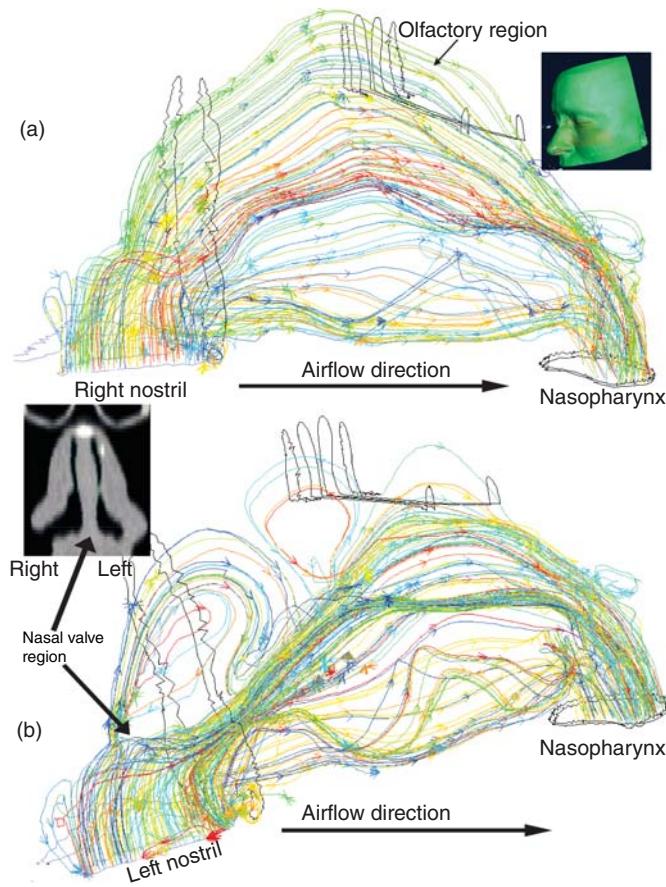

In addition to inter-subject differences, CFD offers a potential tool to predict the impact of various pathologic conditions and surgical maneuvers on nasal airflow [e.g., the effects of septal deviation (Ozlugedik et al., 2008; Chen et al., 2009; Garcia et al., 2010), septal perforation (Pless et al., 2004; Grant et al., 2004), endoscopic sinus surgery (Zhao et al., 2006b), inferior turbinate reduction (Wexler, 2005), turbinectomy (Garcia et al., 2007), and turbinate hypertrophy (Lee et al., 2009)]. However, few studies to date have included odor absorption and olfactory function (Zhao et al., 2006b; see Section 16.4). Even though these CFD studies provide new insights into nasal airflow patterns in both normal and pathologic conditions, most of them are case reports and many more questions remain. Of particular interest is the identification of anatomic and flow pattern parameters that can reliably predict which patients will complain of nasal sinus problems. Such information may be useful in preoperative planning and postoperative analysis.

In summary, for the purposes of measuring aerodynamics of the nasal cavity, rhinomanometry, which indexes

overall nasal resistance, and acoustic rhinometry, which indexes the anterior nasal airway cross-sectional area, remain valuable tools applicable to large population-based clinical studies, despite the fact they do not capture the full picture of nasal airflow details. In vitro models and CFD approaches remain investigational tools, with single or a small number of individuals examined in each study. They both can provide detailed quantitative information about nasal airflow patterns and properties, but the challenges of applying to the general population and determining the functional relevant parameter remain. Nasal airflow and patterns seem to have significant individual differences and are prone to various perturbations. However, it is unclear how to draw a line between the variability among healthy individuals and those with pathological conditions, and whether and which changes under pathological conditions have functional relevance or are the causal factors for symptoms.

## 16.4 NASAL AIRFLOW: IMPLICATIONS FOR OLFACTORY FUNCTION IN HUMANS

Nasal airflow is essential for olfactory perception and is dictated by several factors. First, the location of olfactory epithelium in human nasal anatomy is rather small and confined to a narrow region in a remote portion of the nasal cavity; thus, disturbances of airflow and odor distribution to this regional may have functional consequences. Second, the effects of nasal cavity anatomy on nasal airflow are

**Figure 16.2** Nasal airflow pattern can be highly sensitive to local airway geometry. This figure shows the streamline patterns for inspiratory steady laminar airflow in the left and right sides of the nasal cavity depicted in Figure 16.1. Note the smooth laminar flow on the right side of the nose (a) and the eddies in the anterior part of the left side of the nose (b) induced by a small airway constriction in the nasal valve region. Note also the secondary eddy in the superior and posterior part of the nasal cavity of the left side. When the constriction was artificially removed, the streamline pattern became smooth again (figure not shown) just as in the right side. Adapted from Zhao et al., 2004. (See plate section for color version.)

complex. For example, since airflow travels along the path of least resistance, it is easily redistributed if one path is blocked. Thus, airstream distribution can be profoundly influenced without a substantial change in nasal anatomy, while nasal resistance, measured by rhinomanometry, is typically elevated only by severe nasal anatomic abnormalities. Finally, the receptors do not have direct access to airborne odorants, so sorption into the mucosa is necessary prior to receptor activation, while the sorption further depends on many factors such as odorant diffusivity and solubility. This section reviews evidence for the influence of nasal airflow and nasal resistance on olfactory function in humans. Studies examining this relationship either have used clinical populations of individuals with nasal disease or have studied the relationship of olfactory function and intersubject or intrasubject variations in nasal airflow and nasal resistance. Each of these approaches has advantages and limitations. The emphasis on nasal sinus disease has important health relevance, because a significant portion (~15–25%) of persons with olfactory loss have nasal sinus disease. The etiology and subsequent treatment of olfactory loss accompanied by nasal sinus disease are poorly understood. The overall findings from these studies are summarized at the end of this section.

### 16.4.1 Clinical Studies: Olfactory Function in Nasal Pathology and After Clinical Treatment

A suggestion that nasal airflow and nasal anatomy influence olfactory function has been based historically on the fact that olfactory dysfunction is associated with the same clinical abnormalities that affect nasal airflow, such as allergic rhinitis, polyposis, nasal sinus disease, or adenoid hypertrophy. Further support for this notion is provided by uncontrolled studies that have documented improvement in olfactory function following procedures known to improve nasal airflow and nasal resistance, such as endoscopic nasal sinus surgery (Seiden and Smith, 1988), adenoidectomy (Ghorbanian et al., 1983), septoplasty (Stevens and Stevens, 1985), and inferior turbinectomy (Ophir et al., 1986; Elwany and Harrison, 1990). Below we review the findings of more recent, higher-quality, clinical studies, including clinical trials that have examined improvement in olfaction and nasal airflow as a consequence of surgical and pharmaceutical interventions. Some of these clinical findings are inconsistent, likely reflecting the fact that the clinical effects of nasal anatomy and airflow abnormalities on olfactory function are complex.

#### **16.4.1.1 Rhinosinusitis and Olfactory Loss.**

Overall, anosmia or hyposmia occurs in 15–25% patients with underlying rhinosinusitis disease (Cullen and Leopold, 1999; Seiden and Duncan, 2001; Cowart et al., 1997), and this percentage increases up to 80% when sinus disease co-occurs with nasal polyps (Wolfensberger and Hummel, 2002). In addition, nasal polyps can differentially impair orthonasal vs retranasal olfactory acuity (Landis et al., 2003). It has been widely believed that a conductive mechanism is responsible for olfactory dysfunction in sinus disease, especially in those with polyposis. However, empirical testing of this notion has provided mixed results. In one study, NAR measured by active anterior rhinomanometry was found to correlate with both odor identification and olfactory threshold among rhinosinusitis patients (Damm et al., 2000), but other studies have not been able to document a correlation between NAR and olfactory function in rhinitis patients. For example, Simola and Malmberg (1998), in a rather large controlled study of patients with both allergic and nonallergic rhinitis, demonstrated an olfactory deficit in the rhinitis group compared with the control group, but were unable to document a relationship between olfactory thresholds and NAR as measured by active anterior rhinomanometry.

Although one potential reason for the mixed results in the above studies is that rhinomanometry may not necessarily reflect flow specifically to the olfactory region, other evidence suggests that there may be other inflammatory confounding factors. In two small prospective studies on allergic rhinitis patients, Klimek (1998) demonstrated that abnormalities in olfactory function were much better correlated with a marker of nasal inflammation than with NAR measured by rhinomanometry. Guilemany et al. (2009) demonstrated that olfactory function was correlated with nasal nitric oxide, a marker of nasal inflammation, but not with nasal inspiratory flow or acoustic rhinometry measurements in 49 patients with persistent allergic rhinitis.

These data may indicate that inflammatory processes, which are significantly involved in the pathophysiology of sinus disease, may play a larger role in olfactory dysfunction. Indeed, patients with chronic sinusitis who have inflammatory cell influx into the olfactory mucosa are much more likely to have an olfactory deficit (Kern, 2000). Chronic rhinosinusitis has been associated with pathological changes in the olfactory neural epithelium (Yee et al., 2009) and inflammatory mediators such as tumor necrosis factor alpha have been shown to cause olfactory neuron dysfunction (Sultan et al., 2011). Additional evidence for the salient role of inflammation includes observations that (a) olfactory dysfunction occurs in inflammatory disorders that are not associated with airflow obstruction of the upper nasal cavity (Laudien et al., 2009) and (b) that, in acute rhinitis, smell function, as measured by

event-related potentials, recovers long after resolution of the obstructive component of the illness (Hummel et al., 1998a). Still, one has to recognize the tight interrelation between inflammation and sinus disease severity (and thus conductive airway restriction). For example, Soler et al. (2009) demonstrated that, in patients with chronic rhinosinusitis, smell identification test scores correlated with both mucosal eosinophilia and disease severity, as measured by computer tomography.

#### **16.4.1.2 Clinical Interventions.** One approach to delineate the effect of airflow on olfactory function is to objectively demonstrate the correlation between improvements in airflow and olfaction with interventions in clinical populations.

**LARYNGECTOMY** One clinical condition associated with a close correspondence between rhinomanometry measurements and olfactory function is laryngectomy. Manestar et al. (2011) demonstrated a significant positive correlation between olfactory function and nasal airflow in laryngectomy patients using the polite yawning technique. Further studies by Manestar et al. (2012) demonstrated that the minimum nasal airflow required for olfactory stimulation in successfully rehabilitated patients was approximately 60 cm<sup>3</sup>/s.

**ENDOSCOPIC SINUS SURGERY** Early studies with a limited number of subjects failed to document improvements in NAR or olfactory function with function endoscopic sinus surgery (Lund et al., 1991), while early follow-up studies on larger samples did document improvements in both subjective and objective symptoms of nasal airflow and olfactory function (Lund and Scadding, 1994). More recent studies have confirmed such findings. For example, Wang et al. (2002) demonstrated marked improvements in both NAR, as measured by anterior rhinomanometry, and olfactory function following endoscopic sinus surgery for chronic sinusitis and/or nasal polyps; however, they did not attempt to establish the association between the two. Other researchers have demonstrated that the relationship between nasal airflow and olfaction is more complex and may occur over different time periods. For example, Różańska-Kudelska et al. (2010) demonstrated that improvement in olfaction lagged several months after NAR improvements following endoscopic surgery for nasal polyps. Other studies have suggested that a clear olfactory cleft is most important. Using CT staging of the sinuses, Shin et al. (1999) demonstrated that the blockage of the olfactory cleft was significantly related to the butanol olfactory threshold values in 50 patients with bilateral sinusitis. A more sophisticated study that used CFD modeling was able to predict that airflow delivery to

the neuroepithelium increased by 1000 times as a result of endoscopic polyp removal (Zhao et al., 2006b). Thus, the contribution of NAR in general to improvement in olfactory function endoscopic sinus surgery is unclear at this time. Specific changes in airflow to the olfactory cleft may be more important than general changes in NAR, but are not easily measured.

**SEPTOPLASTY AND TURBINOPLASTY** The olfactory region is located superior in the human nasal cavity, which is not directly touched upon during septo- and turbinoplasty. It is thus worth looking at these anterior nasal surgeries specifically, as they represent an opportunity to isolate the effect of nasal airflow on olfactory function. Several turbinoplasty studies have demonstrated improvement in both olfactory function and NAR. Rhee et al. (2001) reported objective improvement in total nasal volume and NAR, as measured by acoustic rhinometry and rhinomanometry, respectively, as well as improvement in olfactory thresholds in previously hyposmic patients after temperature-monitored radiofrequency or laser vaporizing turbinoplasty. Damm et al. (2003) demonstrated differential nasal airflow and olfactory function improvement following septoplasty and partial inferior turbinectomy. Nasal airflow, as measured by anterior rhinomanometry, improved in 87% of the patients, while odor identification improved in 80%, odor discrimination improved in 70%, and olfactory threshold improved in 54%. In a longitudinal study, radiofrequency inferior turbinate reduction resulted in a significant improvement in NAR, as measured by anterior rhinomanometry, as well as odor identification and threshold, two months (Garzaro et al., 2010) and two years (Garzaro et al., 2012) following the procedure.

However, not all studies have been able to document the correlation between improvement in NAR and olfactory function following turbinoplasty procedures. Three months following CO<sub>2</sub> laser turbinoplasty, Olszewska et al. (2010) found significant improvements in total NAR as measured by anterior rhinomanometry, but improvement in olfactory function in only a minority of patients. Modified vidian neurectomy combined with inferior turbinoplasty resulted in significant improvement in NAR, but subjective resolution of anosmia in only half of the patients (Ikeda et al., 2006).

**PHARMACOLOGICAL TREATMENT** Corticosteroids, antihistamines, and nasal decongestants are the primary medications in sinus disease management; however, their effects on olfactory recovery are mixed. In a double-blind, placebo-controlled trial of 17 patients with seasonal allergic rhinitis and symptoms of impaired olfaction, Sivam et al. (2010) found that the intranasal steroid mometasone improved nasal symptoms, nasal peak inspiratory flow, chemosensory quality of life, nasal

inflammation, and the number of eosinophils in the olfactory epithelium, but not olfactory function. Vaidyanathan et al. (2011) demonstrated that oral steroid prednisolone treatment of 60 adults with chronic rhinosinusitis and nasal polyps significantly decreased polyp grade and the perceived magnitude of the smell loss, but not perceived nasal patency. In 27 patients with persistent allergic rhinitis, Guilemany et al. (2012) demonstrated that levocetirizine, a third-generation antihistamine, resulted in improvement in both perceived smell loss and olfactory function that corresponded more to a reduction of nasal inflammation, as measured by nasal nitric oxide levels, than to the improvement in nasal airflow.

The lack of correspondence between improvements in nasal airflow and olfactory function is echoed by studies investigating nasal decongestants—medications that temporarily constrict blood flow, reduce nasal congestion, increase airflow, and effectively eliminate the nasal cycle (see Section 16.4.2.3), but do not have a direct impact on the inflammation. At least three studies (Hummel et al., 1998b; Temmel et al., 1999; Jung et al., 2011) have investigated the effect of two commonly used nasal decongestants, ephedrine and oxymetazoline, on olfactory function. All three studies employed double-blind random placebo-group designs; one enrolled rhinitis patients (Hummel et al., 1998b) while the other two focused on healthy populations. While all three found a significant reduction of NAR as measured by acoustic rhinometry or rhinomanometry after nasal decongestant treatment, none found any positive or negative effects on olfactory function, as measured by intensity ratings, odor identification, or thresholds. One of the studies also examined trigeminal function and found no effect (Hummel et al., 1998b), while another examined topical application of a commonly used nasal anesthetic agent lidocaine (Jung et al., 2011) and found no effect on odor identification.

Together, these studies highlight the complicated nature of the relationship between nasal airflow and olfaction. The vascular effect of intranasal applied treatments may be mostly localized in erectile tissue along the inferior turbinates and septal body, far away from the olfactory region, a potential explanation for its lack of effect on olfactory function. Another complication is that there is very little control of how much aerosol penetrates into the nasal cavity or into the olfactory region during the nasal spray. It has been reported that direct application of lidocaine onto the olfactory cleft can result in temporary anosmia (Welge-Lussen et al., 2004).

**NASAL DILATOR** As noted earlier, the nasal valve is a dynamic and collapsible tube that contributes significantly to nasal resistance (see Section 16.2.3). A narrower resting nasal valve or an anterior septal deviation may create high baseline valve resistance, which would make one prone to

nasal obstruction. External nasal dilator strips, such as the Breathe Right strip (GSK, Inc.), can effectively increase nasal valve CSA in the pre- and postdecongested nose (Ng et al., 1998) and improve MCA and NAR in normal subjects and in patients with septal deviation that affect the nasal valve area (Roithmann et al., 1998). Nasal dilators have been shown to decrease heart rate, ventilation, and VO<sub>2</sub> in athletes during submaximal exercise (Griffin et al., 1997) and to improve the respiratory disturbance index in a subpopulation of patients with obstructive sleep apnea and snoring (Gosepath et al., 1999). Hornung et al. (1997 and 2001) reported improved odor intensity perception, odor identification, and thresholds after the application of Breathe Right nasal dilators in healthy subjects. They attributed the effect to increased anterior nasal airway CSA (measured by MRI scans) and increased sniffing volume and duration. Surprisingly, there have been no replicating studies with larger sample sizes or clinical populations to validate these results. Raudenbush and Meyer (2001) reported that nasal dilators increased the intensity and pleasantness of food flavor placed in the oral cavity in healthy subjects.

### 16.4.2 Non-clinical Human Studies

Several studies have used natural variations in nasal anatomy and nasal resistance to study their correlation with olfactory function.

**16.4.2.1 Nasal Cavity Volume.** To identify the relationship between nasal anatomy and olfactory dysfunction, Leopold (1988) obtained nasal cavity CT scans of 34 patients with conductive or idiopathic hyposmia. The nasal cavity superior to the middle turbinate was divided into nine sections. Interestingly, a larger volume in the region 10–15 mm below the cribriform plate and a smaller volume 1–5 mm inferior and anterior to the cribriform plate was associated with higher olfactory ability, as measured by olfactory confusion matrix. The study was confirmed by Hornung and Leopold (1999) with unilateral, as opposed to bilateral, olfactory function in another 19 patients with static conductive hyposmia due to polyposis or mucosal edema. A larger volume 5–10 mm below and anterior to the cribriform plate and a smaller nasal vestibule volume correlated with better olfactory function. Damm et al. (2002) replicated the study in 50 healthy males using MRI. Olfactory thresholds were found to correlate with the anterior segment of intranasal volume in the upper meatus below the cribriform plate, as well as the anterior segment of the inferior meatus. Other studies have also indicated that a clear olfactory cleft is important for its function (Shin et al., 1999). These studies suggest that critical areas of the nasal cavity, both near and remote from the olfactory receptors,

influence olfactory function, presumably by directing air toward the olfactory cleft. However, the exact extent of how these regions affect olfactory airflow remains unknown.

**16.4.2.2 Artificial Blocking of the Nasal Cavity.** While it is difficult to derive a convincing conductive mechanism to olfactory losses in clinical studies due to the complex etiology of nasal sinus disease, at least one study has attempted to artificially create blockages inside the nasal cavity and confirmed that the resulting airflow changes can induce olfactory loss. In this double-blind study, sponges with a high saline content were placed in either the anterior olfactory cleft or the lower respiratory region. The results indicated that orthonasal, but not retronasal, olfactory identification ability was lower when the anterior olfactory cleft was blocked (Pfaar et al., 2006). This confirms that the differences between orthonasal and retronasal olfactory function observed in nasal polyps patients (Landis et al., 2003) may, to some degree, be due to mechanical obstruction of the anterior portion of the olfactory cleft.

**16.4.2.3 The Nasal Cycle.** The nasal cycle is a periodic ultradian rhythm that results in a change in nasal cavity volume that may occur in up to 80% of the adult population. The periodicity has been reported to range from 40 minutes to 4 hours (Bojsen-Muller and Fahrenkrug, 1971; Eccles, 1978; Principato and Ozenberger, 1970). Studies using acoustic rhinometry demonstrate that the nasal cycle is present, in some form, in most adults and in children as young as three years of age, even those with structural abnormalities such as septal deviation (Gungor et al., 1999; Lund, 1996; Sung et al., 2000). Classically, the change in volume is in the opposite direction across the two nasal cavities. More recent studies have found that many people do not exhibit this classic cycle—some have fluctuations on only one side of the nose and others have left:right airflow fluctuations that are poorly correlated with one another (Gilbert and Rosenwasser, 1987; Mirza, Doty and Kruger, 1997).

To determine if a relationship exists between the nasal cycle and olfactory sensitivity, Frye and Doty (1992) measured unilateral 2-butanone olfactory thresholds and NAR for 33 men and 44 women in two sessions separated by 4 hours. In approximately half of the subjects, the nostril not sampling the odorant was occluded. If the nasal cycle had not spontaneously changed its phase at the beginning of the second session, an attempt was made to change the phase by applying pressure under the armpit or in the palm of the hand or by auditory stimulation on the side of the more patent airway. In subjects whose contralateral naris was blocked, lower right NAR was associated with decreased olfactory thresholds on both sides of the nose, whereas lower left NAR was associated with comparatively increased olfactory thresholds on both sides of the nose.

These data suggest that NAR per se was not responsible for alterations in olfactory sensitivity; rather, other factors associated with the nasal cycle such as changes in cerebral EEG or central arousal mechanisms likely accounted for these findings. Thus, augmentation of olfactory sensitivity was associated with increased arousal and greater left hemispheric integrated EEG activity, and olfactory sensitivity attenuation was associated with decreased arousal and greater right hemispheric integrated EEG activity.

To better define this relationship, NAR was measured in eight right-handed male subjects every 15 min over 6 hours (Frye, Valle, and Doty, unpublished data). Olfactory sensitivity to phenyl ethyl alcohol and subject response bias were measured using a signal detection paradigm. The perithreshold odor concentration was determined by a unilateral olfactory threshold test preceding the study; the contralateral nostril was blocked during odorant sampling. The nasal cycle and unilateral NAR were also measured. The left dominant phase of the nasal cycle was associated with increased and decreased subject response bias for odors presented to the right and left sides of the nose, respectively. Since asymmetrical changes in integrated hemispheric EEG activity are correlated with the nasal cycle, and most of the olfactory bulb's efferents project unilaterally, interhemispheric alteration in decision processing associated with olfactory recognition may explain this finding.

### 16.4.3 Modeling Approach to Understanding Odorant Deposition and Uptake

The absorption of airborne chemicals into the nasal mucus layer, which marks the initial step in the olfactory process, depends on the interplay of several factors, including airflow, diffusion, and solubility of the chemicals in mucus (Mozell and Jagodowicz, 1973). Very few attempts have been made to directly measure the sorption of odorants in mucosa (Amoore and Buttery, 1978; Hornung et al., 1980, 1987b); rather, most efforts have been theoretical, computational, or inferred from particle deposition study.

**16.4.3.1 Theoretical Model.** Hahn et al. (1994) developed an odorant transport model that included aerodynamic transport of the odorant molecule through bulk and lateral flow mechanisms and local odorant sorption onto olfactory mucosa, as well as olfactory receptor interactions. The model predicted that increasing the flow rate would increase the perceived odor intensity for highly soluble odorants but decrease odor intensity for insoluble odorants. These predictions match several experimental studies. However, if given a substantial decrease in mucus surface area for sorption, the model would predict that perceived

odor intensity would decrease for all odorants regardless of the solubility, which matches electrophysiology recordings in bullfrogs (Mozell et al. 1991).

**16.4.3.2 Particle Deposition and Uptake.** As noted in Chapter 20, particle deposition in the olfactory region may have additional health concerns because some particles can bypass the blood-brain barrier through the olfactory nerve tract (Oberdorster et al., 2004). However, significant differences exist in the mechanism of particle versus odorant deposition. Particle deposition often assumes perfect absorption (i.e., that any particle contacting the mucosa is permanently trapped), whereas odorants may be released into the air phase from the mucosa (Bocca et al., 1956). Particle transport is a function of particle size; for large, micrometer-size particles, inertial force and impaction play significant roles. In vivo experimental data suggested that an impact factor defined as  $\rho d^2 Q$  (where  $\rho$  is the particle density,  $d$  is the particle diameter, and  $Q$  is the volume airflow rate) correlates well with nasal deposition (see review Yu et al., 1998). This impact factor is equivalent to the Stokes force, which suggests that inertial impaction is indeed dominant over the diffusional or gravitational effects for the deposition of micrometer sized particles.

However, most odorants are in the nanometer range, and for nanoparticles diffusion dominates the deposition mechanism. Cheng et al. (1996b), using nanoparticles ranging from 4 to 150 nm in 10 subjects at flow rates of 167 ml/s and 333 ml/s, showed that the deposition is higher for subjects with smaller mean CSA, larger total surface area, and/or larger mean perimeter. In vitro studies of nanoparticle deposition in replicas from CT or MRI scans or from casts of cadavers have also been conducted by many researchers (Cheng et al., 1988, 1993, 1996a; Cheng, 2003; Gradon and Yu, 1989; Guilmette et al., 1994; Yamada et al., 1988; Kelly et al., 2004), the results of which are in general agreement with in vivo results. Based on these data, Cheng (2003) further developed an empirical equation for the nanoparticle deposition in the nasal cavity based on the Reynolds number, Schmidt number ( $Sc = \nu/D$ , where  $D$  is the diffusivity of the particles and  $\nu$ , air viscosity), and the ratio of average CSA to the surface area of the nasal passage (see Cheng, 2003, eq. 12). Despite abundant experimental data on this topic, no data were available for deposition specifically in the olfactory region for either micro or nanometer particles, which necessitates computational approaches.

**16.4.3.3 Computational Studies on Odorant Sorption.** Computational approaches offer a way to theoretically study airflow and odorant transport to the olfactory region. Computing nanoparticle transport often involves the same equations as odorant transport—in

other words, nanoparticles are treated as a gas without inertial impaction. Thus, previous validation of computational nanoparticle transport can serve as validation of the methodology.

Keyhani et al. (1997) were among the first to investigate inspired odorant molecule transport and uptake onto the nasal and olfactory mucosa based on an anatomically accurate computational nasal model. Assuming quasi-steady state and laminar flow, total odorant flux was calculated as a function of several transport parameters, including odorant solubility and diffusivity in the air and in the mucosal lining and the thickness of the mucus layer. Odorant flux increased with inlet flow rate in a nonlinear fashion and depended on odorant solubility. For example, fractional flux decreased for poorly soluble odorants and increased for highly soluble odorants. Odorant flux decreased along the olfactory slit from anterior to posterior and from inferior to superior, with this gradient being dependent on odorant mucus solubility. Thus, different odorants generated discernibly different flux patterns across the olfactory mucosa, confirming previous predictions (Mozell et al., 1987).

Given that the human olfactory cleft receives a relatively small distribution of total airflow, it is often assumed that it may be sensitive to anatomical changes. Zhao et al. (2004) computationally demonstrated that small perturbations in olfactory cleft volume significantly changed airflow to the olfactory region but did not affect NAR. Change in regional airflow rates in the olfactory region also effected odorant absorption, especially for odorants with higher mucosal solubility (*-carvone*) and higher air diffusivity (methanol) as compared to odorants with low-solubility (*d-limonene*).

Applying CFD to the clinical setting, Zhao et al. (2006b) compared pre- and postpolypectomy CT scans in a patient with nasal polyps. Preoperative endoscopy revealed polyps within the olfactory cleft and along the middle turbinate in a patient complaining of nasal obstruction and anosmia. After bilateral endoscopic sinus surgery and polypectomy, CFD analysis revealed decreased overall airflow resistance and an increase in airflow to the middle and superior nasal cavities in the olfactory cleft region, with improved delivery of a highly soluble odorant (phenylethyl alcohol) at a rate greater than 1000 times what was seen preoperatively. These findings correlated with the patient's postoperative recovery of odor detection threshold to that same odorant. However, beyond this case report, few studies have directly related CFD findings to olfactory function either in healthy subjects or in clinical populations.

No direct measurement of odorant sorption in human nasal cavity has been reported. However, in one interesting attempt to combine CFD with an experimental approach (Kurtz et al., 2004), odorants of various solubilities were pumped into one nostril and out of the other, while healthy

subjects performed velopharyngeal closure. The study measured the fraction of odor retained by the nasal passage at different flow rates, which depends on odorant solubility, and demonstrated good agreement with Mozell's early olfactory nerve recordings in animals. The experiments were then replicated computationally with a published CFD model, and calibrated several unknown parameters (odorant diffusivity and mucosa permeability), which were then applied to other odorants of unknown mucosa solubility. While not able to directly measure odor sorption, this study serves as initial validation and confirmation of the functional relevance of CFD approaches.

#### 16.4.4 Summary

In summary, the clinical and empirical studies reviewed in this section provide insight to the relationship between olfaction and nasal airflow and NAR in humans, particularly in clinical populations. Studies from the laryngectomy population demonstrate that a certain amount of nasal airflow is necessary for sufficient quantities of odorants to be delivered to the olfactory cleft, whereas clinical, experimental, and computational studies demonstrate that airflow specifically to the olfactory cleft is important for odorant perception. Both experimental studies examining the relationship between nasal volume and olfaction and computational studies artificially modifying regional nasal volume also suggest that areas of the nose remote from the olfactory cleft can be important for directing airflow upward toward the olfactory cleft.

However, the application of information does not easily translate to clinic relevance. Even though studies suggest that surgical or medical intervention can improve olfaction, success is uncertain. It is difficult to predict which patients will or will not experience restoration of olfactory function following intervention. Nasal sinus disease associated with swelling of the superior nasal cavity likely obstructs airflow to the olfactory region, while disorders associated with the inferior turbinate or nasal septum presumably redistribute the airstream within the nasal cavity. However, airflow obstruction is only one mechanism of olfactory dysfunction, and changes in the olfactory epithelium due to inflammatory processes, may also have significant effects. Clearly, disorders such as rhinitis can influence olfactory function through inflammatory processes and treatment for such disorders may influence olfactory function through factors other than nasal airflow. Currently, most clinical studies perform only simple statistical analyses and use convenient rather than well-stratified samples. Clearly, more sophisticated studies are needed to account for these multiple factors, and more sophisticated analyses will help determine the contribution of each of the pathological factors to olfactory dysfunction.

Several inconsistencies and differences within the clinical studies reviewed above are important to note. Many studies suggest that, following surgery, olfactory thresholds, but not measures of odor identification, improve (Shin et al., 1999), whereas other studies claim that odor identification improves more than olfactory thresholds (Damm et al., 2003). Studies have also pointed out that quantitative and qualitative olfactory measures do not correlate (Shin et al., 1999). Computational (Keyhani et al., 1997) and animal studies (Mozell and Jagodowicz, 1973) have suggested that not all odorants follow the same airflow distribution and that changes in airflow likely affect high- more than low-mucosal-solubility odorants. However, few clinical/human studies have carefully employed odorant sorptive properties in their test designs, which may contribute to the different outcomes due to the different odorants employed.

Many studies have used anterior rhinomanometry and acoustic rhinometry to study nasal airflow and NAR. These techniques have their own limitations. For example, NAR and/or nasal airflow and subjective symptoms of nasal patency correlate well in the presence, but not the absence, of symptoms (Andre et al., 2009). Both techniques index global nasal airflow/airway properties, which may not reflect regional flow or delivery of odorants to olfactory epithelium, as shown by several CFD studies. Thus, they may be unable to mechanistically separate the confounding factors due to either nasal airflow or inflammatory processes among clinical populations. Finally, it may be advantageous to introduce techniques that are very specific to the olfactory cleft into clinical studies, such as the use of the CFD technique (Zhao et al., 2006b). However, such an approach at this time remains investigational, with applications mostly in case studies, due to the technical challenges.

## 16.5 ANIMAL STUDIES: IMPLICATIONS FOR HUMANS

Although this review focuses on humans, data from animal experiments, especially from rodents, are far more abundant and greatly advance our understanding of olfactory system in general. However, the differences in nasal anatomy across species are substantial (Negus, 1958) and most terrestrial mammals have much more complicated nasal anatomy than do humans. The turbinates in animals often consist of more intricate and convoluting scrolls and plates of thin bones, which diverge odorant-carrying airflow into complicated channels and circulations with varying speeds, turbulence, and directions. In this regard, Adrian (1950) postulated the existence of odorant-dependent spatiotemporal patterns at the level of the olfactory mucosa

that corresponded to each odorant's value of some physicochemical property. This notion was confirmed by Mozell et al. (1973, 1987), who showed that different odorants flowing across the mucosa do indeed produce different spatiotemporal patterns of neural activity, with this effect strongly influenced by airflow rate, depending on the solubility of the odorants (Mozell et al., 1991). This differential absorption process was even considered analogous to gas chromatography (Mozell and Jagodowicz, 1973). While early studies by Mozell's group were mostly in bullfrogs and salamanders, amphibians with simple nasal structures, later electroolfactogram (EOG) recordings in rodents confirmed the existence of such patterns (Scott et al., 1997, 2000; Scott and Brierley, 1999).

On the other hand, studies (Kauer and Moulton, 1974; Mackay-Sim et al., 1982) have demonstrated the existence of intrinsic spatial neural activity patterns that were independent of airflow constraints. Moulton (1976) coined the terms "imposed" and "inherent" patterns to differentiate the two mechanisms for odorant-induced mucosal spatial patterns. With the identification of the olfactory receptor gene family (Buck and Axel, 1991), several investigators (Ressler et al., 1993; Strotmann et al., 1994; Vassar et al., 1993) have identified different aggregated receptors zones spatially extending anteroposteriorly throughout the rat olfactory mucosa.

Experimentally quantifying the absorption process in species with more complex nasal structures is difficult. A few successful efforts have relied on the computational approach. Rodent CFD models have shown that the airflow through the nose is laminar, with a central recess of the olfactory region where airflow is high and larger lateral region where the airflow is substantially lower (Kimbell et al., 1997; Yang et al., 2007; Jiang and Zhao, 2010). Consequently, the high-solubility odorants are readily absorbed in the central zone, whereas low-solubility odorants are absorbed more laterally, due to lower flow speed and much larger surface area in the lateral region (Yang, 1999; Zhao et al., 2006a). With increased sniffing flow rate, the absorption of high-solubility odorants increases, whereas the sorption of low-solubility odorants remains unchanged or even decreases as a fraction of total inhaled odorant molecular number, which matches what Mozell described earlier (Mozell et al., 1991). Furthermore, it is interesting to note that the contours of the flow and absorption patterns in these models correspond roughly to the longitudinal mapping zones of receptor genes (Strotmann et al., 1994; Yang et al., 2007). This further implies a structure-function optimization, extending Mozell and colleague's chromatography analogy, that at least in rodents, both imposed and inherent (neuron distribution) patterning may be utilized to optimize odor perception: the turbinate structure distributes the incoming odorants to different mucosal regions based on their physiochemical properties

and aerodynamics where types of receptors that are more sensitive to or better discriminative of those odorants might be located (Yang et al., 2007); reviewed by Schoenfeld and Cleland, 2005, 2006). Computational studies also showed that, proportionally, the inspiration airstream penetrates more into the olfactory region than does the expiration airstream (Zhao et al., 2006a; Yang et al., 2007). This lack of reversibility may trap inhaled air and odorants in the rat olfactory region, which is not immediately washed out on exhalation; this is likely a very important aspect of the airflow in the rat sniffing strategy and allows odorants to be retained longer in the complex ethmoid air spaces, where they have longer contact with olfactory receptors on the epithelium. It has long been noticed that rodents employ complex and precise motor regulation of sniffing behaviors during odor tasks (Youngertob et al., 1987; Wesson et al., 2008). The latest study in dogs (Lawson et al., 2012) has shown a similar, although more complex, lateral turbinate structure as that of rodents, however, the central (dorsal medial) channel and different inspiration vs expiration flow are conserved, which further implicate its potential functional role.

The spatial and temporal activation patterns at the olfactory epithelium are important because they reflect the first event where odor information is represented in the neural system. Such patterns may directly affect the activation pattern in the secondary neural circuits, as epithelial neurons converge to the olfactory bulb in an organized fashion. A number of studies have used various techniques, such as 2-deoxyglucose mapping (Johnson and Leon, 1996), calcium signals (Verhagen et al., 2007), functional MRI (Xu et al 2003), and electrophysiology (Shusterman et al., 2011), to investigate the importance of temporal and spatial patterns in the olfactory bulb during active sniffing. However, the spatial temporal pattern at the epithelial level as a function of nasal structure, aerodynamics, and sniffing parameters remain relatively understudied.

The human olfactory structure appears to diverge evolutionary compared with many other land mammals: the human turbinate structure is much simpler, and the olfactory epithelium is confined to a relatively small patch with fewer functional receptor genes. Sniffing behaviors in humans are much different than those of rodents or dogs. Whether there is a zonal distribution of human receptor genes and whether there are stable organized absorption patterns is unknown. For example, Zhao et al. (2004) has shown completely different absorption patterns between the two sides of the nasal cavity of the same healthy subject. It may be debatable whether our olfactory acuity is poorer than that of other species (Shepherd, 2004); however, these features are likely the reason that our olfactory abilities, relative to other species, may be far more prone to disruption by even small nasal anatomical changes (whether disease, developmental, or surgical,

etc.) that may restrict odorant access to the limited patch of olfactory epithelium. The differences in airflow and odor sorption patterns need to be seriously considered when translating results from animal model to human and addressing the clinical problems that may be unique to the human nose. Nevertheless, this should not deter our efforts to protect our sense of smell, which often offers us priceless enjoyment from food, flavor, and natural and man-made fragrances and, most essentially, provides early detection of environmental hazards.

## 16.6 NASAL PATENCY: HOW WE PERCEIVE NASAL OBSTRUCTION

“Nasal patency” can be either objective or subjective—objective nasal patency often refers to measured NAR, which can be effectively measured with rhinometry. Subjective nasal patency is the self-reported perception of nasal congestion or nasal obstruction, which is often more important to patients with nasal sinus disease than the objective one. In general, anterior defects are more symptomatic, both subjectively and objectively, although posterior nasal airway obstruction does cause airflow and symptomatic changes: Adenoid hypertrophy decreases nasopharyngeal CSA (Cho et al., 1999; Mostafa, 1997).

Nevertheless, it is the perception of a lack of nasal patency that drives these patients to seek medical treatment. More surprisingly, this subjective perception often bears little relationship to the actual physical resistance to airflow in the nose (NAR). Objective evaluation tools, such as acoustic rhinometry, rhinomanometry, CT staging scores, and endoscopic examination, provide inconsistent correlation with subjective patency (Lam et al., 2006; André et al., 2009), even though these objective tools often correlate well with each other. In general, the correlation seems better in studies examining unilateral measurements, and in patients with higher baseline NAR and/or symptoms, and following large modifications in nasal lumen size (reviewed by Andre et al., 2009). The lack of a reliable objective tool to index perceived nasal patency creates a significant clinical problem in the diagnosis and treatment of nasal obstructive symptoms, which are currently based mostly on patient subjective feedback and clinician’s experience.

### 16.6.1 Potential Mechanisms of Nasal Flow Perception

The perception of nasal patency may involve nasal trigeminal activation by the cool inspiratory airflow rather than by NAR or effort in breathing alone. Mucosal temperature, as measured by noncontact infrared thermometry, is correlated with subjective nasal patency (Willatt, 1993; Willatt and Jones, 1996). The thermal perception is possibly

mediated by TRPM8 channels expressed in trigeminal C-fiber or A- $\delta$  fiber endings such as those that innervate nasal epithelium (Lumpkin and Caterina, 2007). Pharmacological modulation of trigeminal feedback has been shown to alter patency perception. For example, topical or oral application of L-menthol produces the illusion of decongestion and improved nasal airflow without actually altering NAR (Eccles and Jones, 1983). In contrast, topical application of local anesthetics on the nasal epithelium results in an artificial sensation of nasal obstruction, presumably due to blockage of the trigeminal feedback (Jones et al., 1987). L-Menthol was widely used as an ingredient in common cold medications, nasal spray, candy, chewing gum, and cigarettes long before its target receptor, the nonselective voltage-dependent cation channel TRPM8, was identified (McKemy et al., 2002; Peier et al., 2002). It is now known that menthol and air temperature both shift TRPM8 voltage-activation dependency toward the physiological range, and their effects are additive (Voets et al., 2007). Thus, when combined, menthol and cool air can greatly enhance TRPM8 activation.

In the human, the palatine nerve (a branch of V2) innervates the turbinates and nasal septum, while the ethmoid nerve (a branch of V1) innervates the vestibule. However, the sensitivity of the nose to an air jet pulse and to temperature changes is greatest at the nasal vestibule (Clarke and Jones, 1994; Clarke and Jones, 1992), which suggests that regional aerodynamics and thermo-events might be more functionally important than overall NAR or thermo-exchange.

To further delineate the physical factors contributing to the perception of patency, a recent study asked 44 healthy subjects to rate their nasal patency while sampling untreated room air, cold air, and dry air (Zhao et al., 2011). The results indicate that both dry and cold air induce less perceived nasal obstruction compared to room air. Since the dry and room air did not differ statistically in temperature, the perceptual difference most likely resulted from differential mucosal cooling—the combination of both conductive heat loss (driven by temperature gradient) and evaporative heat loss (driven by water vapor pressure gradient), rather than from static air temperature alone.

Although there has been no direct documentation on alteration of trigeminal afferents during nasal sinus disease and/or inflammation processes, the literature does support the notion that trigeminal senses in general may undergo different adaptive processes during acute or prolonged inflammation. Chronic occupational exposure to irritants such as acetic acid or acetone specifically decreases trigeminal sensitivity to those chemicals (Dalton et al., 2007; Wysocki et al., 1997), whereas conditions such as allergic rhinitis, leading to inflammation in the nasal mucosa, are associated with greater sensitivity to nociceptive stimuli such as CO<sub>2</sub> and acetic acid (Shusterman et al., 2003;

Shusterman and Murphy, 2007). Benoliel et al. (2006) have shown that warm and electrical current perception thresholds were hypersensitized during the acute phase of rhinosinusitis but hyposensitized during chronic (>3 months) rhinosinusitis.

Based on these studies, it is clear that we may need to drastically change how we view the perception of nasal obstruction. A constricted airway with an insufficient airstream, as we often think about with physical nasal obstruction, produces less cooling. However, wide nasal passages with the bulk of the airstream having little contact with the mucosal wall may also produce less mucosal cooling. Thus, nasal airway abnormalities may have diverse clinical manifestations in a patient's subjective symptoms, depending on the mucosal/airflow interaction and the patient's thermosensory sensitivities, which may also undergo diverse changes during disease processes. Clinical evidence include the “empty nose” or “atrophic rhinitis” syndrome, in which patients with complete turbinate removed may still complain of the perception of nasal congestion, despite exhibiting very little objective NAR (Moore et al., 1985). Still, other, potential factors may also contribute to perceived patency. For example, the nonspecific cation channel TRPA1, which is activated at much colder (noxious) temperatures than the mechanosensors, could contribute to the sensation of patency. In addition, aging does affect nasal mechanosensitivity (Wrobel et al., 2006). TRMP8, TRPA1, and mechanoreceptors can be activated chemically, which offers a unique dual investigatory tool that has the potential to enhance our understanding of chemosensory functions in nasal/inflammatory disease.

## 16.7 CONCLUSIONS: AIRFLOW DYNAMICS IN RELATION TO CHEMOPERCEPTION

Nasal airflow in the human is complex and subject to both intersubject and intrasubject variability. Turbulent flow is likely present at higher sniffing rates and contributes to mixing of odorant molecules and the proper humidification and filtering of the incoming air. Although Reynolds numbers are not indicative of turbulent flow, such flow may develop in the expanded post nasal valve region during inspiration. Disorders within this region may alter vortices and turbulent flow by redirecting airstreams and augmenting nasal resistance. However, turbulence prior to reaching the olfactory cleft may not be particularly important since secondary air currents and diffusion across the boundary layer are probably dominant in the olfactory cleft during inspiration. Instead, inspiratory airflow velocity and volume flow may have a major influence on odorant deposition and the proportion of odorized air transported to the olfactory region. Under some circumstances, humans may

adjust their sniff durations to optimize odorant perception (Sobel et al., 2000). Airflow rate is positively correlated with odor intensity (Rehn, 1978), the number of odorants identified in a confusion matrix (Schwartz et al., 1987), and the magnitude of the olfactory evoked potential (Kobal and Hummel, 1991). The expiratory airstream exhibits higher velocities and a more direct path to the olfactory regions than the inspiratory airstream in humans, which is contrary to rodents. While animal studies provide important insight into the human olfactory system, nasal structural and airflow differences must be taken into account.

In the clinical setting, it is widely believed that conductive airway abnormalities are responsible for some olfactory losses; however, conclusive evidence is lacking. Endoscopic operative procedures, septoplasty, turbinoplasty or adenoidectomy can improve nasal airflow and olfactory function. Nonetheless, many patients do not experience restoration of olfactory function following such interventions. Since only a small percentage of air flows through the olfactory region, abnormalities and subsequent surgery, while profoundly affecting NAR, may or may not have the same effect on delivery of odorant to the olfactory cleft. It is also likely that airflow obstruction only accounts for a subset of alterations in olfactory perception, while inflammatory processes may affect the olfactory neuroepithelium. The lack of correlation of olfactory function with changes in nasal airflow and the many factors besides nasal airflow that affect olfactory function make management of olfactory dysfunction complicated.

The clinical implications of changes in nasal airflow are clearly important but differences in the perceived vs measured nasal airflow create complexity when treating symptoms. Hopefully the studies reviewed in this chapter will be of future help, in advancing our understanding of the relationship between nasal airflow and olfactory function.

# Chapter 17

---

## Clinical Disorders of Olfaction

RICHARD L. DOTY

### 17.1 INTRODUCTION

Chronic olfactory dysfunction is not uncommon, being present in 1–2% of the population under the age of 65 years and in well over half the population older than 65 years (Doty et al., 1984a; Hoffman et al., 1998; Murphy et al., 2002). Such dysfunction can profoundly influence a patient's safety and quality of life. In a study of 750 consecutive patients presenting to our center with chemosensory complaints, 68% reported altered quality of life, 46% changes in appetite or body weight, and 56% adverse influences on daily living or psychological well-being (Deems et al., 1991). In another study of 445 such patients, at least one hazardous event, such as food poisoning or failure to detect fire or leaking natural gas, was reported by 45.2% of those with anosmia, 34.1% of those with severe hyposmia, 32.8% of those with moderate hyposmia, 24.2% of those with mild hyposmia, and 19.0% of those with normal olfactory function (Santos et al., 2004). In a longitudinal study of 1,162 non-demented older persons, mortality risk was 36% higher in those with low than with high scores on a 12-item odor identification test after adjusting for such variables as sex, age, and education (Wilson et al., 2010).

In this chapter I describe the olfactory deficits associated with a range of diseases and disorders, how they are classified, and how they are evaluated and treated. Since other chapters focus on olfactory dysfunction due to toxic chemical exposure (Chapters 19 and 20), nutritional disturbances (Chapter 37), and neurodegenerative diseases and schizophrenia (Chapter 18), these conditions are not specifically addressed in this chapter. The reader is referred to Chapter 39 for disorders of taste function, *per se*, that is, those that influence taste-bud mediated sensations.

### 17.2 CLASSIFICATION OF OLFACTORY DISORDERS

Olfactory disorders can be classified as follows: **Complete anosmia:** absence of smell function; **Partial anosmia:** ability to perceive some, but not all, odorants; **Hyposmia or microsmia:** decreased sensitivity to odorants; **Dysosmia** (also termed parosmia): distorted or perverted smell perception to odorant stimulation; **Phantosmia:** a dysosmia sensation perceived in the absence of an odor stimulus (a.k.a. olfactory hallucination); **Olfactory agnosia:** inability to recognize an odor sensation, even though olfactory processing, language, and general intellectual functions are essentially intact, as in some stroke patients; **Hypersmia:** abnormally acute smell function. **Presbyosmia** is sometimes used to describe smell loss due to aging, but this term is less specific than those noted above (e.g., it does not distinguish between anosmia and hyposmia) and is laden, by definition, with the notion that it is age, *per se*, that is causing the age-related deficit.

It should be noted that hypersmia is very rare and most persons claiming to be hypersensitive to odorants, such as those with “multiple chemical hypersensitivity,” in fact have normal olfactory thresholds (Caccappolo et al., 2000; Doty et al., 1988; Nordin et al., 2005). A number of such persons may suffer from environmental chemosensory responsibility (CR), a condition correlated with neuroticism (Karnekull et al., 2011). While complaints of dysosmia and phantosmia are often correlated with psychophysical test results, that is, lower test scores, the results of such tests cannot validate their presence. Nevertheless, these conditions are accompanied by enhanced brain activity in the anterior frontal cortex and temporal lobes, as determined

by functional imaging (fMRI) (Henkin et al., 2000; Levy and Henkin, 2000).

When possible, it is useful to classify olfactory impairment into three general classes: (1) conductive or transport impairments from obstruction of the nasal passages (e.g., by chronic nasal inflammation, polyposis); (2) sensorineuronal impairment from damage to the olfactory neuroepithelium (e.g., by viruses, airborne toxins); and (3) central olfactory neural impairment from central nervous system (CNS) damage (e.g., tumors, masses impacting on olfactory tract, neurodegenerative disease). However, such definitive classification is often not feasible, and these categories are not mutually exclusive. For example, both damage and blockage of airflow to the receptors can occur from chronic rhinosinusitis, and some viruses and nanoparticles that damage the olfactory neuroepithelium also can be transported into the CNS via the olfactory nerves, subsequently altering central elements of the system as well (see Chapters 19 and 20).

## 17.3 CLINICAL EVALUATION OF OLFACTORY DISORDERS

### 17.3.1 Medical History

The etiology of most cases of olfactory dysfunction can be ascertained from carefully questioning the patient about the nature, timing, onset, duration, and pattern of their symptoms, as well as a historical determination of antecedent events (e.g., head trauma, upper respiratory infections, toxic exposures, nasal surgeries). Fluctuations in function usually reflect obstructive, rather than neural, factors. Subtle symptoms of central tumors, dementia, tremor, and seizure activity (e.g., automatisms, occurrence of blackouts, auras, and *déjà vu*) should be sought, given the frequent association between smell dysfunction and not only brain tumors, but a range of neurological disorders, including neurodegenerative ones (see Chapter 18). Delayed puberty in association with some degree of smell loss, with or without midline craniofacial abnormalities, deafness, and renal anomalies, suggest the possibility of Kallmann syndrome or one of its variants (Lewkowitz-Shpuntov et al., 2012). Medications being used prior to or at the time of the symptom onset should be determined, as some may influence olfaction, although in most cases such effects are specific to taste, *per se* [e.g., antifungal agents, angiotensin-converting enzyme (ACE) inhibitors; see Chapter 38]. Medical conditions potentially associated with smell impairments should also be identified (e.g., liver disease, hypothyroidism, diabetes). A history of epistaxis, discharge (clear, purulent, or bloody), nasal obstruction, and somatic symptoms, including headache or irritation, as well as a report as to whether the problem

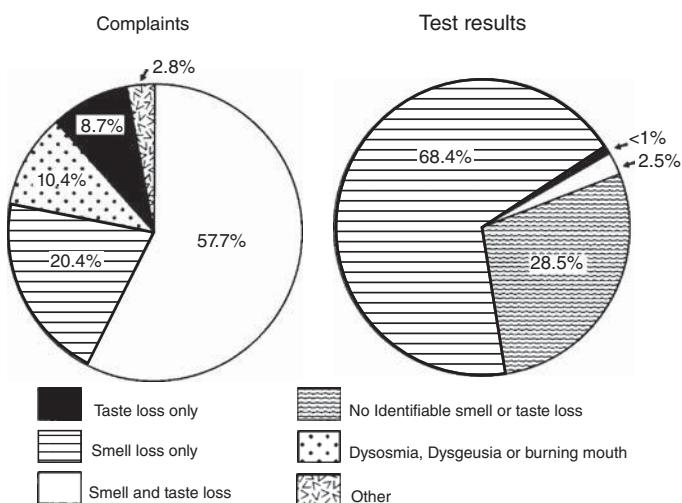

seems to be more prevalent on one side of the nose or the other, may be of localizing value. Idiopathic cases that present during winter months, which is not uncommon (Konstantinidis et al., 2006), suggest the possibility of a bacterial or viral origin, even if other elements of an upper respiratory infection are not present or recognized.

It is critical for the clinician to be aware that while patients often present with the complaint of taste loss, quantitative testing usually reveals only an olfactory problem (Deems et al., 1991), reflecting decreased retronasal stimulation of the olfactory receptors during deglutition (Burdach and Doty, 1987). Importantly, the clinician should be cognizant of the fact that combinations of causal factors may be present that need to be considered. For example, older persons and persons with allergies may be more susceptible than others to smell loss from viral and other causes because of previous cumulative damage to the olfactory epithelium.

Nasal endoscopy can assess the health of the nasal cavity, although complete visualization of the olfactory epithelium is not generally possible even with the use of rhinoscopes. Modern imaging techniques can detect inflammatory processes within the nose and sinuses, as well as brain lesions and the integrity of the olfactory bulbs, tracts, and cortical parenchyma (Chapter 13). As described later in this chapter, patients complaining of never having a sense of smell, that is, congenital anosmia, typically lack normal olfactory bulbs or tracts upon appropriate magnetic resonance imaging (MRI) (Yousem et al., 1996). Some laboratory tests (e.g., blood serum tests) are helpful in detecting underlying medical conditions suggested by history and physical examination, such as infection, nutritional deficiencies (e.g., vitamins B6, B12), allergy, diabetes mellitus, and thyroid, liver, and kidney disease. Visual acuity, visual field, and optic disc examinations can aid in the detection of possible intracranial mass lesions that, in addition to producing visual deficits, impinge upon the olfactory tract.

### 17.3.2 Quantitative Olfactory Testing and MR Imaging

A common error made on the part of clinicians is to accept a patient's self-report of sensory dysfunction and to fail to verify the presence or magnitude of the problem via tests, despite the commercial availability of such tests (Chapter 11). Many persons, particularly the elderly and those with dementia, are unaware of their dysfunction or are inaccurate in assessing its magnitude (Figure 17.1). Standardized quantitative olfactory testing allows, in most instances, for (1) the characterization of the nature and degree of the chemosensory problem, (2) establishing the validity of the patient's complaint, including the detection of malingering, (3) monitoring changes in function over

**Figure 17.1** Distribution of primary chemosensory complaints (left diagram) and test results (right diagram) in 750 consecutive patients who presented to the University of Pennsylvania Smell and Taste Center during the period extending from 1980 through 1986. Note that the complaint categories of smell loss, taste loss, and smell and taste loss include some patients with secondary complaints of chemosensory distortion and sensations of burning mouth. time, and (4) providing objective data for establishing disability compensation.

Although smell can be tested using psychophysical, electrophysiological, and psychophysiological procedures, only psychophysical tests are widely used, reflecting issues of cost, practicality, and utility (Chapter 11). Despite the fact that electrical activity can be directly measured from the olfactory epithelium (electro-olfactogram or EOG), this measure cannot be obtained from all patients, is variable, and is influenced by sampling issues. Moreover, many patients have difficulty tolerating electrodes placed in their non-anesthetized noses. Since a normal EOG is present in some anosmic patients and can be recorded even after death in animals, it cannot be used alone to define dysfunction. Unfortunately, the odor event-related potential (OERP), unlike auditory brainstem evoked potentials, sheds little light on localizing anomalies within the neural pathway. As noted in Chapter 12, however, recent advances in analysis and measurement of EEG waveforms may lead to broader application of these techniques within the clinic.

Some physicians, as well as lawyers seeking to denigrate psychophysical test results, divide sensory tests into “subjective” and “objective” categories. In this context, “subjective” usually refers to tests that require a conscious response, whereas “objective” refers to electrophysiological tests. Unfortunately, this dichotomy is misleading and laden with a value judgment, since objective always trumps subjective. As pointed out for audition by the Nobel laureate Georg von Bekésy 45 years ago, putative “subjective” tests can be more sensitive and reliable than putative “objective” tests (von Bekésy, 1968). Although it is presumed that “subjective” tests are easier to malinger than “objective” tests, forced-choice psychophysical tests can detect most malingering on the basis of improbable responses (Doty and Crastnopol, 2010). Moreover, so-called “objective” olfactory tests are not immune to malingering, since, for

example, reliable measurement of electrophysiological responses requires considerable subject cooperation, such as sitting very still during recording sessions.

Modern imaging procedures can now quantify, *in vivo*, the volume of the olfactory bulbs and other olfactory structures. Based on MRI measures, decreases in olfactory bulb volumes have been noted in older persons (Yousem et al., 1998) and in patients with Alzheimer’s disease (Thomann et al., 2009), head trauma (Collet et al., 2009; Doty et al., 1997c; Rombaux et al., 2006a; Yousem et al., 1995), idiopathic congenital smell loss (Croy et al., 2010; Yousem et al., 1996), Kallmann syndrome (Bajaj et al., 1993; Koenigkam-Santos et al., 2011; Yousem et al., 1993), multiple sclerosis (Schmidt et al., 2011), Parkinson’s disease (Brodoehl et al., 2012; Hummel et al., 2010; Kim et al., 2007), total laryngectomy (Veyseller et al., 2011), and viral-related smell dysfunction (Rombaux et al., 2006b). Patients with schizophrenia, as well as their first-order relatives, exhibit decrements in olfactory bulb size (Nguyen et al., 2011; Turetsky et al., 2000, 2003). Interestingly, one study reports that early blind persons have larger olfactory bulbs than sighted persons (Rombaux et al., 2010).

The clinical utility of volumetric measures is yet to be determined since, in most cases, correlations between the structure sizes and psychophysical test measures are moderate and the volume measures are dynamic and not disease specific. Currently standardization is lacking in defining morphological parameters to be assessed and considerable age-related variability in bulbar measures can be present in normal individuals (Yousem et al., 1998). That being said, a recent study has provided evidence that olfactory bulb volumes may have considerable prognostic value (Rombaux et al., 2012): no future improvement in olfactory function is likely in head trauma patients and patients with upper respiratory infection (URI)-related

smell loss whose olfactory bulb volumes are less than 40 mm<sup>3</sup>.

## 17.4 CAUSES OF OLFACTORY DYSFUNCTION

As can be seen in Table 17.1, there are many reported etiologies for olfactory disturbance. Approximately two thirds of cases of chronic anosmia or hyposmia (i.e., those which are presumably permanent) that present to a clinic are due

**Table 17.1** Agents, Diseases, Drugs, Interventions, and other Etiological Categories Associated in the Medical or Toxicological Literature with Olfactory Dysfunction

### Drugs

Adrenal steroids (chronic use)

Amino acids (excess)

Cysteine

Histidine

Analgesics

Antipyrine

Anesthetics, local

Cocaine HCl

Procaine HCl

Tetracaine HCl

Anticancer agents (e.g., methotrexate)

Antihistamines (e.g., chlorpheniramine malate)

Antimicrobials

Griseofulvin

Lincomycin

Macro!ides

Neomycin

Pencillins

Streptomycin

Tetracyclines

Tyrothricin

Antirheumatics

Mercury/gold salts

D-Penicillamine

Antithyroids

Methimazole

Propylthiouracil

Thiouracil

Antivirals

Cardiovascular/hypertensives

Gastric medications

Cimetidine

Hyperlipoproteinemia medications

Artovastatin calcium (Lipitor)

Cholestyramine

Clofibrate

Intranasal saline solutions with:

Acetylcholine

Acetyl, β-methylcholine

**Table 17.1 (Continued)**

Intranasal saline solutions with: (Cont.)

Menthol

Strychnine

Zinc sulfate, gluconate

Local vasoconstrictors

Opiates

Codeine

Hydromorphone HCl

Morphine

Psychopharmaceuticals (e.g., LSD, psilocybin)

Sympathomimetics

Amphetamine sulfate

Fenbutrazate HCl

Phenmetrazine theoclinate

### Endocrine/Metabolic

Addison's disease

Congenital adrenal hyperplasia

Cushing's syndrome

Diabetes mellitus

Froelich's syndrome

Gigantism

Hypergonadotropic hypogonadism

Hypothyroidism

Kallmann's syndrome

Pregnancy

Panhypopituitarism

Pseudohypoparathyroidism

Sjogren's syndrome

Turner's syndrome

### Industrial Dusts, Metals, Volatiles

Acetone

Acids (e.g., sulfuric)

Ashes

Benzene

Benzol

Butyl acetate

Cadmium

Carbon disulfide

Cement

Chalk Chlorine

Chromium

Coke/coal

Cotton

Cresol

Ethyl acetate

Ethyl and methyl acrylate

Flour

Formaldehyde

Grain

Hydrazine

Hydrogen selenide

Hydrogen sulfide

Iron carboxyl

Lead

Manganese

**Table 17.1 (Continued)****Industrial Dusts, Metals, Volatiles (Cont.)**

Mercury  
Nickel  
Nitrous gases  
Paint solvents  
Pepper  
Peppermint oil  
Phosphorus oxychloride  
Potash  
Silicone dioxide  
Spices

to prior upper respiratory infections (URIs), head trauma, and nasal and paranasal sinus disease (Deems et al., 1991), and most can be expected to reflect significant damage to the olfactory neuroepithelium (Holbrook et al., 2005). Major causes of smell loss, save those due to neurodegenerative diseases and schizophrenia (Chapter 18), are described below.

#### 17.4.1 Upper Respiratory Infections

Although rarely appreciated, the most frequent cause of *chronic* and often permanent loss of smell in the adult is an URI. URIs that produce olfactory loss include those as

ones associated with the common cold, influenza, pneumonia, or human immunodeficiency virus (HIV) (Akerlund et al., 1995; Deems et al., 1991; Hummel et al., 1998a). Often the respiratory illness is described as being more severe than usual and, in many cases, dysosmia or phantosmia is present for some period. Usually the dysosmia, which is generally associated with at least some smell function, subsides over time, often leaving the patient with a noticeable olfactory deficit, most commonly anosmia. It should be noted that most viral infections are either entirely asymptomatic or are so mildly symptomatic that they go unrecognized (Stroop, 1995). Thus, during seasonal epidemics, the quantity of serologically documented infections of influenza or arboviral encephalitis exceeds the number of acute cases by several hundredfold, raising the possibility that many unexplained cases of smell dysfunction are due to unrecognized viral infections.

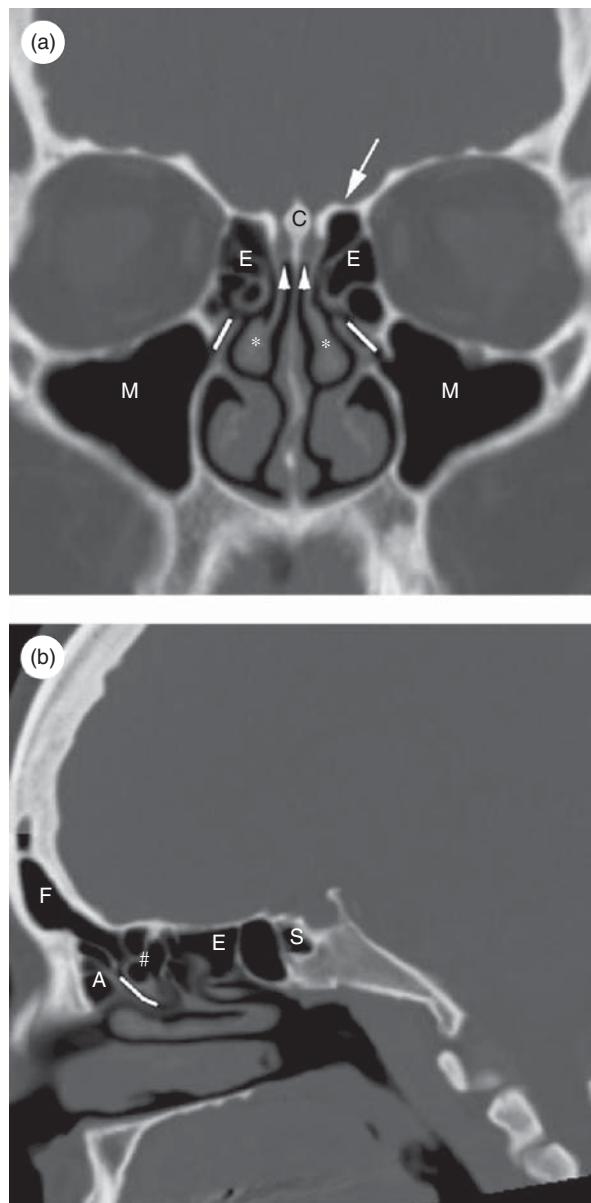

Exactly what predisposes someone to viral or bacterial-induced smell dysfunction or the mechanisms underlying it remains unclear. Most such losses become manifest in middle or older age, suggesting the potential importance of cumulative insult and the challenge of regeneration of the neuroepithelium in advancing age when proliferation of basal cells and immature neurons is significantly reduced (Loo et al., 1996). Direct insult to the olfactory neuroepithelium is presumably the primary basis of the problem in URIs, as biopsy studies of olfactory epithelia from patients with post-URI anosmia evidence extensive cicatrization, decreases in receptor cell number, absent or decreased numbers of cilia on remaining receptor cells, and the replacement of sensory epithelium with respiratory epithelium (Douek et al., 1975; Jafek et al., 1990b; Yamagishi 1988; Yamagishi et al., 1994). As noted in Chapters 19 and 20, many viruses have the capability of invading the CNS via the olfactory neuroepithelium, and some may damage the olfactory bulb and other central structures in addition to, or independent of, peripheral damage to the olfactory epithelium (Doty, 2008).

Recent data suggest that susceptibility to URIs is influenced by the presence of T2R38 receptors within the respiratory mucosa (Lee et al., 2012). While T2R receptors were first discovered in the taste system and are known to transduce bitter tastes via taste buds, they are also found in both the upper and lower respiratory epithelia of humans (Shah et al., 2009) where they regulate nitric oxide (NO) excretion and increase intracellular Ca<sup>2+</sup> and ciliary beat frequency (Jain et al., 1993). NO, which is released at high levels into nasal cavity and the paranasal sinuses, has antimicrobial properties and plays a critical role in defending against respiratory infections. In patients with chronic rhinosinusitis, nasal levels of NO are positively correlated with olfactory threshold sensitivity (Elsherif et al., 2007).

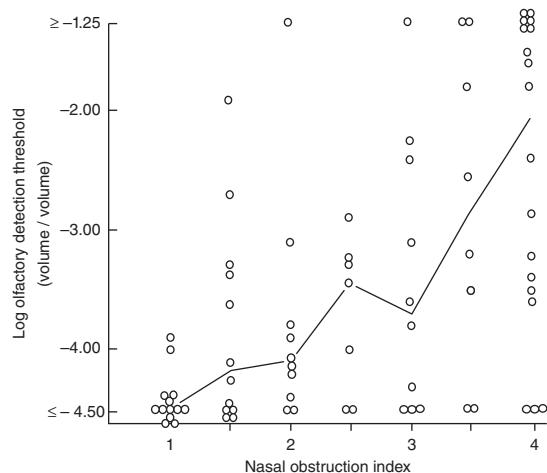

### 17.4.2 Nasosinus Disease and Disorders Associated with Nasal Obstruction

Olfactory impairment that accompanies most nasosinus diseases has been traditionally viewed as being solely conductive, altering the normal airflow into the olfactory meatus, a very small cleft located in the superior sector of the nose. This narrow cleft is evident in a computerized tomography (CT) scan which also shows the general anatomy of the nose and paranasal sinuses (Figure 17.2). Although marked airflow blockage, particularly secondary to polyps, diminishes the olfactory function of some patients, surgical interventions or the administration of systemic or topical steroids often fails to return function to normal, as measured by quantitative tests. In many cases, airway blockage alone cannot completely explain the olfactory loss, and inflammatory infiltrates may alter olfaction in the absence of mucosal hypertrophy (for reviews, see Dalton, 2004; Doty and Mishra, 2001). While, in general, olfactory dysfunction is related to the severity of the rhinosinusitis [e.g., in one study, the mean scores on the University of Pennsylvania Smell Identification Test (UPSIT; see Chapter 11) were 35, 31, 26 and 23 for Kennedy Stages I to IV of the disease, respectively (Downey et al., 1996)], the defining factor may be, in fact, the severity of histopathological changes within the olfactory mucosa (Jafek et al., 1987). Kern (2000) found such severity to be related to olfactory test scores in patients with chronic rhinosinusitis. Moreover, biopsies from the olfactory mucosal region of patients with nasal disease are less likely to yield olfactory-related tissue than such biopsies from controls (Feron et al., 1998). The same is true for anosmic vs. nonanosmic rhinosinusitis patients, the former of whom exhibit a more pathological epithelium (Lee et al., 2000; Yee et al., 2010). This hypothesis is further supported by findings of weak or no associations between olfactory test scores and measures of nasal airway patency (save severe blockage), whether measured by rhinoscopy, rhinomanometry, or acoustic rhinometry (Apter et al., 1999; Cowart et al., 1993; Nordin et al., 1998; Scott et al., 1988).

**17.4.2.1 Hypertrophied Adenoids.** Hypertrophied adenoid tissue can significantly block the nasal airflow of children whose airways are otherwise patent. In general, nasal resistance decreases by 20–40% following adenoidectomy (Crysdale et al., 1985; Fielder, 1985). Olfactory thresholds to phenyl ethyl alcohol measured in children with varying degrees of nasal obstruction are directly related to clinical ratings of obstruction (Figure 17.3) and improve after adenoidectomy (Figure 17.4) (Delank, 1992; Ghorbanian et al.,

**Figure 17.2** **a.** Normal sinus anatomy. Coronal computed tomographic (CT) image of the paranasal sinuses (a). The paired maxillary sinuses (M) drain through the maxillary infundibulum (white lines) into the middle meatus. Along the medial margin of the infundibulum is the uncinate process. Ethmoid air cells (E) are present on both sides, between the lamina papyracea laterally and the vertical lamella medially. The middle turbinates (\*) are attached to the anterior skull base by the vertical lamella. The crista galli (C) lies in the midline between the two sides of the cribriform plate (arrowheads). The vertical lamella (arrow) is slightly elevated relative to the crista galli, and is separated by the intervening lateral lamella. **b.** Sagittal CT of the paranasal sinuses shows the frontal sinus (F), which is drained by the frontal recess (white line). Anterior and inferior to the frontal recess is the agger nasi air cell (A), and along its posterior superior margin is the ethmoid bulla (#). The sphenoid sinus (S) is located posterior to the ethmoid air cells (E). Reprinted with permission from Mossa-Basha and Blitz (2013). Copyright © 2013 Elsevier, Inc.

1983). Such improvement is particularly evident for retronasal olfactory function (Konstantinidis et al., 2005).

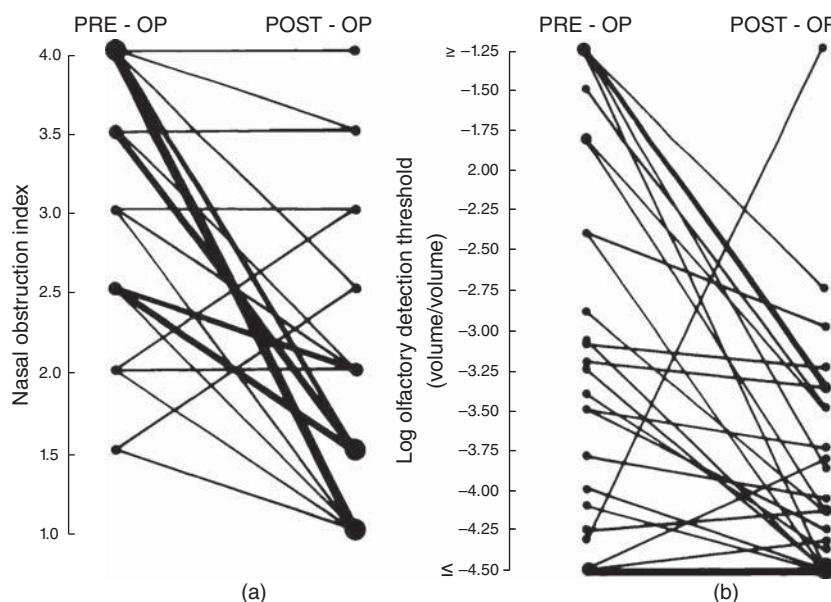

#### 17.4.2.2 Acute Viral-Related Rhinosinusitis.

Several studies have measured olfaction longitudinally following the onset of the common cold. Akerlund et al. (1995) assessed 1-butanol odor-detection thresholds in student volunteers before and four days after nasal inoculation with the coronavirus 229E. The nine students who developed a cold had elevated olfactory thresholds on the

post-inoculation test relative to the controls—impairment that correlated with nasal congestion but not nasal discharge. Hummel et al. (1998b) evaluated smell function and nasal patency in 18 women and 18 men at the time of onset of a natural cold as well as 2, 4, 6, and 35 days thereafter. The cold produced a decrease in the volume of the anterior nasal cavity and increased mucus secretion, heightened olfactory thresholds, lowered odor intensity ratings, and decreased the amplitude of the odor event-related potential to both olfactory and trigeminal stimuli. Even when airway patency was normal and mucus secretion was minimal, evoked potential amplitudes to olfactory stimuli were still depressed, supporting the concept that URIs may influence olfactory function independently of nasal congestion.

#### 17.4.2.3 Acute and Chronic Rhinosinusitis.

The first large-scale empirical study of the influences of allergic rhinitis on olfactory function was that of Cowart et al. (1993). Detection thresholds to phenyl ethyl alcohol were obtained from 91 patients with symptoms of allergic rhinitis and from 80 non-atopic controls. The allergy patients exhibited greater dysfunction than the controls, with 23% having a threshold at or above the 2.5th percentile of the controls. Clinical or radiographic evidence of rhinosinusitis or nasal polyps or both was associated with hyposmia in the allergy patients: 14% with no associated rhinosinusitis exhibited hyposmia, whereas 43% with associated rhinosinusitis did so. Similar general observations have been noted by others (Apter et al., 1992; Golding-Wood et al., 1996a; Guss et al., 2009; Kondo et al., 1998; Litvack et al., 2008; Mott et al., 1997; Paparo et al., 1996; Rydzewski et al., 2000; Simola and Malmberg, 1998). Interestingly, there are cases in which the

**Figure 17.4** Nasal obstruction index (a) and phenyl ethyl alcohol olfactory detection threshold values in 28 children before and after adenoidectomy. Larger negative threshold values indicate better odor detection. Each line joins preoperative and postoperative values for each subject. Heavy lines denote confluence of several subjects who had same preoperative detection threshold score. Reprinted with permission from Ghorbanian et al. (1983). Copyright © 1983 American Academy of Pediatrics.

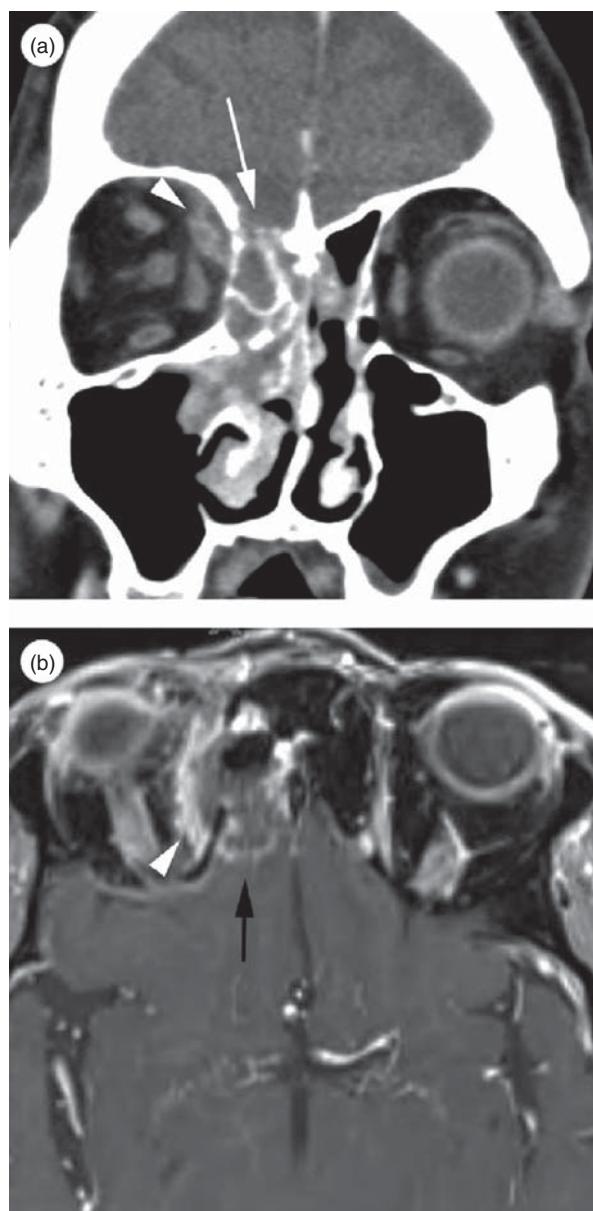

inflammatory process seems to be confined to the olfactory cleft (Trotier et al., 2007). In many instances, improvement of function occurs after topical nasal administration of corticosteroids (Sivam et al., 2010). An example of extreme acute sinusitis in which there has been invasion of the disease into the right orbit and cranium is shown in Figure 17.5. Note that the invasion has occurred through the right cribriform plate, undoubtedly compromising the patient's ability to smell.

Overall, there appears to be general correspondence between a patient's self-report of olfactory loss and empirical test results. Golding-Wood et al. (1996), for example, evaluated odor identification ability before and after six weeks of betamethasone treatment in 25 well-documented perennial rhinitis patients. The patient group was initially divided into two groups: those who affirmatively answered the question "is your sense of smell impaired?" ( $n = 15$ ) and those who did not ( $n = 10$ ). The UPSIT scores of each of the 15 members of the former group were higher after the betamethasone treatment [respective group means (SD) = 18.93 (9.4) and 33.4 (4.01)]. This was not the case for those who initially felt that they had no problems smelling [respective pre-/post-treatment means (SD) = 33.40 (4.01) and 32.8 (4.94)]. Moderate correlations between the UPSIT scores and the self-ratings of olfactory function were found both before ( $r = -0.52$ ) and after ( $r = -0.58$ ) treatment. As has been noted by others, however, the average post-treatment UPSIT score was still indicative of a mild hyposmic condition. The UPSIT scores retained, among the patients, a similar rank order before and after treatment (Spearman  $r = 0.75$ ).

Several studies have examined olfactory function before and after allergen challenges (Hilberg, 1995; Hinkriksson et al., 1997; Klimek and Eggers, 1997; Lane et al., 1996; Moll et al., 1998). In all cases, smell function decreased as a result of the challenges, although in the few cases that examined measures of airway patency, no association was noted between the degree of smell dysfunction and the patency measure. Hilberg (1995) assessed the comparative effects of the oral antihistamine terfenadine (an H1-blocker) and the topical steroid, budesonide, on an allergen challenge in subjects with nasal allergy uncomplicated by polyposis or olfactory dysfunction and various other hay fever symptoms. Although both drugs had an effect on the non-olfactory hay fever symptoms during the nasal pollen challenge, only the budesonide improved the challenge-related decrement in olfactory sensitivity. This steroid was also more effective in increasing nasal volume. Unfortunately, the improvement in olfactory function occurred in less than half of the patients (7/17; 41%).

### 17.4.3 Nasal Surgery

Gross-Isseroff et al. (1989) obtained detection threshold and UPSIT measures in children and adults with choanal

**Figure 17.5** **a.** Coronal CT image of the orbits and paranasal sinuses of a 68-year-old man presenting with headaches, right orbital pain, and blurry vision. Acute sinusitis is apparent with right orbital and intracranial invasion. Note opacification of the right ethmoid air cells and maxillary infundibulum, with soft-tissue attenuation extending into the right maxillary ostium. There is orbital involvement with peripherally enhancing soft tissue extending into the medial superior right orbit, with involvement of the right superior oblique muscle (arrowhead). Erosion of the right cribriform plate (arrow) is present, undoubtedly influencing smell function and suggesting the possibility of intracranial involvement. **b.** Axial T1 postcontrast image at the level of the orbits showing a rim-enhancing collection in the medial right orbit (arrowhead), representing subperiosteal abscess and peripherally enhancing soft tissue extending intracranially (black arrow) consistent with accumulation of pus and fluid from infected tissue (empyema). atresia before and after surgical repair, which occurred at relatively advanced ages (8–31 years). The three patients who had suffered from bilateral atresia had permanent olfactory deficits, whereas the one patient who had suffered from unilateral atresia had normal function. These findings suggested to the authors the question as to whether early sensory exposure is needed for normal development of olfactory function.

The limited empirical data suggest that septoplasty and rhinoplasty can modestly improve olfactory function in cases where the airway is significantly constricted (Damm et al., 2003; Kimmelman, 1994; Stevens and Stevens, 1985). However, several studies suggest that such operations can damage the olfactory system (e.g., Damm et al., 2003; Pfaar et al., 2004). Olfactory function has been evaluated before and after common operative procedures for chronic rhinosinusitis and/or polyposis unresponsive to more conservative treatments (e.g., allergen avoidance, nasal corticosteroids). Among such operations are middle turbinate medialization, polypectomy, uncinatectomy, anterior ethmoidectomy, posterior ethmoidectomy, and sphenoidectomy, alone or in combination. With rare exception, olfactory function improves to some degree following such surgeries (Delank and Stoll, 1998; Downey et al., 1996; Federspil et al., 2008; Gupta et al., 2014; Hoseman et al., 2000; Hu et al., 2010; Johansson et al., 2004; Katomichelakis et al., 2010; Kim et al., 2011; Kimmelman, 1994; Klossek et al., 1997; Konstantinidis et al., 2007; Leonard et al., 1988; Litvack et al., 2009; Minovi et al., 2008; Olsson et al., 2010; Olsson and Stjarne, 2010), even though the proportion of patients regaining normal olfactory function is typically less than 40% (e.g., Delank and Stoll, 1998; Leonard et al., 1988; Min et al., 1995; Pade and Hummel, 2008) and in many, but not all, cases the dysfunction regresses within a year to preoperative levels (Briner et al., 2012; Jiang et al., 2008; Klimek et al., 1997). The degree of improvement is well exemplified by examining the median pre- and postoperative UPSIT scores calculated across six studies in which five or more patients were tested (Eichel, 1994; el Naggar et al., 1995; Friedman et al., 1999; Kimmelman, 1994; Lund and Scadding, 1994; Seiden and Smith, 1998). These values, 17.0 and 25.5, respectively, are indicative of an average change in function from total anosmia to a borderline moderate/severe microsmia, a degree of improvement also observed in subsequent studies (Kim et al., 2011; Soler et al., 2010). For a recent review of this literature, see Rudmik and Smith (2012).

#### 17.4.4 Tumors

Olfactory dysfunction can result from a variety of intranasal and intracranial tumors. McCormack and Harris (1955) reported on five cases in which neurogenic tumors arising in the lateral nasal wall were accompanied by anosmia

and noted that over 100 such cases had been cited in the literature up to that time. In one study, Ho et al. (2002) assessed the olfactory function of 48 patients undergoing radiotherapy for nasopharyngeal carcinoma before and up to 12 months after radiotherapy. Olfactory function returned to pre-radiotherapy levels by 12 months. Around 20% of the tumors of the temporal lobe or lesions of the uncinate convolution are said to produce some form of olfactory disturbance, most typically the hallucination of a bad smell (Furstenberg et al., 1943).

The olfactory bulbs and tracts are very sensitive to pressure from meningiomas from the dura of the cribriform plate and surrounding regions (e.g., olfactory groove meningiomas, suprasellar ridge meningiomas), pituitary growths that extend above the diaphragm of the sella turcica, and tumors inside or on the floor of the third ventricle. Thus, both unilateral and bilateral hyposmia and anosmia have been reported in cases of frontal lobe glioma, suprasellar meningioma, and sphenoidal ridge meningioma, as well as in cases involving non-neoplastic space-filling lesions, such as large internal carotid aneurysms extending over the pituitary fossa, aneurysms of the anterior communicating bifurcation, and hydrocephalus that pushes the floor of the third ventricle downward. Although signs other than olfactory ones are typically present in such cases, olfactory dysfunction can, in fact, be the sole sign (McCormack and Harris, 1955). In some cases, the olfactory dysfunction is relieved after tumor removal and decompression on olfactory eloquent structures (Ishimaru et al., 1999).

According to Finelli and Mair (1991), the single most egregious error of neurologists is failure to recognize the symptom of anosmia as the principal or sole feature of an olfactory groove neoplasm. However, olfactory dysfunction is often only evident after such tumors have achieved a considerable size and, even then, separate testing of each side of the nose may be needed to identify a deficit. Many such patients are not aware of an olfactory deficit and most present with headache, visual disturbances, or cognitive problems such as memory deficits (Welge-Luessen et al., 2001).

Unfortunately, the classical surgical approach to anterior skull base tumors—bifrontal craniotomy—is almost always associated with postoperative anosmia and other complications. Moreover, subcranial endoscopic approaches to such tumors can also produce olfactory deficits (Kinnunen and Aitasalo, 2006; Tam et al., 2013). Fortunately, a number of surgical approaches that better spare the olfactory system have been devised (e.g., unilateral frontal craniotomy with orbital osteotomy; the translabellar/subcranial approach) (Babu et al., 1995; Jung et al., 1997). Nevertheless, with special care and adherence to certain procedures, the olfactory bulbs and tracts can be preserved using the bilateral sub-frontal approach to anterior skull base tumors (Cömert et al., 2011; Sepehrnia and Knopp, 1999). Moreover, different

approaches to palliative whole brain radiotherapies have been found that minimize complaints of smell problems (Akhtar et al., 2012).

It is of interest that olfactory tests were employed over 80 years ago to help diagnose cribriform plate meningiomas and to localize other tumors impinging upon the olfactory nerve (Elsberg, 1935a,b). Despite the limitations of the olfactory test procedure used (i.e., the so-called blast injection technique; see Chapter 11), the olfactory recognition threshold was generally elevated on the side where a neoplasm exerted pressure on one olfactory nerve. When both nerves were involved, bilateral threshold elevation was noted, with greater elevation on the most affected side. Such changes were observed for expanding lesions on the ventral surfaces of the frontal lobes, as well as for suprasellar meningiomas and aneurysms of the internal carotid artery or the anterior part of the circle of Willis. Threshold values were not influenced by pituitary adenomas confined to the region of the sella turcica, but were heightened if growth occurred above the sella. Although most intracranial tumors were not associated with altered recognition thresholds, they were associated with prolonged duration of olfactory adaptation or fatigue. Thus, tumors in or near the midline of the cranial cavity produced long-lasting adaptation (e.g., parasagittal meningiomas, tumors of the corpus callosum, and infiltrating growths extending to the medial surface of a cerebral hemisphere). When generalized intracranial pressure was observed, decreased recognition threshold sensitivity was sometimes present. Although modern imaging techniques make such testing somewhat archaic, olfactory testing may still be of value today in the early detection of some brain tumors.

Daniels et al. (2001) examined odor discrimination performance and OERPs in 20 subjects with unilateral frontal or temporal lobe brain tumors. Patients with right-side lesions exhibited deficits in odor discrimination in both the left and right sides of the nose. Patients with left-side lesions only exhibited attenuated function when the odorant was presented to the left side. The amplitude of the OERPs was decreased after left-side stimulation, but not after right-side stimulation. Interestingly, a correlation was present between olfactory and acoustic event-related potentials in patients with right-side lesions after right-side stimulation.

#### 17.4.5 Exposures to Airborne Pollutants

Decrements in smell function are common in highly polluted urban areas (Calderon-Garciduenas et al., 2010; Guarneros et al., 2009; Hudson et al., 2006), as well as in some occupational settings where workers are exposed on

a relatively continuous basis to airborne particulates, metals, and chemicals (Adams and Crabtree, 1961; Ahlstrom et al., 1986; Antunes et al., 2007; Dalton, 2003; Hisamitsu et al., 2011; Lucchini et al., 1999; Schwartz et al., 1989) (see Chapter 20). Olfactory dysfunction has been demonstrated in residents, firefighters, and workers exposed to the air pollution from the demolition and clean-up of the World Trade Center (WTC) following September 11, 2001 (Altman et al., 2011; Dalton et al., 2010). In a number of cases, damage to the olfactory epithelium, as well as other sectors of the olfactory pathway, is evident, and inflammation of both the upper and lower respiratory tracts is common (Doty and Hastings, 2001; Holt, 1996; Trevino, 1996). At autopsy, ultrafine particulate matter (UFPM <100 nm) has been found in the olfactory bulbs of dogs, children, and young adults who have been chronically exposed to extreme air pollution, reflecting the transit of materials from the nasal cavity into the brain via the olfactory fila (Calderon-Garciduenas et al., 2008a,b; 2010).

A classic study of how chemical exposure in a modern workplace can influence olfaction was performed by Schwartz et al. (1989). These investigators administered the UPSIT to 731 workers exposed to acrylates and methacrylate vapors in a chemical manufacturing plant and for whom quantitative work exposure histories were well documented. A logistic regression analysis which adjusted for multiple confounders revealed exposure odds ratios of 2.8 (1.1, 7.0) for all workers and 13.5 (2.1, 87.6) for workers who never smoked cigarettes.

#### 17.4.6 Head Trauma

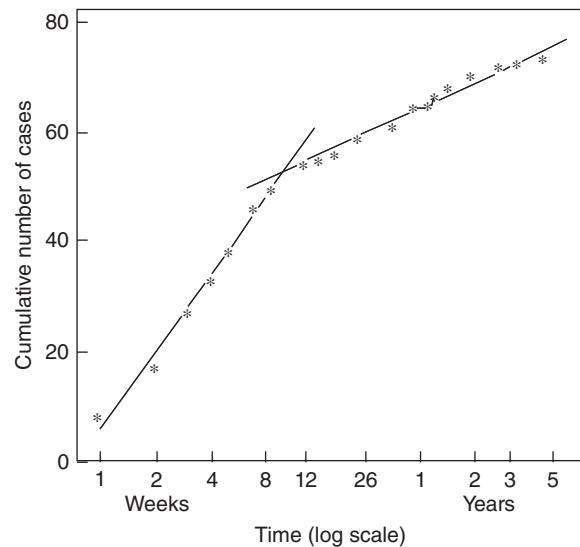

Olfactory dysfunction secondary to head trauma (HT) has been reported in the medical literature since the 19th century. In apparently the first description of this phenomenon, Jackson (1864) described a 50-year-old man who complained of loss of smell after falling off of a horse. Three years later Ogle (1870) provided case descriptions of three HT patients with smell loss and made the important point that blows to the back of the head can induce smell loss by shearing the olfactory fila at the base of the brain, a point subsequently reiterated by Althaus (1881) and others. That same year, Notta reported that anosmia could exist in patients who do not lose consciousness and mentioned that, in his experience, recovery may occur in 8 weeks to 7 months after the injury (Notta, 1870). The first description of dysosmia induced by HT was provided by Legg (1873): a man fell off a cart and thereafter reported that food had the flavor of “gas or paraffin.” Although this individual reported having lost both his senses of smell and taste, upon testing his ability to detect sweet, sour, bitter, and salty tasting substances was intact. Numerous other reports subsequently appeared in the 19th century on

post-traumatic loss of smell function (e.g., (Ferrier, 1876; Gowers, 1893; Jacob, 1882; Mollière, 1871; Rotch, 1878).

The first large scale study of HT-related smell loss was published during World War II (Leigh, 1943). In this study of 1000 consecutive cases admitted to a military hospital for head injuries, Leigh found 72 with impaired smell function (7.2%), of which 41 had complete anosmia (4.1%). Blows to the front and the back of the head were most common (18 occipital and 30 frontal), and nearly all cases in which smell loss was present represented severe trauma. Leigh found that only six of his 72 HT cases regained smell function (8%) during this study, half of whom went through a period of dysosmia. Time to recovery of function varied from 20 days to 12 months (median = 3 months).

In a large study of 1167 unselected HT cases performed two decades later, Sumner (1964) observed a remarkably similar percentage of cases with smell loss (7.1%). Sumner examined the site of the blows in anosmics whose HT was relatively minor, i.e., who had no amnesia or amnesia lasting less than an hour. Independent of a smell problem, many more patients had HT due to frontal than to vertical or occipital blows. However, occipital blows were five times more likely than frontal blows to produce anosmia. Interestingly, an abrupt change occurred in the number of cases that improved over time at ~10 weeks (Figure 17.6). This suggested to Sumner that two different processes may be involved in recovery, one that reflects the disappearance of compression, edema, and blood clot formation, and the other presumably a neural and longer-lasting process. No meaningful association was found between the severity of the head trauma and the time required for the anosmia to resolve. Sumner notes that his study differed from earlier ones in that (a) anosmia was sought out in patients soon after their trauma, (b) his sample contained many patients with minor HT, and (c) patients were followed for a relatively long time after injury (up to five years).

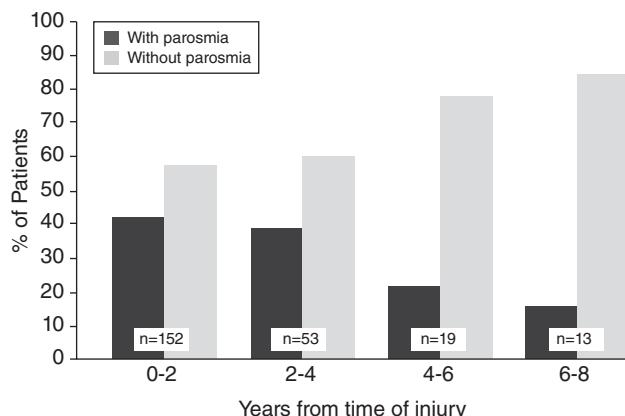

Since 1980, numerous studies have appeared on this topic, many from specialized smell and taste centers (Atighechi et al., 2013; Charland-Verville et al., 2012; Collet et al., 2009; Costanzo et al., 1987; Deems et al., 1991; Doty et al., 1997c; Duncan and Seiden, 1995; Fujii et al., 2002; Haxel et al., 2008; Ikeda et al., 1995; Jafek et al., 1989; Kern et al., 2000; Kim et al., 2014; Levin et al., 1985; London et al., 2008; Mann and Vento, 2006; Reden et al., 2006; Reiter et al., 2004; Rombaux et al., 2012, 2012a; Schechter and Henkin, 1974; Vent et al., 2010a; Welge-Lüssen et al., 2012; Wise et al., 2006; Yousem et al., 1999). Unlike the earlier studies, quantitative olfactory testing was performed. Because most studies examined HT in patients who presented with complaints of smell loss, a much higher percentage of smell and taste center patient populations have olfactory dysfunction than noted above. For example, in one large study of 268 such persons, 87.3% had demonstrable smell loss, with 66.8% having anosmia

**Figure 17.6** The number of patients whose smell function recovered over time since injury onset. Note abrupt change in slope of function. This may reflect two different underlying factors, i.e., the shorter-term disappearance of compression, edema, and blood clot formation, and longer-term neuronal recovery. and 20.5% having microsmia (Doty et al., 1997c). In one of the more recent studies that administered olfactory tests to patients who had presented with head trauma rather than olfaction secondary to head trauma, an estimated 12.7% incidence of olfactory dysfunction was noted (Haxel et al., 2008). There is now evidence that head trauma impacts olfactory function even in young children (Bakker et al., 2014).

Several important observations accrued from the Doty et al. (1997c) study. First, of 168 patients for whom explicit information regarding a single impact focus was available, 36.3% received the primary impact to the front, 39.3% to the back, 10.1% to the right, 11.3% to the left, and 3% to the top of the head. Blows to the back or side of the head resulted in significantly ( $p < 0.03$ ) larger deficits in function than did blows to the front of the head [mean UPSIT scores = 15.38 for the back, 16.31 for the side, and 19.90 for the front]. Second, the olfactory test scores were not meaningfully related to patient sex or age at the time of trauma or at the time of testing. Third, patients who had some smell function (UPSIT scores  $> 18$ ) and who had never experienced parosmia had significantly higher UPSIT scores than their counterparts who currently or previously experienced parosmia ( $p < 0.001$ ). This suggests that parosmia is associated with greater damage to the olfactory system. Fourth, as shown in Figure 17.7, the prevalence of parosmia decreased over time. Fifth, no association was evident between the smell test scores and the duration of loss of consciousness (LOC; a measure of HT

**Figure 17.7** Relationship between proportion of patients reporting current parosmia (intermittent and chronic combined) and time since head injury. Years falling exactly on an even value were placed in the earlier category (i.e., in the case of 2, data are in the 0–2 year category rather than the 2–4 year category). severity) when all of the data were included in the analysis. However, when the data from the anosmic patients were excluded, the mean UPSIT scores of patients with LOC > 24 hours were significantly lower than those of patients who had never lost consciousness or who had LOC < 24 hours. Indeed, a  $-0.56$  correlation was present between the duration of LOC and UPSIT score ( $p < 0.05$ ). Sixth, in the nonanosmic HT group, patients who had not been hospitalized had better olfactory function than those who had been hospitalized; no meaningful correlation was present between the UPSIT scores and the length of hospitalization ( $r = -0.08$ ,  $p = 0.76$ ). Seventh, no associations between UPSIT scores and psychological depression, as measured by the Beck Depression Inventory, were observed. Eighth, of 66 patients who were retested at intervals ranging from 0.5 to 13 years, nearly half showed no change in their function (respective pre/post mean UPSIT scores = 19.10 and 19.73). Test scores declined in 1/5th of the group, moving from severe microsmia to total anosmia (respective mean UPSIT scores = 20.08 and 13.08). Slightly more than a third of patients improved somewhat on retesting, moving, on average, from anosmia (17.83) to borderline moderate microsmia (25.46), although only three subjects improved into the absolute normal range (4.5%). The time between the two test sessions was statistically unrelated to whether the UPSIT scores improved, worsened, or stayed the same on the second test occasion. Ninth, in a subgroup of 30 patients for whom olfactory bulb volume measures were obtained, smaller olfactory bulbs were present in male, but not female, HT patients relative to sex- and age-matched controls (Figure 17.8).

**Figure 17.8** Olfactory bulb volumes (left and right) in cubic millimeters for male and female post-trauma and control subjects determined from MRI images. Vertical bars represent SEM. Two studies have suggested that anosmia is a reliable predictor of vocational outcome in patients with closed head injury (CHI). In these studies, 80% to 93% of patients with *mild CHI* and anosmia were said to be vocationally disabled, that is, being employed less than 25% of the time after receiving medical clearance to return to work (Martzke et al., 1991; Muliol et al., 2008). Correia et al. (2001) sought to verify these findings, since (a) such rates are as high or higher than those observed in severe head trauma, (b) no quantitative olfactory testing was performed, and (c) a sampling bias may have been present (patients are often referred for neuropsychological testing because of concerns about adaptive functioning). Instead of focusing on patients referred to a neuropsychological clinic, they interviewed patients who had been previously referred to the University of Pennsylvania Smell and Taste Center for head trauma-related smell loss. In addition to quantitative olfactory test scores, medical histories and hospital reports were available to confirm the smell loss and the severity of the CHI. These investigators found that only 7% of mild CHI patients with severe smell loss were vocationally disabled.

#### 17.4.7 Congenital Anosmia

A number of patients report never having ever experienced smell function.<sup>1</sup> In the vast majority of such cases,

<sup>1</sup>Most persons are said to be constitutionally unable to detect a few specific odorants, a phenomenon termed specific anosmia. First described by Blakeslee for the fragrance of verbena flowers (Blakeslee, 1918), dozens of specific anosmias have been reported in the literature, including ones for musks, trimethylamine, hydrogen cyanide, n-butyl mercaptan, and isovaleric acid (for review, see Takagi, 1989). However, like the blind spot of the retina, specific anosmias are not typically recognized by a patient

appropriate MRI evaluation of the cribriform plate and gyrus rectus regions reveals agenesis or dysgenesis of the olfactory bulbs and tracks (Yousem et al., 1996). While some of these cases may represent long-term degeneration from viral or traumatic insults to the olfactory epithelium or fila (reflecting the withdrawal of trophic influences on the bulb from intact olfactory neuron), most are assumed to be hereditary. Lygonis (1969) reported total anosmia (without any apparent associated disorders) in members of four generations of a family living in an isolated island community and suggested that the pattern of inheritance was likely autosomal dominant. Singh et al. (1970) described cases of familial anosmia loosely associated with premature baldness and vascular headaches, which appeared to be inherited as dominant with varying penetrance. Several congenital olfactory syndromes are accompanied by endocrine dysfunction and are discussed in the next section. Indeed, there has been suggestion that all individuals with congenital anosmia should undergo genetic testing to determine whether they harbor any of the 19 or so Kallmann-related genotypes.

### 17.4.8 Endocrine Disorders

Although a number of endocrine disorders have been associated with smell dysfunction, many more have not been assessed for this problem. Of those that have been examined, the mechanisms responsible for the smell loss—aside from obvious anatomical alterations in the primary olfactory pathways—are poorly understood. Listed below are disorders for which at least some quantitative olfactory test data are available.

#### 17.4.8.1 Adrenocortical Insufficiency (Addison's Disease).

Henkin and Bartter (1966) reported that patients with untreated adrenocortical insufficiency exhibited greater odor detection threshold sensitivity, relative to normal controls, not only for the odorants pyridine,

and are rarely a reason for seeking clinical help. Moreover, some specific anosmias can, in fact, detect high concentrations of odorants to which they are said to be anosmic, implying hyposmia rather than anosmia. Moreover, not all specific anosmias are really that specific. Amoore (1971), for example, tested the thresholds of 10 subjects who exhibited specific anosmia to isobutyric acid to 17 other compounds, finding heightened thresholds for straight chain fatty acids with four to seven carbon atoms. Importantly, exposure to, or repeated testing with, some odorants, including ones associated with specific anosmias, can result in an increase in their sensitivity in both humans and rats (Doty et al., 1981; Doty and Ferguson-Segall, 1989). For example, Wysocki et al. (1989) found that the ability to perceive androstenone could be induced in 10 of 20 initially insensitive subjects by systematically exposing them to this odorant, an observation confirmed by others (Möller et al., 1999). This finding led Wysocki et al. to suggest that three categories of human subjects may exist in regards to responsiveness to this substance; namely, the truly anosmic, the inducible, and those who are either constitutionally sensitive or have experienced incidental past exposure.

thiophene, and nitrobenzene, but for the vapors above aqueous solutions of six tastants (NaCl, KCl, HCl, NaHCO<sub>3</sub>, sucrose, and urea). These effects were remarkable, with none of the distributions of scores from the patient and control groups showing any overlap. In the case of the volatiles arising from the tastants, the patients detected differences between the water and the vapors of the tastants at 1/10,000 the concentration of that noted for normals. The increased sensitivity did not return to normal following daily 20 mg injections of deoxycorticosterone acetate (DOCA) for periods up to 10 days. In contrast, treatment of the subjects with 20 mg of the carbohydrate-active steroid prednisolone returned sensitivity to normal within 24 hours.

Attempts to replicate or extend these findings have not been forthcoming. Empirically measured hypersensitivity is rare in the chemical senses literature, and numerous tests of auditory, gustatory, and olfactory function in rats before and after adrenalectomy have found no evidence of hypersensitivity of any sort. Indeed, the available data suggest that adrenalectomy may, in fact, produce not only altered odor preferences, but *decrements* in general sensory function (Brosvic et al., 1989; Conn and Mast, 1973; Doty et al., 1991; Kosten and Contreras, 1985; Weigel et al., 1989).

#### 17.4.8.2 Chromatin Negative Gonadal Dysgenesis (Turner's Syndrome).

Turner's syndrome (TS) is a form of gonadal dysgenesis resulting from a 45X karyotype (X-chromosomal monosomy). It is characterized by a female phenotype, a shield-like chest, short stature, short and sometimes webbed neck, low-set ears, small mandible, a high-arched palate, and sexual infantilism. Other problems often include congenital lymphedema, skeletal anomalies, abnormalities of the nails, and cardiac and renal deficits. A pioneering study reported that nine TS patients had elevated detection and recognition thresholds to three odorants that were assessed (pyridine, thiophene, nitrobenzene) (Henkin, 1967). Gonadal hormone therapy reversed the chemosensory deficits. Interestingly, the mothers of the patients exhibited similar olfactory abnormalities, which the author suggests is in accord with a potential genetic basis for the chemosensory disorder. More recent work has suggested that TS influences odor memory and odor identification (Ros et al., 2012).

#### 17.4.8.3 Cushing's Syndrome.

Cushing's syndrome (CS) is a disease characterized by chronic excessive secretion of adrenal corticosteroids (i.e., hypercortisolism). Approximately 80% of cases reflect excessive secretion of adrenocorticotrophic hormone (ACTH) (e.g., from ACTH-producing pituitary tumors), whereas the remainder reflect ACTH-independent etiologies (e.g., adrenal gland adenomas and carcinomas, cortisol-secreting tumors) (Ferrante, 1999). According to Henkin (1975),

patients with CS exhibit a decrease in sensory detection acuity for olfaction, gustation, hearing, and proprioception. Dogs given chronic dexamethasone (an animal model of Cushing's syndrome) appear to have increased detection thresholds for benzaldehyde and eugenol, in accord with this notion (Ezeh et al., 1992).

**17.4.8.4 Hypothyroidism.** A number of hypothyroid patients complain of chemosensory problems (Deems et al., 1991). Lewitt et al. (1989) reported that 11 of 16 (69%) of the hypothyroid patients they evaluated complained of altered smell and taste function, and McConnell et al. (1975) found that 7 of 18 patients with untreated hypothyroidism (39%) were cognizant of some alteration in their sense of smell, with 3 (17%) experiencing dysosmia.

Intuitively, one might expect hypothyroidism to be associated with measurable chemosensory deficits, since 36–83% of hypothyroid patients reportedly experience somesthetic disturbances, and 25–45% auditory or visual disturbances, with night blindness reportedly being a common feature of the disorder (Mattes et al., 1986). However, the few available studies are not in agreement on this point. McConnell et al. (1975) reported that odor detection thresholds for pyridine and nitrobenzene, as well as various taste threshold measures, were strikingly elevated in patients with untreated hypothyroidism—a problem that resolved following thyroxine treatment. In contrast, Lewitt et al. (1989) found no detection threshold differences between 16 patients and 17 controls for the odorant phenyl ethyl alcohol and only a slight, but statistically significant, difference on a suprathreshold test of odor identification. Various measures of suprathreshold taste function, as well as auditory and visual evoked potentials, did not differ between the patients and the controls, and no pre-/post-thyroxin differences were observed for any measure. Negative findings have been reported by others for various taste measures (Pittman and Beschi, 1967).

The basis of these discrepancies is not clear, although the various studies have used different odorants and procedures, and it is not apparent whether the patients were comparable in terms of the nature, duration, and severity of their hypothyroid problems. It is noteworthy that well-controlled psychophysical studies employing rats have found no influences of hypothyroidism on their ability to detect low concentrations of either tastes or smells (Brosvic et al., 1992; Brosvic et al., 1996). However, taste preference differences were found for NaCl, HCl, and quinine, but not sucrose (Brosvic et al., 1996). While an earlier mouse study linked hypothyroidism to anosmia, the paradigm employed was, in fact, a two-bottle preference test, leaving open the possibility to dysosmia, not anosmia, as the basis for the behavioral changes (Beard and Mackay-Sim, 1987).

**17.4.8.5 Pseudohypoparathyroidism.** Pseudohypoparathyroidism (PHP) is an endocrine disorder characterized by deficiencies in responsiveness to, but not in the production of, parathyroid hormone. Individuals with Type Ia PHP exhibit a generalized hormone resistance, a deficiency of the alpha chain of the stimulatory guanine nucleotide-binding protein ( $G_{\alpha}$ ) of adenylyl cyclase, and an unusual constellation of skeletal and developmental abnormalities termed Albright hereditary osteodystrophy (AHO). Among the abnormalities expressed in AHO are obesity, short stature, brachydactyly, round facies, and subcutaneous ossifications. Type Ib PHP patients, in contrast, exhibit a specific hormone resistance to parathyroid hormone, do not express a deficiency in  $G_{\alpha}$  protein activity, and do not have AHO.

PHP was first associated with olfactory dysfunction in 1968 (Henkin, 1968). Subsequent studies reported that Type Ia, but not Type Ib, PHP is accompanied by decreased olfactory function (Ikeda et al., 1988; Weinstock et al., 1986). The olfactory problem was believed to reflect the  $G_{\alpha}$  protein deficiency of the Type Ia patients, since  $G_{\alpha}$  proteins are involved in the first stages of olfactory transduction (see Chapters 5 and 6). However, a more recent and comprehensive study, while confirming that Type Ia PHP patients exhibit altered olfactory function, also found that Type Ib patients have olfactory dysfunction, making it unlikely that the olfactory dysfunction is related to the proposed  $G_{\alpha}$  protein deficiency (Doty et al., 1997a). In this same study, relatively normal function was documented in patients with pseudopseudohypoparathyroidism (PPHP), a disorder found in some relatives of patients with Type Ia PHP. Like PHP Type Ia, PPHP is accompanied by a  $G_{\alpha}$  protein deficiency and by AHO, but not by a generalized end organ hormone insensitivity.

**17.4.8.6 Kallmann Syndrome.** Kallmann syndrome (KS) is a congenital form of idiopathic hypogonadotropic hypogonadism (IHH) and, by definition, is the form of IHH associated with anosmia (Kallmann et al., 1944). IHH is a heterogeneous group of disorders characterized by frank hypogonadism secondary to deficient release of gonadotropin releasing hormone (GnRH) from the hypothalamus and, as has been shown in large-scale studies employing the UPSIT, a spectrum of olfactory deficits ranging from total anosmia (KS) to normosmia (nIHH) (Lewkowitz-Shpuntov et al., 2012). KS is generally believed to be caused by an autosomal dominant mode of inheritance with incomplete expressivity (Quinton et al., 2001). It is much more prevalent in men than in women, and is sometimes associated with midline craniofacial abnormalities, tooth agenesis, deafness, and renal anomalies, among others. Family members related to KS individuals may be normal or have both hypogonadism

and anosmia, anosmia with no hypogonadism, or hypogonadism without anosmia. Although MRI studies generally reveal bilateral agenesis of the olfactory bulbs and tracts (Bajaj et al., 1993; Klingmuller et al., 1987; Yousem et al., 1993), there is one report of a KS patient with aplasia of the left, but not the right, olfactory tract and bulb (Wustenberg et al., 2001).
