The origin of IHH and the various degrees of olfactory loss stem from anomalies in the development of the olfactory and GnRH pathways (Schwanzel-Fukuda et al., 1989). During embryogenesis, olfactory and GnRH neurons germinate from the same general stem cell population within the olfactory placode. Following fate specification, the GnRH neurons migrate on structural scaffolding provided by the olfactory axons before entering the CNS via the cribriform plate. While the olfactory axons terminate within the olfactory bulb, the GnRH neurons do so within the mediobasal hypothalamus, where they eventually form a functional network that initiates pulsatile GnRH secretion (Lewkowitz-Shpuntov et al., 2012). To date, mutations in 19 different genes have been associated with KS and its variants. Among the most important are the Kallmann syndrome 1 sequence gene (*KAL1*), which encodes a protein important for the cell adhesion and migration in the developing brain (anosmin-1) (Franco et al., 1991), fibroblast growth factor (*FGF*) signaling pathway genes (*FGF8* and *FGFR1*), important for regulating embryonic cell proliferation, differentiation, and migration (Hu et al., 2012), *PROK2* signaling pathway genes (*PROK2* and *PROKR2*), which influence olfactory bulb morphogenesis (Pitteloud et al., 2007), and *CHD7*, a calcium dependent cell-cell adhesion glycoprotein (Kim and Layman, 2011). *CHD7* is closely associated with CHARGE syndrome, a disorder with Coloboma, Heart defects, Atresia choanae (also known as choanal atresia), Retarded growth and development, Genital abnormalities, and Ear abnormalities, as well as olfactory dysfunction (Bergman et al., 2011) and narrowed or completely blocked nasal passages (choanal stenosis or choanal atresia) (Janssen et al., 2012).

The olfactory epithelia of patients with KS have pathological changes analogous to those of mammals whose connections between the olfactory bulb and the epithelium have been severed; namely, the presence of morphologically immature receptor neurons lacking cilia, a decrease in the number of olfactory receptor cells, and the formation of intraepithelial neuromas (Schwob et al., 1993). Nevertheless, based upon calcium imaging, some mature olfactory receptor cells have been identified in nasal biopsies from KS patients (Rawson et al., 1995). In one nasal biopsy study, the total lack of an olfactory epithelium in a KS subject was reported (Jafek et al., 1990a), although this observation must be viewed conservatively in light of sampling problems endemic to such biopsy studies (Paik et al., 1992).

Unfortunately, the anosmia noted in Kallmann syndrome is not reversed by either gonadotropin or gonadal steroid therapy. However, because the GnRH deficiency can be successfully treated when administered at the appropriate time, it is important that attempts be made to detect the endocrine problem as soon as possible. Sparkes et al. (1968) stress that anosmia serves as an important diagnostic marker in the early detection of such problems, and Mroueh and Kase (1968) suggest that perhaps all pediatric patients presenting with anosmia should undergo a specific gonadal evaluation to prevent the possible development of irreversible atrophic changes. Unfortunately, many individuals lacking smell ability (particularly youngsters who do not recognize the deficit or who are too shy to mention it to their parents) do not seek help for this difficulty, and routine pediatric examinations rarely test olfactory function. Most importantly, delay in diagnosis can have significant psychological and physiological consequences, as eloquently described in a detailed description of what a young man went through before receiving a proper diagnosis of KS at the age of 22 years (Smith and Quinton, 2012).

**17.4.8.7 Diabetes.** Although some studies have found no alterations in olfactory function in patients with diabetes relative to controls (Naka et al., 2010; Patterso et al., 1966), others have reported decreases in such function (Le Floch et al., 1993; Weinstock et al., 1993). In one study of 111 patients, the odor identification deficit was unrelated to disease duration, type of diabetes, presence of neuropathy, retinopathy, nephropathy, hypertension or impotence (Weinstock et al., 1993). Test scores were associated with the presence of macrovascular disease, implying that the olfactory deficit may be enhanced, if not dependent upon, the development of this condition. It is noteworthy that insulin receptors are particularly prevalent throughout olfactory and limbic regions of the brain (Hill et al., 1986).

### 17.4.9 Psychiatric Disorders

A number of psychiatric disorders are accompanied by altered smell function, including schizophrenia and chronic hallucinatory psychoses (Chapter 18), seasonal affective disorder (Postolache et al., 1998; Postolache et al., 1999; Postolache et al., 2002), and severe stage anorexia nervosa (Aschenbrenner et al., 2008; Fedoroff et al., 1995; Rapps et al., 2010; Roessner et al., 2005). Among the more interesting of the psychiatric disorders is “olfactory reference syndrome,” a condition generally reviewed as distinct from schizophrenia or affective disorders (Begum and McKenna, 2011; Bishop, Jr., 1980; Pryse-Phillips, 1971). In this disorder, the patient believes that smells emanate either from his or her person (intrinsic hallucinations) or from elsewhere (extrinsic hallucinations). The

hallucinations can be “minimal,” where the odor is complained about but the patient does not take steps to remove it, or the “reasonable” reaction, in which the patient takes steps to eliminate the odor (e.g., complaining to authorities, visiting a dermatologist, or plugging up the chimney with newspapers). In intrinsic hallucinatory cases, compulsive washing behavior, changing clothes, and restriction of social activity is common. In many cases, this syndrome is closely linked with an obsessive-compulsive disorder and is amenable to treatment with serotonin-uptake inhibitors (Dominguez and Puig, 1997; O’Sullivan et al., 2000; Stein et al., 1998).

### 17.4.10 Autoimmune Diseases

It is now apparent that a number of classic autoimmune diseases are associated with smell loss. Those with the best documented losses are as follows.

**17.4.10.1 Multiple Sclerosis (see also Chapter 18).** Decreased olfactory function has been reported to be present in 20 to 70% of patients with multiple sclerosis (MS) (Doty et al., 1997b; Fleiner et al., 2010; Pinching, 1977), although some authors have not observed such dysfunction (Ansari, 1976). The frequency of impairment is higher in patients with secondary progressive MS than in those with relapsing-remitting MS (Silva et al., 2012). The dysfunction, which in rare instances can be a presenting symptom (Constantinescu et al., 1994), is correlated with the lesion load and number of demyelinating plaques within the inferior temporal and frontal lobes (Doty et al., 1997b; Zorzon et al., 2000). Interestingly, odor identification test scores wax and wane over time relative to the fluctuations in plaque activity that occur within these brain regions (Doty et al., 1999) and are significantly correlated with symptoms of depression, anxiety, and severity of neurological impairment (Zivadinov et al., 1999). MS-related smell dysfunction is observed using both psychophysical and event-related potential electrophysiological measures (Dahlslett et al., 2012; Hawkes et al., 1997).

#### 17.4.10.2 Systemic Lupus Erythematosus.

Systemic lupus erythematosus (SLE), better known as simply lupus, is an autoimmune disorder that can damage the nervous system, blood vessels, joints, skin, and internal organs. It is more prevalent in women than in men. Like MS, periods of exacerbation (flares) often alternate with periods of remission. In a study of 50 SLE patients and 50 controls, Shoenfeld et al. (2009) found that decreased smell function was present in 46% of patients as compared to 25% of controls. Anosmia was present in 10% of the patients and in none of the controls. Among the auto-antibodies found in this disease are anti-ribosomal P

antibodies. These investigators found, in a mouse study, that injection of such antibodies into the brain preferentially penetrated the limbic system and induced decreased ability to smell menthol (Katzav et al., 2008).

**17.4.10.3 Sjögren’s Syndrome.** Sjögren’s syndrome is an autoimmune exocrinopathy in which the salivary and lacrimal glands are destroyed. Smell loss is prevalent in such patients and is evident in tests of olfactory thresholds and odor identification (Henkin et al., 1972; Kamel et al., 2009; Weiffenbach and Fox, 1993). For example, Weiffenbach and Fox (1993) administered the UPSIT to 30 patients who met strict criteria for Sjögren’s syndrome and to 60 matched normal controls. 30% of the patients and 10% of the controls evidenced some olfactory impairment. Although the median score of the patients fell within normal limits (36.5), considerable variation was present and the median was significantly lower ( $p < 0.02$ ) than that of the controls (38.0). Only one of the 30 patients (3%) with Sjögren’s syndrome scored perfectly on the UPSIT, in contrast to 19 (32%) of the controls ( $p < 0.001$ ). The only anosmic that was identified had Sjögren’s.

**17.4.10.4 Myasthenia Gravis.** Myasthenia gravis (MG), an autoimmune disease identified with deficient acetylcholine receptor transmission at the post-synaptic neuromuscular junction, is accompanied by a profound loss of olfactory function. In the sole study on this topic, Leon-Sarmiento et al. (2012) administered the UPSIT to 27 MG patients, 27 matched healthy controls, and 11 patients with polymyositis (PM). PM is a disease with peripheral neuromuscular symptoms analogous to MG with no known central nervous system involvement. The UPSIT scores of the MG patients [mean (SD) = 20.15 (6.40)] were at the same level typically seen in early stage Alzheimer’s disease and Parkinson’s disease (see Chapter 18) and were markedly lower ( $p < 0.0001$ ) than those of the PM patients [mean (SD) = 33.30 (1.42)] and age- and sex-matched normal controls [mean (SD) = 35.67 (4.95)]. No correlations between the olfactory test scores and thymectomy, time since diagnosis, type of treatment regimen, or the presence or absence of serum anti-nicotinic or muscarinic antibodies were present.

### 17.4.11 Cystic Fibrosis

Cystic fibrosis (CF; mucoviscidosis) is an autosomal recessive disease due to a mutation in a protein critical for regulating exocrine gland secretions (e.g., mucus, sweat, saliva, digestive fluids). CF is accompanied by thick and viscous secretions due to abnormalities in sodium and chloride transport across epithelial membranes. This disease affects the lungs, liver, pancreas, intestine, and sweat

glands, and is associated with difficult breathing and both upper and lower respiratory system infections. CF receives its name from the cysts and fibrosis (scarring) that were first noticed within the pancreas.

Although one study reported that smell sensitivity was heightened in CF (Henkin and Powell, 1962), all other studies have found evidence for the opposite, i.e., lower sensitivity (Aitken et al., 1997; Hertz et al., 1975; Lindig et al., 2013; Mueller et al., 2007; Sherman et al., 1979; Weiffenbach and McCarthy, 1984). The abnormalities may reflect the influences of nasosinus infections and decreased numbers of receptor cells, the latter of which has been observed in CF mouse models with the CF mutation (Grubb et al., 2007). One reason for the decrease in receptor cell number may be due to sodium hyperabsorption by supporting (sustentacular cells) within the olfactory epithelium.

## 17.5 TREATMENT OF OLFACTORY DYSFUNCTION

Spontaneous recovery of olfactory function can occur over time in a considerable number of patients without treatment. In one longitudinal study, 542 patients (234 men, 308 women) presenting with complaints of smell dysfunction were tested twice at individual intervals ranging from one month to 24 years [median (IQR) follow-up = 2.9 yrs (1.4–4.2)] (London et al., 2008). The most common etiologies were severe upper respiratory infections ( $n = 208$ ), head trauma ( $n = 106$ ), and nasosinus disease ( $n = 98$ ). Eighty-one had no identifiable cause, and the remainder had problems due to a variety of etiologies. On average, statistically significant improvement in smell function occurred over the two test occasions—improvement that, surprisingly, did not differ among the major etiology categories. The percentages of initially anosmic and hyposmic patients who, in an absolute sense, regained normal function were 7.24% and 22.28%, respectively. Corresponding figures for those who regained normal *age-related* function was 11.76% and 42.49%. Severity of initial olfactory loss, patient age, and the time between the onset of the dysfunction and the patient's initial presentation to the clinic were significant predictors of the amount of change. Sex, time between the two test administrations, and initial smoking behavior were not meaningful predictors. Clearly, spontaneous recovery can be expected in many patients who experience smell loss from a range of causes.

As noted earlier in the chapter, there is little doubt that meaningful treatments are available for some patients whose olfactory dysfunction results from nasal inflammation or blockage of airflow to the olfactory neuroepithelium (e.g., those with allergic rhinitis, polyposis, rhinitis, or chronic sinusitis) (Doty and Mishra, 2001; Vaidyanathan et al., 2011). Effective therapies for olfactory loss

secondary to allergic rhinitis include allergy management, topical cromolyn, topical and systemic corticosteroid therapies, and surgical procedures to reduce inflammation or obstruction, including ones that allow for better mucus drainage from the sinuses to the nasal cavity. The effects of such surgeries are described earlier in the chapter. A brief course of systemic steroid therapy can help in distinguishing between conductive and sensorineural olfactory loss, as patients with the former will often respond positively to some extent to the treatment. However, longer-term systemic steroid therapy is not advised (Scott, 1989).

Once inflammation is quelled with a systemic steroid, maintaining normal olfactory function and the associated decrease in inflammation is challenging. In most cases, nasal sprays do not reach the higher recesses of the nose, although increased efficacy may be obtained by spraying the agents in an upside-down head position, such as the “head-low” or “lateral head low” position (Canciani and Mastella, 1988; Moffett, 1941). In cases where the nasal spray mechanism does not work well upside down, one can first spray the nose and then avert the head for a few minutes to allow the material to enter the olfactory meatus. Some otolaryngologists use steroid drops in place of sprays to increase steroid penetrance through the olfactory meatus, although such treatments must be used with caution to minimize high systemic steroid uptake. Recent research has found that applying topical corticosteroids with a squirt system is more effective than using a nasal spray in maintaining olfactory function, although improvement often subsides unless the therapy is combined with periodic intervals of short-term oral corticosteroids (Shu et al., 2012).

Numerous drugs and vitamin supplements have been claimed to successfully treat anosmia or hyposmia, including alpha-lipoic acid (Hummel et al., 2002), theophylline (Henkin et al., 2009; Levy et al., 1998), caroverine (Quint et al., 2002), zinc sulfate (Henkin et al., 1975), Vitamin A (Duncan and Briggs, 1962), and vitamin B complex (Heilmann et al., 2004). Unfortunately, none of the studies supporting these claims were double blinded and all lacked a control group. In most cases the agent was presented after a control baseline test, confounding test order with the outcome measure. It is well established that olfactory test scores improve upon repeated testing (Doty et al., 1984b) and, as noted above, spontaneous improvement occurs over time in many patients (London et al., 2008). In the case of Vitamin A, the rationale for efficacy was based upon the now disproved concept that pigment is essential for olfactory transduction (Briggs and Duncan 1962; Moulton 1971). Where double-blind studies have been employed, no evidence for efficacy of either zinc sulfate or Vitamin A has been found (Henkin et al., 1976; Lyckholm et al., 2012; Reden et al., 2012).

One large study has purported to show positive and dose-related effects of theophylline on smell test scores

(Henkin et al., 2009). Unfortunately, the dose-related effects were confounded by the time since the onset of the problem, subject discontinuation bias, and the frequency of testing. Moreover, no statistical correction was made for inflated alpha due to the calculation of multiple individual t-tests. When such a correction is made, no significant effects emerge, as is the case with a later study claiming even more positive effects from intranasally administered theophylline (Henkin et al., 2012).

Several studies have suggested that practicing smelling odorants at night and upon awakening improves olfactory function (Hummel et al., 2002; Damm et al., 2013; Haehner et al., 2013). Unfortunately, these studies were also not double blinded and the magnitude of the effects are not large. One recent study found no meaningful alterations of such olfactory training in older subjects (Schriever et al., 2014). Nonetheless, a strong rationale for such a concept comes from both rodent and human studies in which repeated testing to odorants increased sensitivity to them, even in cases where they were initially imperceptible (Dalton et al., 2002; Doty et al., 1981; Doty and Ferguson-Segall, 1989; Wysocki et al., 1989). Rodent studies show that ‘mere exposure’ to odorants increases neural activity within odor-specific regions of the olfactory bulb (Coopersmith et al., 1986). In light of evidence that experience can influence a wide range of olfactory measures, including brain processes (see Royet et al., 2013, for review), double blind studies addressing this issue are sorely needed.

Two studies have reported that persons with smell loss may benefit from acupuncture. The first is a case report of a healthy individual with no apparent nasal disease who, on the basis of self report and the presentation of a few odorants, was anosmic before treatment (Wevitavidanalage, 2003). After treatment she was reported to have accurately identified the odors of lime, apple, banana, strawberry, and perfumes upon ‘crude’ testing. The second study assessed olfactory function in 15 patients with post-viral smell loss before and after 10 weekly acupuncture treatments (Vent et al., 2010b). Testing was similarly made of a comparison group of post-viral patients who were being treated over the same time period with vitamin B complex (thiamine, pyridoxine, and cobalamine). The authors concluded that “Eight patients treated with TCA (traditional Chinese acupuncture) had improved olfactory function compared with two treated with vitamin B complex.” The data of this study were reanalyzed by Silas and Doty (2010) using a mixed analysis of covariance with the between subject factors of sex and treatment group (TCA, vitamin B complex) and the within subject factor of treatment condition (before and after treatment). Age served as a covariate. No significant effects were observed for any of the variables ( $p > 0.15$ ).

Since Vent et al., had originally matched the two study groups on the basis of sex and age, an ANOVA was performed without these measures in the analysis. A main effect of test occasion was found irrespective of treatment group ( $p < 0.01$ ), but no significant interaction was present. Since a non-treatment group was not tested in this non-blind study, it is impossible to determine whether both acupuncture and the vitamin B complex both improved function in an equivalent manner or whether the putative improvement simply reflected the effects of spontaneous recovery, repeated testing, or both. A definitive double blind study (e.g., where meridian points not expected to alter nasal function are employed in a control group) is clearly needed before one can conclude that acupuncture is useful for improving olfaction. In support of possible efficacy are the results of a double blind study that found acupuncture enhances olfactory function in *normal* subjects, at least for some short period of time after treatment (Anzinger et al., 2009). This phenomenon may reflect the well-known influence of autonomic responses on nasal tissue engorgement (Cole et al., 1985) and on other processes, including general arousal (Chen et al., 2011).

One study has claimed that transcranial magnetic stimulation (TMS) is effective for treating chronic phantosmia and “global oral phantogeusia” (Henkin et al., 2011). Seventeen patients were treated on two occasions separated by 4 to 32 weeks. On each of these occasions, two “sham” TMS procedures were then followed by a “real” TMS procedure. The first sham consisted of 20 stimuli presented at 1- to 5-second intervals sequentially over the right shoulder, then the left shoulder, and then to the back of the neck, at 25% and 40% of maximum output (1.5 T). The second sham was a series of stimulations (10–15% of maximum output) to the front, back, and sides of the skull. The “real” stimulation was directed to the same skull sights in the same order with the stimulator at 40–55% of maximum output. Smell and taste tests were administered at the beginning and end of each of the two 3-stimulation sessions. Brief assessments of the magnitude of the phantosmias “and/or” phantogeusias “and/or” responses to a single odorant presentation were assessed after each sham or real stimulation. If improvement was noted at one site, stimulation was continued until no further changes were noted.

As pointed out by Silas et al. (2011), this pioneering study suffers from multiple methodological problems, including lack of double blinding and analytical rigor. Only anecdotal information was presented on potential effects of the sites that were stimulated, and multiple variables and covariates were assessed without consideration of interaction effects or correlations. Efforts to lessen the likelihood of placebo effects are absent from the study (e.g., randomization, control sites over the cortex, and questioning of the patient as to which condition “felt” most

effective) (see Loo et al., 2000). Both sham procedures were perceptively distinct from the “real” procedure, being either at a different location or employing a smaller magnitude stimulus. Importantly, no correction for inflated alpha was applied for 24 t-test multiple comparisons which, when Bonferroni corrected, result in no significant effects. Clearly, as with many of the purported treatments noted in this section, well-controlled double-blind studies are needed to determine whether TMS may be of value in treating some patients with olfactory dysfunction. It is not unreasonable to assume that global magnetic stimulation might induce neurochemical or cortical electrical changes that could influence olfactory function in some patients, although this specific study fails to establish such an influence.

A recent epidemiological study suggests that exercise can reduce the risk of olfactory impairment in later life. Schubert et al. (2013) reported, in a longitudinal study of 1611 patients initially without olfactory impairment, that those who exercised twice a week and achieved a sweat had a decreased risk of developing olfactory impairment 10 years later (age- and sex-adjusted hazard ratio = 0.76 (95% CI, 0.60–0.97). These findings accord with other studies suggesting that regular exercise has significant cardiovascular and cognitive benefits.

Despite the fact that there are few bona fide treatments for the vast majority of cases of smell loss, it is important to reiterate that prognosis is better for patients with less severe microsmia than for those with anosmia or severe microsmia. In some etiologies, this reflects the less extensive damage into the basal cell layer of the epithelium and possibly less fibrosis around the foramina of the cribriform plate through which the olfactory nerve axons must pass. An often overlooked element of therapy for many patients is the quantitative determination of the true degree of olfactory loss. This helps to put into perspective the degree of dysfunction for many patients. For example, even if demonstrable smell loss is present, the test scores of a number of patients will fall above the median (50th percentile) for normal individuals of their same sex and age. It can be very therapeutic for an older person to learn that, while his or her smell function has indeed decreased and is not what it used to be, it still falls above the average of his or her peer group.

## Odor Perception and Neuropathology in Neurodegenerative Diseases and Schizophrenia

RICHARD L. DOTY, CHRISTOPHER H. HAWKES, KIMBERLEY P. GOOD, and  
JOHN E. DUDA

### 18.1 INTRODUCTION

It is now well established that the ability to smell is compromised in a number of neurodegenerative and neurodevelopmental diseases, including Alzheimer's disease (AD), Down's syndrome (DS), Huntington's disease (HD), idiopathic Parkinson's disease (PD), multiple sclerosis (MS; see Chapter 17), schizophrenia (SZ), and the Parkinsonism-dementia complex of Guam (PDG). While reports of alterations in the ability to smell in patients with AD and PD appeared in the 1970s (e.g., Waldton, 1974; Ansari and Johnson, 1975), the breadth of smell losses in neurodegenerative and neurodevelopmental diseases only became apparent after the development and widespread use of standardized and commercially available odor identification tests in the early 1980s (see Chapter 11).

This chapter is a review of what is known about the olfactory function of a range of neurodegenerative diseases and schizophrenia. The physiological bases for the losses observed in such disorders are explored, including, when available, their associations with known genetic mutations and other factors. The diseases are presented in alphabetical order to make it easy for the reader to locate a particular entity.

### 18.2 ALZHEIMER'S DISEASE

The diagnosis of AD is pathologically based, possible only at autopsy. Probable AD, a diagnosis based upon a set of well-defined clinical criteria (e.g., idiopathic slowly developing memory loss), is typically referred to as AD in living persons (McKhann et al., 1984). Early diagnosis is important, not only for long-term care and planning, but for the development and application of therapeutics that may eliminate or delay disease progression. Hence, markers for early AD, such as smell dysfunction, are of significant value to the physician and patient, and are focus of active research throughout the world.

Much is known about the olfactory dysfunction of AD, as a large number of studies have been performed on this topic (Table 18.1). A number of generalizations can be made from these studies. **First**, the loss – which is usually not total – is present in both nasal chambers and in the earliest stages of the disease, including in many cases of so-called mild cognitive impairment (MCI). **Second**, the deficit is robust, present in a large proportion of even early stage patients (85–90%) and detected by a wide range of nominally distinct olfactory tests, including tests of odor identification and detection threshold sensitivity (Table 18.1). Interestingly, suprathreshold

**Table 18.1** Procedural details of Alzheimer's disease olfactory function studies. P values reflect lower AD-related performances. See footnote for abbreviations

**Figure 18.1** An example showing that both odor identification (a) and detection (b) are clearly influenced by Alzheimer's disease. Identification is measured by the University of Pennsylvania Smell Identification Test (UPSIT) and detection by the phenyl ethyl alcohol single-staircase odor detection threshold test. Controls are matched on the basis of age, gender, and ethnicity. Data from Doty et al. (1987). Copyright © 2013 Richard L. Doty.

intensity ratings appear to be little influenced by the deficit (Green et al., 1989; Royet et al., 2001), conceivably reflecting divergence of such ratings from other types of olfactory measurements (Doty et al., 1994). In one meta-analysis of olfactory/AD studies, effect sizes as large as 12.15 (median = 2.17) were noted (effect sizes  $> 0.80$  are considered “enormous”) (Mesholam et al., 1998). **Third**, the olfactory dysfunction is accompanied by decreased odor-related activation of central structures (e.g., subfrontal temporal lobe), as measured by functional imaging procedures such as positron emission tomography (PET) (Buchsbaum et al., 1991; Kareken et al., 2001). **Fourth**, many AD patients are unaware of their olfactory deficit until formal testing (Doty et al., 1987; Fusetti et al., 2010; Nordin et al., 1995a). For example, Doty et al. (1987) reported that only 2 of 34 early stage AD patients (6%) responded affirmatively to the question, posed before olfactory testing, “Do you suffer from smell and/or taste problems?”, despite the fact that over 90% of the patients exhibited abnormal scores on the 40-item University of Pennsylvania Smell Identification Test (UPSIT). **Fifth**, the olfactory loss is, on average, equivalent to that observed in PD, PDG, Down’s syndrome, and even myasthenia gravis, begging the question as to whether the olfactory loss reflects a common pathological substrate of a number of diseases (Doty et al., 1991; Doty, 2012; Leon-Sarmiento et al., 2012; Moberg et al., 1997a). That being said, inverse associations have been noted between odor identification scores and tau-related pathology within the hippocampus and entorhinal cortex (Wilson et al., 2007). **Sixth**, the olfactory dysfunction appears to progress as AD progresses over time (Corwin and Serby, 1985; Jimbo et al., 2011; Knupfer and Spiegel, 1986; Murphy et al., 1990; Nordin et al., 1997; Serby et al., 1985a; see, however, Tissingh et al., 2001), although controls for the confounding of dementia, per se, on non-olfactory elements of psychophysical tests are often lacking and the reliability of findings from significantly demented patients must be questioned. **Seventh**, olfactory testing is useful in the differential diagnosis of AD from disorders commonly misdiagnosed as AD, such

as depression (Pentzek et al., 2007). Indeed, even a 3-item odor identification test accurately discriminates patients with AD from patients with depression (McCaffrey et al., 2000; Solomon et al., 1998). **Eighth**, there is evidence that smell loss is present in some inherited forms of AD (Nee and Lippa, 2001) and, moreover, that the loss in idiopathic AD correlates with a family history of dementia (Schiffman et al., 1990), implying genetic linkage. Indeed, persons with the ApoE ε4 allele, a risk factor for AD, are more likely to exhibit olfactory dysfunction than those not having this allele (Bacon et al., 1998; Gilbert and Murphy, 2004; Handley et al., 2006; Hozumi et al., 2003; Salerno-Kennedy et al., 2005; Wang et al., 2002; Wetter and Murphy, 2001).<sup>1</sup>

Olfactory dysfunction – particularly in conjunction with other risk factors – may aid, to some degree, in the prediction of subsequent development of cognitive decline and AD in older persons (Bacon et al., 1998; Fusetti et al., 2010; Schubert et al., 2008; Sohrabi et al., 2012; Wilson et al., 2007b). For example, Devanand et al. (2000) evaluated both the cognitive and olfactory function of 90 outpatients with MCI at 6-month intervals for both cognitive and olfactory function. Scores on the UPSIT were lower in patients with MCI than in healthy controls. Of 77 patients that were followed over a two-year period, those with mild, moderate, or severe smell loss, as well as those with low UPSIT scores who reported no subjective problems smelling, were more likely to develop AD than other individuals. Although low UPSIT scores alone did not forecast the time until development of AD, low UPSIT scores accompanied by lack of awareness of olfactory

<sup>1</sup>Apolipoprotein E is a widely distributed cholesterol transport protein that circulates in the plasma after synthesis by the liver, spleen and kidneys. In the CNS, it is synthesized by macrophages, neurons, and glia. In the PNS, it is synthesized by macrophages, nonmyelinated Schwann cells, and ganglionic satellite cells. Common isoforms include ε2, ε3, and ε4, with ε2 seemingly having a neuroprotectant action, and E4 being associated with a higher risk of not only developing some neurodegenerative diseases, such as AD, but in having a more malignant course of degeneration (Bedlack et al., 2000).

problems did so. Even in patients with relatively high Mini-Mental State Exam scores ( $\geq 27$ ), low UPSIT scores with lack of deficit awareness remained a significant, albeit imperfect, predictor of AD. UPSIT scores of 30–35 showed moderate to strong sensitivity and specificity for diagnosis of AD at follow-up.

More recently, this group administered the UPSIT to 1092 non-demented older persons (average age 80 years) from a multi-ethnic community in New York (Devanand et al., 2010). UPSIT scores varied as a function of the degree of memory impairment [respective mean (SD) scores for no mild cognitive impairment (MCI), non-amnestic MCI, and amnestic MCI = 26.6 (6.8), 24.4 (7.2), and 23.5 (6.7)]. The scores correlated weakly with hippocampal volume ( $r = 0.16$ ,  $p < 0.001$ ), but not with entorhinal cortex volume or total number of white matter hyperintensities. They also correlated negatively with age ( $r = -0.24$ ,  $p < 0.001$ ) and positively with several cognitive measures, including Selective Reminding Test immediate recall ( $r = 0.33$ ,  $p < 0.001$ ), delayed recall ( $r = 0.28$ ,  $p < 0.001$ ), category fluency ( $r = 0.28$ ,  $p < 0.001$ ), and the Boston Naming Test ( $r = 0.23$ ,  $p < 0.001$ ).

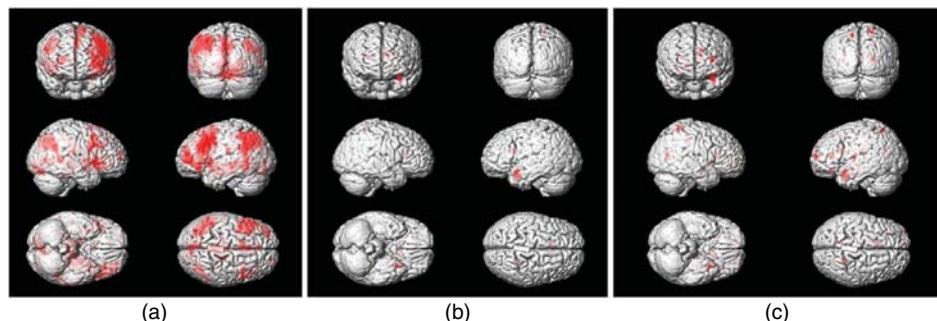

In a similarly large study, Graves et al. (1999) administered the 12-item version of the UPSIT (the Brief Smell Identification Test<sup>TM</sup> or B-SIT; see Chapter 11) to 1,604 non-demented community-dwelling senior citizens 65 years of age or older. Over a subsequent 2-year time period, the B-SIT scores were found to be a better predictor of cognitive decline than scores on a global cognitive test. Persons who were anosmic and possessed at least one ApoE ε4 allele had 4.9 times the risk of having cognitive decline than normosmic persons not possessing this allele (i.e., an odds ratio of 4.9). This is in contrast to the 1.23 times greater risk for cognitive decline in normosmic individuals possessing at least one such APOE allele – a risk rate that may be greater in older persons (Devanand et al., 2005). When the data were stratified by sex, women who were anosmic and possessed at least one ApoE ε4 allele had an odds ratio of 9.71, compared to an odds ratio of 1.90 for women who were normosmic and possessed at least one allele. The corresponding odds ratios for men were 3.18 and 0.67, respectively.

In light of such findings, it is of interest that some close relatives of AD patients exhibit less smell function than non-relatives of the same age and sex. Serby et al. (1996) administered the UPSIT to 28 first-degree relatives of AD patients and to 28 healthy controls. Despite similar global cognitive scores (MMSE), the relatives exhibited lower UPSIT scores than those of the controls ( $p < 0.01$ ). Although olfactory testing was suggested by Nee and Lippa (2001) as not being useful in predicting the symptom onset of one relatively rare genetically-determined form of AD (presenilin-1 AD), such data, along with evidence of (a) poorer odor detection or identification performance in

individuals having one or more ApoE ε4 alleles (Bacon et al., 1998; Bahar-Fuchs et al., 2010) and (b) delayed latencies to olfactory event-related potentials (OERPs) in individuals with the ApoE ε4 allele (Corby et al., 2012; Wetter and Murphy, 2001), are in agreement with the concept of genetic vulnerability to olfactory dysfunction in this disease. The finding that olfactory event-related potentials from an odor/visual congruity paradigm exhibit high sensitivity and specificity in differentiating non-demented ApoE ε4 carriers from non-carriers also accords well with this concept (Kowalewski and Murphy, 2012). Interestingly, one study found an association between younger age of onset of AD and the presence of high copy number of submicroscopic DNA segments in the olfactory receptor region of 14q11.2 (Shaw et al., 2011). This association was independent of and in addition to that observed for the ApoE ε4 allele.

There is evidence that older persons with olfactory loss also are more likely to report that they experience more memory problems (Sohrabi et al., 2009). Hence, olfactory and cognitive impairment may be interrelated in older persons. Some investigators have, in fact, increased the sensitivity and specificity of predicting conversion of at-risk older patients to AD by combining olfactory test scores with psychological measures, as well as with MRI-determined volumes of limbic brain structures. Devanand et al. (2008) found, for example, that at a specificity point of 90%, the UPSIT alone had a sensitivity of 49% in making this prediction in 148 outpatients with MCI. When combined with age, hippocampal volume, entorhinal cortex volume, and scores from the MMSE, the Pfeiffer Functional Activities Questionnaire (FAQ), and the Selective Reminding Test (SRT) immediate recall (verbal memory), this value increased to 81.3%. More recently, Lojkowska et al. (2011) reported that, in a 24-month follow up study of 49 MCI patients, combining the results of odor identification tests with those of neuropsychological measures markedly increased the sensitivity of prediction. The odor identification test alone had a sensitivity and specificity of 57% and 88%, respectively, in predicting conversion. By combining the olfactory test results with neuropsychological measures, sensitivity and specificity increased to 100% and 84%, respectively.

The specific physiological basis or bases for the olfactory loss of AD is unknown and probably multifactorial. AD-related pathology is seen throughout the olfactory pathways, as reviewed in more detail elsewhere (Hawkes and Doty, 2009; Smutzer et al., 2003). Thus, dystrophic neurites and neurofibrillary tangles have been found in the olfactory epithelia of AD patients, although their density is not marked and these entities are also found in the epithelia of healthy older persons, as well as in that of persons with other neurodegenerative diseases, including progressive supranuclear palsy (PSP), a disorder with relatively

**Figure 18.2** Three-dimensional representation of average brain activation maps in response to lavender odor. (a) Healthy control group (one-sample  $t$ -test, voxel-wise threshold  $p < 0.005$ , uncorrected with extent threshold = 6) at lowest and first exposed odorant concentration (0.10%). (b) Early AD group at same statistical threshold and at the highest odorant concentration exposure (1.0%). (c) AD group with more relaxed statistical threshold (one-sample  $t$ -test, voxel-wise threshold  $p < 0.01$ , uncorrected with extent threshold = 0) and at the highest odorant concentration exposure (1.0%). From Wang et al. (2010). (See plate section for color version.)

little olfactory dysfunction (Trojanowski et al., 1991). In AD, neurofibrillary tangles and amyloid plaques are evident throughout the olfactory bulb, the anterior olfactory nucleus, and in higher brain regions, most notably those that receive projections from the olfactory bulb (e.g., the piriform cortex and the corticomедial nucleus of the amygdala). Functional imaging studies clearly demonstrate decreased odor-induced activity in a range of brain regions (Figure 18.2).

Bahar-Fuchs et al., (2010) sought to determine whether olfactory identification test scores were associated, in patients with amnestic MCI, with in vivo measures of  $\beta$ -amyloid burden, as measured by PET imaging using Pittsburgh Compound B (PiB). The olfactory test scores did not differ between the patients who were PiB-positive and those who were PiB-negative, leading the authors to conclude that AD-related olfactory identification deficits are probably not directly related to levels of  $\beta$ -amyloid. This is in agreement with the conclusions of earlier studies of both non-demented and demented older subjects who received olfactory testing and postmortem brain analyses (Pentzek et al., 2007; Wilson et al., 2007). No meaningful associations were evident between olfactory test scores, obtained prior to death, and levels of  $\beta$ -amyloid in olfactory eloquent brain regions. However, an inverse correlation was found between odor identification test scores and tau-related NFT accumulation within the entorhinal cortex and the CA1/subiculum area of the hippocampus.

Although there are proponents of the concept that AD-related pathology begins within the olfactory bulb and spreads to other brain regions, this is a matter of controversy. Pathological studies by Braak and Braak (1991) suggested that the earliest pathology is found in the transentorhinal cortex, a brain region between the entorhinal cortex and the hippocampus. On the other hand, Kovacs et al. (2001) have noted cases of AD in which neurofibrillary tangles (NFTs) were most evident in the

olfactory bulb, but not in other brain structures. Moreover, they found cases where the primary olfactory cortex was less severely affected than the so-called secondary olfactory cortex (i.e., the medial orbitofrontal cortex), implying the NFT formation developed independently of synaptic connections. In other words, it need not be a process that advanced from the periphery along established neural pathways.

As noted in Chapter 20, there is evidence that environmental factors, such as severe air pollution, can induce AD-like pathology in human brains, most notably the olfactory bulbs. Moreover, there is evidence that some, even young, residents in metropolitan areas with very high air pollution exhibit smell dysfunction (Calderon-Garciduenas et al., 2010; Guarneros et al., 2009). While it is unknown whether the AD-like pathology is secondary to olfactory dysfunction induced by the pollutants, it is of interest that rats whose olfactory bulbs are removed and transgenic mice lacking intact olfactory CNG channels exhibit increased neurofilament hyperphosphorylation in both the hippocampus and cortex (Hu et al., 2012). Such observations are in general accord with elements of the olfactory vector hypothesis (Doty, 2008).

It is important to note that neurotransmitter and neuromodulator anomalies may be present within the olfactory system of early stage AD patients before meaningful degeneration occurs. Thus, cholinergic dysfunction is present in some early stage AD patients and in patients with mild cognitive impairment (MCI) unaccompanied by significant cell loss (Schliebs and Arendt, 2011). Associated with this dysfunction are imbalances in the expression of nerve growth factor (NGF), its precursor proNGF, and in NGF receptors (trkA and p75NTR, respectively), as well as changes in acetylcholine release, high-affinity choline uptake, and alterations in muscarinic and nicotinic acetylcholine expression. Massive loss of cholinergic centrifugal inputs to all layers of the olfactory bulb have

been demonstrated in patients with AD, as well as PD and dementia with Lewy bodies (Mundinano et al., 2013).

### 18.3 AMYOTROPHIC LATERAL SCLEROSIS

Amyotrophic lateral sclerosis (ALS), popularly known as Lou Gehrig's disease, is the most common form of motor neuron disease. It is typified by degeneration of neurons within the anterior horn of the spinal cord and cortical neurons with which they interact. Although most forms are considered sporadic, the A4V mutation of the superoxide dismutase SOD1 gene along with FUS positive basophilic inclusions have been described in early onset forms of ALS (Aksoy et al., 2003; Baumer et al., 2010; Juneja et al., 1997). Accumulation of lipofuscin in cells has been noted within the anterior olfactory nucleus (AON) and the mitral and tufted cells of the olfactory bulb of ALS patients (Hawkes et al., 1998).

It is now apparent that ALS is more than just a motor neuron disease. In a pioneering study, Elian (1991) found nine male and six female ALS patients of varying disease severity to have UPSIT scores significantly lower than those of age- and sex-matched controls. However, the magnitude of the deficit was modest, with the scores averaging around 30. Subsequently, Sajjadi et al. (1994) administered the UPSIT bilaterally to 17 female and 20 male ALS patients, and unilaterally (i.e., each nostril separately) to 7 male and 7 female ALS patients. Age-, gender-, smoking habit-, and race-matched controls were also evaluated. While the UPSIT scores on the ALS patients were significantly lower than those of the controls, no left:right differences were observed and the degree of dysfunction was similar to that seen by Elian. Only 11% of the ALS patients had UPSIT scores indicative of total or near total anosmia and nearly half had scores falling within the normal range. Nevertheless, three quarters of the patients scored below their individually matched controls. Significant correlations were found between UPSIT scores and neurophysiological measures of peripheral nerve conductance, conceivably reflecting an association with cholinergic dysfunction.

Evidence for a modest loss of smell function in ALS was also found in a study of 58 ALS patients and 135 controls to whom the UPSIT was administered (Hawkes et al., 1998). Olfactory event-related potentials (OERPs) in response to H<sub>2</sub>S were recorded in 15 patients. Only the bulbar patients exhibited significant UPSIT decrements, although, overall, the UPSIT scores were slightly worse in the ALS patients. OERPs were normal in nine patients and delayed in one; those of the remaining five subjects were not able to be recorded. Histological analysis of olfactory bulb tissue from eight deceased ALS patients revealed, in all cases, excessive lipofuscin deposition.

### 18.4 DOWN SYNDROME

Down syndrome (DS), a trisomy 21 disorder, is the most common form of mental disability, accounting for ~17% of the intellectually disabled population. It was suggested as early as 1928 that individuals with DS have difficulty smelling (Brousseau and Brainerd, 1928). More modern studies have found adult DS patients to have olfactory deficits, as measured by tests of odor identification, detection, memory, and EEG responses to odorants (Hemdal et al., 1993; Murphy and Jinich, 1996; Warner et al., 1988; Wetter and Murphy, 1999; Zucco and Negrin, 1994). Such observations are of significance, given that the average smell loss observed in DS is very close to that observed in AD (i.e., UPSIT scores ~20; McKeown et al. 1996; Warner et al., 1988) and DS patients who live into early adulthood inevitably develop the neuropathological features of AD, such as senile plaques and neurofibrillary tangles (Oliver and Holland, 1986). Importantly, deposition of amyloid in the form of senile plaques or diffuse amyloid deposits occurs in cortical brain regions associated with olfactory processing (e.g., entorhinal cortex) (Hof et al., 1995).

That being said, classic AD pathology – neuritic plaques and neurofibrillary tangles – is unlikely to be the basis for the smell loss of DS, since olfactory dysfunction appears in children with DS who would not yet be expected to exhibit such pathology. McKeown et al. (1996) administered the UPSIT and a 16-item odor discrimination test to (a) 20 children with DS [mean age (SD) = 13.89 yrs (1.98)], (b) 20 non-DS intellectually disabled children matched on the basis of mental age (Peabody Picture Vocabulary Test-Revised (PPVT-R; Dunn, 1981), and (c) 20 non-intellectually disabled children also matched on mental age. Although no meaningful differences in olfactory function were found among the three study groups, the test scores of both the DS and non-DS intellectually disabled subjects were markedly lower than non-intellectually disabled children matched on chronologic, rather than mental, age. Moreover, the UPSIT scores of these young people were similar in magnitude to those of adult DS subjects (~20).

The basis for the olfactory loss of Down syndrome is not known, although it conceivably reflects abnormal development of the cholinergic basal forebrain which is known to be involved in both cognition and olfaction (Berger-Sweeney, 1998). There is a growing body of evidence that suggests dysregulation of cholinergic circuits could explain the olfactory dysfunction observed in a number of diseases, including AD, PD, and DS (Doty, 2012; Schliebs and Arendt, 2011). Although the Down syndrome critical gene region 1 (DSCR1) interacts with the Fragile X mental retardation protein (FMRP) to regulate local protein synthesis and dendritic spine morphogenesis in numerous brain regions (Wang et al., 2012), the olfactory dysfunction

seen in FMRP and other trinucleotide repeat disorders, such as spinocerebellar ataxias (see Section 18.14), is much less than that observed in DS (Juncos et al., 2012).

## 18.5 ESSENTIAL TREMOR

Unlike PD, essential tremor (ET) is usually associated with an action tremor, not a resting tremor, and is unaccompanied by stooped posture, slow movement, or a shuffling gait. Unlike the tremors of PD, which predominate in the hands, those of ET are more likely to involve the legs, hands, voice, and head. Nonetheless, persons with ET are more at risk than those in the general population for future development of AD and PD (Laroia and Louis, 2011; Louis, 2009). No studies have uniformly found neuropathology of any sort within the olfactory bulbs or higher olfactory structures of ET patients.

Patients with ET have no meaningful olfactory dysfunction, unlike the case of PD. In 1992, Busenbark reported that 15 ET patients scored normally on the UPSIT (Busenbark et al., 1992). Although a later study claimed that a number of ET patients had mild impairment on the UPSIT (Louis et al., 2002), all subsequent studies have found normal UPSIT scores in ET patients (Shah et al., 2008; Ward, 2003). Shah et al. (2008), for example, compared UPSIT scores of 59 ET patients to those of 64 tremor-dominant PD patients. Nearly complete separation of the two groups was made on the basis of UPSIT scores and to a lesser degree on measures from OERPs. Surprisingly, when ET subjects were separated by family history of tremor in a first degree relative, this group scored significantly *better* than age- and gender-matched controls, a finding that begs replication.

## 18.6 HUNTINGTON'S DISEASE

Huntington's disease (HD) is an autosomal genetic disorder of dysfunctional movement, cognitive deterioration, and altered behavior that becomes phenotypically expressed progressively relatively late in life. Among its primary motor symptoms are hyperkinesias that initially take the form of chorea, being characterized by fleeting movements which, in some persons, appear semi-purposively within the context of overall heightened activity and motor restlessness (Shoulson, 1986). Like a number of other neurodegenerative diseases, HD is associated with marked deficits in odor identification, discrimination, detection, and odor memory (Bylsma et al., 1997; Hamilton et al., 1999; Lazic et al., 2007; Moberg et al., 1987a; Moberg and Doty, 1997; Nordin et al., 1995b). The P3 component of the olfactory event-related potential (OERP), like that of the auditory event-related potential, is significantly delayed

in HD, with an amplitude inversely correlated with the number of CAG repeats and UHDRS movement scores (Wetter et al., 2005). A study employing diffusion tensor MRI found negative correlations between UPSIT scores and mean diffusivity in multiple subcortical and cortical brain regions, including the insula, anterior caudate, and medial temporal cortex (Delmaire et al., 2013), supporting the concept of involvement of central olfactory processing neural circuits.

The question arises as to whether asymptomatic individuals who carry the HD mutation have decreased olfactory function. In one study of 25 probands with HD, 12 at-risk offspring, and 37 unrelated controls, significant UPSIT and PEA threshold deficits were apparent only in the HD group (Moberg and Doty, 1997). Since HD is an autosomal dominant genetic disorder with 100% penetrance, on average half of the at-risk offspring would have been expected to have the mutation and to evidence smell dysfunction if it was a very early marker of HD. A subsequent study administered the UPSIT to 20 HD patients who had the disease for a mean of 8.0 years (range: 4 to 14 years), 20 normal subjects with the genetic mutation that causes HD, and 20 mutation-negative adults (Bylsma et al., 1997). Again, only the patients with clinical signs of HD exhibited depressed olfaction.

While others have similarly seen no odor identification or detection deficits in non-symptomatic HD gene carriers (Larsson et al., 2006; Pirogovsky et al., 2007), subtle deficits in some other olfaction-related measures have been reported. For example, Larsson et al. (2006) found 10 gene carriers to perform more poorly than 10 controls on a match-to-sample odor quality discrimination test in which 12 different combinations of four fruit-like odors were presented ( $p < 0.03$ ). Pirogovsky et al. (2007) found that HD patients performed more poorly than controls on visual and olfactory measures of "source memory" (i.e., whether a male or female had presented a given stimulus on earlier trials), but not for the memory of the smell or pictured item itself ("item memory").

## 18.7 IDIOPATHIC RAPID EYE MOVEMENT SLEEP BEHAVIOR DISORDER

Idiopathic rapid eye movement sleep behavior disorder (RBD) is a unique parasomnia associated with degeneration of pontine and medullary brain regions, such as the sublaterodorsal nucleus, and their glutaminergic projections to the medulary or magnocellular reticular formation (Postuma et al., 2012). The majority of patients with this disorder eventually develop some type of neurodegenerative disease, including PD, MSA, or LBD. Importantly, many exhibit olfactory dysfunction, as measured by a variety of olfactory tests (Miyamoto et al., 2010; Postuma

et al., 2011). In a five-year prospective follow-up study of 62 patients with idiopathic RBD, those with impaired olfaction at baseline had a 65% 5-year risk of developing a defined neurodegenerative disease, compared to a 14% risk in those with normal olfaction (Postuma et al., 2011). As with PD, olfactory dysfunction was present in a number of the patients up to five years before diagnosis.

## 18.8 LEWY BODY DISEASE

Lewy body disease (LBD), commonly termed “diffuse Lewy body disease,” is the second most common dementing illness, being surpassed only by AD. In this disorder, Lewy bodies (LBs) – spherical intracellular cytoplasmic inclusions made up of aberrant  $\alpha$ -synuclein – are present throughout the cortex, in contrast to the neuritic plaques and neurofibrillary tangles of AD. Related structures – Lewy neurites – extend for considerable distances within axons. LBD is associated with dementia. If the dementia occurs before, during, or within a year of the motor symptoms, the syndrome is termed *Dementia with Lewy bodies* (Lippa et al., 2007).

Smell dysfunction is common in LBD and appears unrelated to disease duration or severity (Liberini et al., 2000; McShane et al., 2001; Olichney et al., 2005; Williams et al., 2009; Wilson et al., 2011). McShane et al. (2001) reported that anosmia was present in 9 of 22 autopsy confirmed LBD patients (41%), 7 of 43 autopsy confirmed AD patients (16%), and 6 of 94 age-matched controls (6%). Unfortunately, the olfactory test consisted of simply sniffing a bottle of lavender water. Westervelt et al. (2003) administered the B-SIT to 9 LBD patients and 9 AD patients matched on the basis of age, gender, and dementia level. Five of the 9 LBD patients were anosmic (56%), as compared to only one AD patient (11%), and the B-SIT scores were markedly lower in the LBD than in the AD group. More recently, Wilson et al. (2011) identified 26 persons with LBD from a sample of 201 autopsied brains of older persons. None had PD prior to death and all had been tested with the B-SIT. Those without Lewy bodies performed at the level expected for someone of their age [mean (SD) age at time of death = 88.0 (6.54) yrs], whereas those with Lewy bodies exhibited test scores similar to those expected from older patients with PD (Aden et al., 2011). Those with Lewy bodies located within limbic or cortical regions exhibited decreased smell function, whereas those with Lewy bodies confined to the substantia nigra showed no meaningful deficit. Although the olfactory bulbs were not examined for Lewy pathology, such pathology is known to exist, along with neurofibrillary tangles and tau pathology, in the bulbs of patients with LBD and patients with PD (Mundinano et al., 2011; Tsuboi et al., 2003).

It is noteworthy that Ross et al. (2006), in the Honolulu-Asian aging study, found an association between the presence of post-mortem incidental Lewy bodies and pre-mortem B-SIT scores in persons without Parkinsonism or dementia during life. The age-adjusted relative odds of ILB in the lowest v. the highest B-SIT tertile was 11.0 ( $p = 0.02$ ).

## 18.9 PARKINSON'S DISEASE AND PARKINSON-LIKE DISORDERS

### 18.9.1 Sporadic Parkinson's Disease

Until the 1980s, Parkinson's disease (PD) was widely considered to be solely a disease of the extrapyramidal motor system. It is now apparent that PD is also associated with a range of autonomic, cognitive, and sensory changes. Some occur during its so-called preclinical or premotor stage, when motor symptoms are not evident. Among the most salient of these changes are alterations in the ability to smell.

At the time of this writing, nearly 100 peer-reviewed studies have been published in which olfactory test scores of sporadic or idiopathic PD patients were compared to those of controls. In essentially every study, test scores were lower in PD patients than in controls (Table 18.2). From this literature, a number of generalizations can be made. **First**, the smell dysfunction is bilateral and occurs in 90% or more of such cases (Doty et al., 1984; Hawkes and Doty, 2009). **Second**, it is robust and detectable with both ortho- and retro-nasal testing (Landis et al., 2009). In one meta-analysis, Cohen effect sizes  $> 3$  were found for tests of odor identification, discrimination, detection, and memory (Mesholam et al., 1998). One study examining the sensitivity and specificity of the UPSIT in differentiating between clinically-diagnosed PD patients and normal controls found these values to be quite high (0.91 and 0.88, respectively, in males  $\leq 60$  years of age) (Doty et al., 1995a). **Third**, women with PD generally outperform their male counterparts on olfactory tests (Stern et al., 1994), a sex difference seen not only in the general population (Doty and Cameron, 2009), but in diseases ranging from AD (Doty et al., 1987) to schizophrenia (Good et al., 2007; Seidman et al., 1997). **Fourth**, anosmia is not the norm. In one study, only 38% of 81 PD patients had UPSIT scores suggestive of anosmia and 87% of 38 patients could reliably detect the highest stimulus concentration presented in an odor detection threshold test (Doty et al., 1988). In another study, all but one of 41 PD patients reported that 35 or more of the 40 UPSIT items had some type of odor, even though the perceived sensation did not correspond to any of the response alternatives (Doty et al., 1992b).

**Table 18.2** Procedural details of Parkinson's disease olfactory function studies

Interestingly, unlike what appears to be the case in AD and schizophrenia, PD patients evidence a decrement in the build-up of perceived intensity across increasing suprathreshold concentrations of an odor (Doty et al., 2014). **Fifth**, the olfactory deficit is not confined to specific odors. Although there are reports that some odorants differentiate PD from controls better than others, little consistency has been found among studies and confounding from such variables as culture, odorant intensity, odorant type, and the choice of response alternatives is likely present (Boesveldt et al., 2008b; Bohnen et al., 2007; Daum et al., 2000; Double et al., 2003; Hawkes et al., 1997; Silveira-Moriyama et al., 2005). Since most stimuli are comprised of a melody of chemicals, and different sets of chemicals can sometimes produce the same odor quality, the focus on nominal odor qualities appears questionable. **Sixth**, the same degree of dysfunction found in PD occurs in some other neurodegenerative diseases. For example, the UPSIT scores of patients with early stage AD, PD, and the Parkinson-Dementia Complex of Guam (PDG) are essentially equivalent (Doty et al., 1991; Mesholam et al., 1998). However, olfactory testing can aid in differential diagnosis among selected movement disorders, since some have comparatively little or no olfactory dysfunction, including progressive supranuclear palsy (PSP), MPTP-induced parkinsonism (MPTP-P), multiple system atrophy (MSA), and essential tremor (ET) (Busenbark et al., 1992; Doty et al., 1993; Doty et al., 1995a; Ondo and Lai, 2005; Shah et al., 2008; Wenning et al., 1995). **Seventh**, PD-related olfactory dysfunction is not meaningfully influenced by medications used to mitigate the motor dysfunction, i.e., L-DOPA, dopamine agonists, and anticholinergic compounds (Doty et al., 1992b; Quinn et al., 1987a; Roth et al., 1998). **Eighth**, in well-established PD the dysfunction is surprisingly stable over time and typically unrelated to disease stage or duration (Barz et al., 1997; Doty et al., 1988; Doty et al., 1992b; Hawkes et al., 1997; Oka et al., 2010; Verbaan et al., 2008), although exceptions occur (Sharma and Turton, 2012) and associations have been noted between olfactory test scores and the degree of damage to dopaminergic brain regions, as inferred from functional imaging of the dopamine transporter within the caudate and putamen (Berendse et al., 2011; Herting et al., 2008; Siderowf et al., 2005). **Ninth**, PD patients with the most olfactory dysfunction tend to be those with the lowest body weight (Sharma and Turton, 2012). **Tenth**, suboptimal sniffing may contribute to the olfactory problem, particularly in later stages of the disease (Sobel et al., 2001). However, the degree of this contribution is small and in most investigations is null so long as adequate sniffing has occurred. **Eleventh**, the olfactory dysfunction is associated with some other PD-related changes, such as those related to cardiac sympathetic function. For example, strong correlations have been noted between UPSIT scores and cardiac  $^{123}\text{I}$ -metaiodobenzylguanidine (MIBG) uptake

(Goldstein et al., 2008). Such associations appear to be independent of disease duration and clinical ratings of motor function (Lee et al., 2006). **Twelfth**, olfactory test scores are weakly correlated with some cognitive measures, most notably ones involving verbal memory and executive function (Bohen et al., 2010; Morley et al., 2011; Parrao et al., 2012; Devanand et al., 2014). Although strong relationships among olfactory and cognitive test scores are generally lacking in most PD cohorts (Doty et al., 1989), longitudinal studies suggest that olfactory dysfunction is associated with a much higher risk of subsequent development of dementia (Baba et al., 2012). **Thirteenth**, some studies report that olfactory bulb volume is decreased in patients with PD (Brodoehl et al., 2012; Wang et al., 2011b), although others have not found this association (Hummel et al., 2010b; Mueller et al., 2005; Mundinano et al., 2011). If this does occur, it should be pointed out that decreased olfactory bulb volumes have also been observed in older persons (Yousem et al., 1998) and individuals with AD (Thomann et al., 2009), head trauma (Collet et al., 2009; Doty et al., 1997b; Rombaux et al., 2006a; Yousem et al., 1995), multiple sclerosis (Schmidt et al., 2011), and viral-related smell dysfunction (Rombaux et al., 2006b), implying lack of specificity (see Chapter 17). **Fourteenth**, the olfactory deficit often precedes the classical clinical PD motor signs by a considerable period, serving as a ‘pre-clinical’ or ‘pre-motor’ marker (Haehner et al., 2007; Ponsen et al., 2004; Ross et al., 2005). **Fifteenth**, olfactory testing is sensitive to a number of risk factors associated with future development of PD, including age (Doty et al., 1984) and head trauma (Doty et al., 1997b). **Sixteenth**, such factors as cigarette smoking and lifetime intake of caffeinated beverages may mitigate to some degree the olfactory dysfunction observed in PD (Lucassen et al., 2014; Sharer et al., 2015; Siderowf et al., 2007). **Seventeenth**, some asymptomatic first-degree relatives of patients with sporadic PD exhibit olfactory dysfunction that predicts, to some degree, future development of PD (Berendse et al., 2001; Montgomery, Jr. et al., 1999; Montgomery, Jr. et al., 2000b; Ponsen et al., 2004). In one study, Ponsen et al. (2004) tested the olfactory function of 361 asymptomatic relatives of PD patients. Those who performed in the top 10% and bottom 10% were then scanned for dopamine transporter function within the striatum using the  $^{123}\text{I}$ - $\beta$ -CIT labelled DA transporter. A number of those in the bottom 10% exhibited substantial reduction in DA transporter uptake, whereas none of those in the top 10% did so. When assessed two years later, none of the 38 relatives who scored in the top 10% had developed clinically defined PD or exhibited DA transporter dysfunction. All of those in the bottom 10% exhibited DA transporter dysfunction and four had developed clinically defined PD.

As with AD, the physiological basis for the olfactory loss of PD is obscure, although most likely multifactorial.

**Figure 18.3** Lewy pathology of the olfactory bulb demonstrated with alpha-synuclein immunohistochemistry. Lewy body and Lewy neurites are seen throughout the bulb, but particularly in the internal plexiform layer (IPL) and the intrabulbar anterior olfactory nucleus (iAON). Scale bar = 100 µm. Abbreviations: ONL: olfactory nerve layer; GLOM: glomerular layer; EPL: external plexiform layer; MCL: mitral cell layer; IPL: internal plexiform layer; GRAN: granular cell layer; iAON: intrabulbar anterior olfactory nucleus. From Duda (2010) (See plate section for color version.)

Among suggested causes are decrements in cholinergic function and the presence of Lewy bodies and neurites within the olfactory system (Figure 18.3) (Doty, 2011; Duda, 2010).

## 18.9.2 Familial Parkinson's Disease

Twin studies generally fail to find meaningful heritability of olfactory loss in PD patients (Tanner, 2003; Ward et al., 1983; Ward et al., 1984). Nevertheless, specific mutations have been identified in a number of familial forms of PD associated with olfactory system compromise. Such mono-genetic forms of PD are rare in most, but not all, populations. For example, in PD cases within the Arab-Berbers of North Africa, over 40% have a mutation in the leucine-rich repeat kinase 2 gene (LRRK2) (Lesage et al., 2005). In North American, only around 1% of PD cases have this mutation (Correia et al., 2010). Identified genes associated with familial PD are listed in Table 18.3.

As with PD itself, genetic forms of PD exhibit heterogeneity in olfactory dysfunction. As discussed below for each of the known PD-related mutations, in many instances

the olfactory test scores are very similar to those observed in sporadic PD. In others, no meaningful smell dysfunction is evident.

### 18.9.2.1 PARK1/PARK4 Locus Mutations ( $\alpha$ -synuclein)

In PARK1/PARK4, an autosomal-dominant form of PD, the motor phenotype is typically exhibited early in life, usually in the 30's and 40's, although later onset may occur in some with the A30P mutation (Kruger et al., 1998).  $\alpha$ -synuclein is the encoded protein. Several studies have demonstrated olfactory dysfunction in subjects with the PARK1 mutation in small numbers of subjects (Bostantjopoulou et al., 2001; Kertelje et al., 2010; Nishioka et al., 2009). For example, Bostantjopoulou et al. (2001) demonstrated that two out of the eight Greek PD patients carrying the G209A PARK1 mutation were anosmic, whereas the others were normal. No evidence of smell loss was observed by Tijero et al. (2010) in an asymptomatic carrier of the E46K substitution in the  $\alpha$ -synuclein gene.

### 18.9.2.2 PARK2 Locus Mutations (Parkin gene)

The most common form of *early-onset* parkinsonism carries the autosomal recessive Parkin gene (PARK2). This gene is closely associated with the function of actin filaments within the cytoplasm and neuronal processes. Parkin mutations appear to have little influence on olfaction. Thus, Khan et al. (2004) found normal UPSIT scores in all 27 PARK2 patients they tested. Deficits were observed in a PARK2 negative PD group and a sporadic PD patient group. Normal UPSIT scores were also reported by Alcalay et al. for compound PARK2 heterozygotes – that is, individuals who had PARK2 mutations on both the paternal and maternal alleles (Alcalay et al., 2011). PD patients who did not carry the PARK2 gene and non-compound PARK2 heterozygotes had UPSIT scores analogous to those observed in sporadic PD. Yoritaka et al. (2011) reported that all but one of three men and three women with PARK2 mutations, apparently a mixture of homozygous and heterozygous mutations or deletions, had elevated thresholds relative to controls, although the patients were older than the controls which may explain their positive finding [respective mean (range) ages = 69.6 (60–89) and 46.0 (39–79)].

### 18.9.2.3 PARK6 Locus Mutations (PINK1 gene)

This autosomal-recessive disorder, whose clinical features are similar to those of PARK2, exhibits mutations in the PTEN-induced putative kinase 1 (PINK1) gene. After *Parkin*, *PINK1* mutations are the most frequent cause of autosomal recessive parkinsonism. This gene appears to inhibit the formation of reactive oxygen species

**Table 18.3** Genetic forms of PD or parkinsonism. Those forms for which olfactory tests have been administered are indicated in the light gray rows. Other genetic forms, namely PARK5 (4p14), PARK11 (2q36-q37) and PARK13 (2p12), are not indicated since they are now considered to have questionable associations with the expression of parkinsonism.

Locus (Map Position)	Protein	Inheritance Pattern	Mutations	Clinical Features
PARK1/PARK4 (4q21-q23)	<i>α-synuclein</i>	Autosomal Dominant	A30P, A53T, E46K; duplications and triplications	Early onset; dementia; autonomic dysfunction. Rare and not yet observed in sporadic PD cases.
PARK2 (6q25.2-q27)	<i>Parkin</i>	Autosomal Recessive	A wide variety of mutations, exonic deletions, duplications and triplications	Juvenile and early onset; slow progression; good L-DOPA response
PARK3 (2p13)	Unknown	Autosomal Dominant	Not Identified	Late onset; typical PD features
PARK6 (1p35-p36)	<i>Pink-1</i>	Autosomal Recessive	G309D, exonic deletions	Early onset; slow progression; good L-DOPA response
PARK7 (1p36)	<i>DJ-1</i>	Autosomal Recessive	Homozigotic exonic deletion, L166P	Early onset, slow progression; very rare
PARK8 (12q12)	<i>LRRK2</i>	Autosomal Dominant (incomplete penetrance)	G2019S (most common), R1441C/G/H, Y1699C, I2020T, G2385R, others	Late onset, Tremor dominant PD symptoms
PARK9 (1p36)	<i>ATP13A2</i>	Autosomal Recessive	Loss-of-function mutations	Atypical PD features; Kufor-Rakeb syndrome; juvenile and early onset (11–16 yrs); dementia; pyramidal degeneration; spasticity; paralysis of gaze
PARK10 (1p32)	Unknown	Not clear	Not identified	Late onset, typical PD features
PARK12 (Xq21-25)	Unknown	Not clear	Not identified	Late onset PD
PARK14 (22q13.1)	<i>PLA2G6</i>	Autosomal Recessive	Two missense mutations	Early cerebellar signs and visual disturbances; late-onset dystonia with PD features; good L-DOPA response
PARK15 (22q12-q13)	<i>FBXO7</i>	Autosomal Recessive	Three point mutations	Early onset, progressive pallidio-pyramidal syndrome
PARK16 (1q32)	<i>RAB7</i>	Risk	<i>RAB7L1, SLC41A1</i>	Late onset PD
PARK17 (4P16)	<i>GAK</i>	Risk	Not identified	Late onset PD
PARK18 (6p21.3)	<i>HLA-DRA</i>	Risk	Not identified	Late onset PD

(Wang et al., 2011a). Ferraris et al. (2009) administered olfactory tests to seven patients with homozygous PARK6 PD, six patients with heterozygous PARK6 PD, and 12 healthy individuals heterozygous for the PINK1 gene. All 13 PARK6 cases, and 8 of the 12 healthy heterozygotes, scored below normal relative to non-PD persons of their age. In contrast, Eggers et al. (2010) reported that none of four homozygous PARK6 PD patients they tested had UPSIT scores falling outside of the 10th percentile of age- and sex-matched normal controls. Although 4 of 10 heterozygotes did so, only one was at or below the 5th percentile, suggesting to these authors that PARK6 mutations have only modest influences on smell function.

**18.9.2.4 PARK 8 Locus Mutations (LRRK2 gene).** This is the most common form of dominantly inherited PD. Mutations are found in the leucine-rich repeat kinase 2 gene (LRRK2/Dardarin). The absence of a gene dose effect is suggested by the fact that both homozygotes and heterozygotes have the same clinical features (Ishihara et al., 2006). Penetrance of the most common LRRK2 mutation (G2019S on exon 41) is incomplete and age-dependent (Lesage et al., 2007).

The olfactory dysfunction of PARK8 cases is variable but generally similar to that of sporadic PD. However, despite having abnormal smell scores, several studies have noted that G2019S PD mutation carriers have olfactory test scores somewhat higher than those of non-mutation carrying PD patients (Berg et al., 2005; Kertelge et al., 2010; Khan et al., 2005; Lin et al., 2008; Saunders-Pullman et al., 2011; Silveira-Moriyama et al., 2010b). *Asymptomatic* LRRK2 mutation carriers generally exhibit no smell dysfunction (Johansen et al., 2011; Saunders-Pullman et al., 2011; Silveira-Moriyama et al., 2008).

### 18.9.3 Other Forms of Parkinsonism

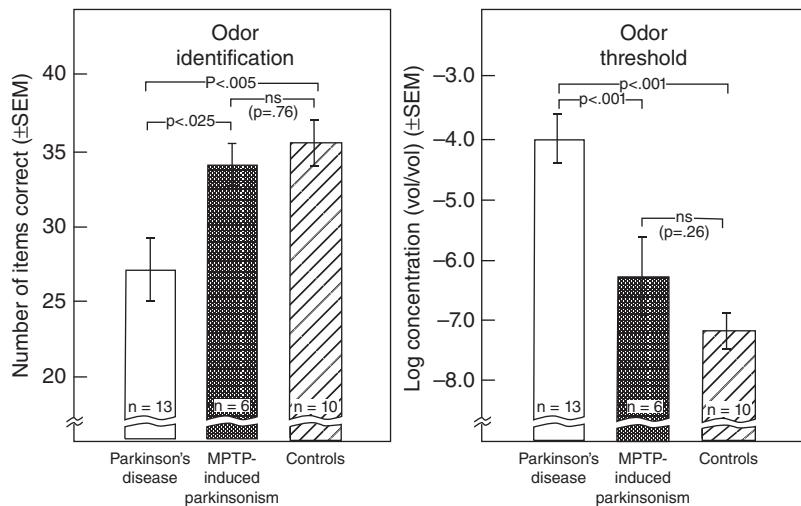

**18.9.3.1 Corticobasal Degeneration.** In corticobasal degeneration (CBD), parkinsonian features are evident along with limb dystonia, ideomotor apraxia, myoclonus, and ultimately, cognitive decline. This disease is noted for the accumulation of tau protein largely in the basal ganglia and fronto-parietal cortex. The olfactory bulbs and temporal cortex appear to be spared from meaningful tau pathology (Tsuboi et al., 2003). In one study of seven patients with clinically suspected CBD, UPSIT scores did not differ significantly from those of age-matched controls (Wenning et al., 1995). A similar finding was noted in a more recent study of seven patients with clinically defined CBD for odor discrimination, although mild deficits in odor naming and odor picture matching were reported (Luzzi et al., 2007).

**18.9.3.2 Drug-induced Parkinsonism.** Drug-induced parkinsonism, more commonly termed drug-induced Parkinson's disease (DPD), is usually caused by neuroleptic drugs. The prevalence of DPD is lower today than 25 years ago, reflecting the introduction of selective D<sub>2</sub> dopamine receptor and 5-hydroxytryptamine (5HT) blocking agents for treating psychotic disorders. The influences of DPD on smell function are not entirely clear, as the range of involved drugs is large and only a few studies with relatively small sample sizes have addressed this topic in detail.

In a study by Lee et al. (2007a), normal B-SIT scores were observed in 15 DPD patients that were tested. The DPD had been induced by levosulpiride, haloperidone, flunarizine, perphenazine, metoclopramide, or risperidone. In contrast, Hensiek et al. (2000) tested 10 patients whose DPD had been induced by phenothiazine. Five had abnormal UPSIT scores and did not completely recover even after medication cessation or change. The UPSIT scores in all but one of the other five patients returned to normal after such adjustment. More recently, Bovi et al. (2010) administered olfactory tests to 16 DPD patients (seven haloperidol, five amisulpride, two perphenazine, one fluphenazine, one clomipramine), 13 PD patients, and 19 age- and sex-matched normal controls. The DPD patients were divided into those with normal ( $n=9$ ) or abnormal ( $n=7$ ) putamen DA transporter binding as determined from <sup>123</sup>I-FP-CIT SPECT imaging. Only those patients with a pathological putamen uptake had abnormal olfactory test scores – scores which, like those for PD, correlated with putamen uptake values, suggesting that the olfactory losses were more closely associated with central DA damage than with drug-induced DA receptor blockade.

The most publicized case of drug-induced parkinsonism is that which appeared in young drug addicts in northern California in the early 1980s. These cases resulted in an error in the synthesis of a heroin-like substance which produced 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). MPTP is metabolically converted within the brain, mainly in glial cells, to the toxic ion 1-methyl-4-phenyl-piperidinium (MPP<sup>+</sup>) by monoamine oxidase B. MPP<sup>+</sup> selectively damages striatal DA neurons by interfering with complex 1 of the electron transport chain. MPP<sup>+</sup> has a high binding affinity to the dopamine transporter and readily enters dopaminergic terminals. Mice that lack this transporter are protected from MPTP toxicity (Bezard et al., 1999).

In the only human study to assess olfactory function in patients with MPTP-induced parkinsonism (Doty et al., 1992a), the UPSIT and a phenyl ethyl alcohol detection threshold test were administered to six of the original young MPTP-induced parkinsonism patients. Scores were compared to those of 13 young PD patients and

**Figure 18.4** University of Pennsylvania Smell Identification Test (UPSTIT) and phenyl ethyl alcohol odor detection threshold test scores for patients with MPTP-induced parkinsonism (MPTP-P), young patients with idiopathic Parkinson's disease (PD), and matched normal controls. From Doty et al. (1992a).

ten normal subjects. The UPSTIT scores of the MPTP-P patients did not differ significantly from those of normal controls, which was not the case for the young PD patients (Figure 18.4). It is conceivable that olfactory dysfunction would have been detected in the MPTP patients if testing had been performed sooner after their MPTP exposure or if greater MPTP exposure had occurred, either via higher doses or frequency of exposures. The olfactory bulbs of MPTP-treated mice exhibit inflammatory microgliosis and increased expression of cytokines associated with apoptosis such as interleukin-1 $\alpha$  (IL-1 $\alpha$ ) and IL-1 $\beta$  (Vroon et al., 2007). The olfactory dysfunction of mice who receive intranasal MPTP recovers over time (Prediger et al., 2006), as does at least one non-motor measure of MPTP-treated monkeys which correlates with olfactory dysfunction in humans (i.e., cardiac denervation) (Elsworth et al., 2000; Goldstein et al., 2003).

**18.9.3.3 Glucocerebrosidase-Related Parkinsonism.** Glucocerebrosidase (GBA) is a gene implicated in parkinsonism that causes Gaucher's disease (GD), the most prevalent autosomal recessive lysosomal disorder. Although parkinsonism can be a presenting feature of GD, the most prominent features are bone, hematologic, and pulmonary abnormalities (Saunders-Pullman et al., 2010). In one study of six GBA mutation carriers, three were anosmic, two severely microsmic, and one moderately microsmic, with the mean UPSTIT score falling within the range expected for patients with sporadic PD (Goker-Alpan et al., 2008). In a second study, 20 PD patients heterozygous for one of the two GBA mutations (N370S, L444P) exhibited lower scores on a 12-item odor identification test, although the effects were not significant at the 0.05  $\alpha$  level ( $p = 0.08$ ) (Brockmann et al., 2011). In a third study, one of two GBA cases, both of whom were anosmic, was a 54-year-old man who reported that the smell dysfunction

appeared when he was a teenager (Saunders-Pullman et al., 2010). The initial PD sign, a right-hand rest tremor, appeared at 48 years of age. Such symptoms as anxiety, depression, orthostasis, urinary urgency, and medication sensitivity followed soon thereafter.

**18.9.3.4 Multiple System Atrophy.** Multiple system atrophy (MSA) is a rapidly progressing type of parkinsonism which is often misdiagnosed as PD in its earliest stages, but evolves to include prominent autonomic and cerebellar dysfunction. Clinical features typically include dysarthria, stridor, contractures, dystonia, altered orthostatic blood pressure, digestive problems, bladder control issues, sexual dysfunction, and rapid eye movement (REM) sleep behavior disorder (Kaufmann and Biaggioni, 2003). MSA's pathology is found within the basal ganglia, cortex and spinal cord, but peripheral autonomic neurons are spared. Pathological changes have been noted in the olfactory bulbs of MSA (Kovacs et al., 2003). MSA-Parkinsonism (MSA-P), the most common form of MSA (~80% of cases), is defined by akinesia and rigidity. MSA-Cerebellar (MSA-C) is a form in which cerebellar ataxia is dominant. The discovery in 1989 of glial cytoplasmic inclusions (GCIs) in MSA brains confirmed beliefs that striatonigral degeneration, sporadic olivopontocerebellar atrophy, and the Shy-Drager syndrome are, in fact, different clinical expressions of MSA (Papp et al., 1989).

Wenning et al. (1995) administered the UPSTIT to 29 patients with MSA and 123 controls. Moderate loss of function was observed in the MSA patients relative to the controls (respective means = 26.7 and 33.5). No differences were apparent between the MSA-P and MSA-C types. Similar findings have subsequently been reported by others (Abele et al., 2003; Garland et al., 2011; Goldstein et al., 2008; Muller et al., 2002; Nee et al., 1993). No meaningful relationship has been found between

odor identification test scores and measures of cardiac  $^{123}\text{I}$ -metaiodobenzylguanidine (MIBG) uptake, unlike with PD (Lee et al., 2006).

#### **18.9.3.5 Parkinson Dementia Complex of Guam.**

The Parkinson Dementia Complex of Guam (PDG), also known as the ALS/parkinsonism-dementia Complex of Guam (ALS/PDG), is a progressive neurodegenerative disease that has the features and pathology, in variable combinations, of atypical parkinsonism, dementia, and ALS. It is largely confined to the residents of Guam, the Mariana islands, the Kii peninsula of Japan, and the coastal plain of West New Guinea (McGeer and Steele, 2011). Although this disease accounted for at least 15% of adult deaths in the Chamorro population between 1957 and 1965 (Reed et al., 1966; Reed and Brody, 1975), its prevalence has since dropped markedly and by 1999 the ALS component was no longer evident (Plato et al., 2003). Significant olfactory bulb pathology is present in PDG, with nearly complete loss of the cells within the AON (Perl and Doty, unpublished). A retinopathy with an appearance similar to a larval migration has been noted in a significant number of PDG patients (Cox et al., 1989; Kato et al., 1992; Kokubo et al., 2006). This unique retinopathy has not been found in any other part of the world or in any other neurodegenerative disease.

Doty et al. (1991) administered the UPSIT to 24 PDG patients. Their test scores were significantly depressed, being equivalent to those from 24 AD and 24 PD North American patients matched on smoking behavior, gender, and age. More recently, Ahlskog et al. (1998) administered an abbreviated version of the UPSIT to 9 Guamanians with symptoms of ALS, 9 with symptoms of pure parkinsonism, 11 patients with pure dementia, and 31 patients with PDG, as well as to 53 neurologically normal Guamanians and 25 neurologically normal North American controls. The UPSIT scores were markedly and equivalently depressed in the four disease groups.

**18.9.3.6 Vascular Parkinsonism.** Vascular parkinsonism (VP) occurs in patients with extensive cerebrovascular disease involving the basal ganglia. It differs from PD in that it rarely has resting tremor, is variably responsive to L-DOPA, and exhibits variable DA transporter deficits on SPECT or PET imaging. Acute onset cases have disproportionately more lesions in the subcortical gray nuclei (striatum, globus pallidus, and thalamus), whereas insidious onset cases tend to have more diffusely distributed lesions (Zijlmans et al., 1995).

Katzenbach et al. (2004) administered the UPSIT to 14 VP patients, 18 PD patients, and 27 normal controls of similar age. The UPSIT scores of the VP patients did not differ significantly from those of the controls (respective

means = 26.1 and 27.6), unlike the scores of the PD patients (mean = 17.1;  $p < 0.0001$ ). These findings, along with more recent research (Navarro-Otano et al., 2014), suggest that olfactory testing may be useful in differentiating VP from PD.

#### **18.9.3.7 X-linked Recessive Dystonia-parkinsonism.**

X-linked Recessive Dystonia-parkinsonism, also termed ‘Lubag’, is found mostly among adult male Filipinos with maternal roots from the Philippine Island of Panay. Dystonia, mainly in the jaw, neck, trunk, and eyes, but sometimes in the limbs, tongue, pharynx and larynx, becomes salient as the disease progresses. The disease, whose average age of onset is approximately 40 years, can rapidly progress and often results in death from pneumonia or other infections within a few years of onset. In the sole olfactory study on this topic, slight dysfunction on a culturally modified 25-item version of the UPSIT was observed in 20 affected men relative to 20 control men (respective means adjusted to 40-item UPSIT scale = 29 and 33,  $p < 0.001$ ) (Evidente et al., 2004). Smell loss was present in the earliest disease stages and was unrelated to disease duration, severity, and the degree of dystonia.

### **18.10 PROGRESSIVE SUPRANUCLEAR PALSY**

Progressive supranuclear palsy (PSP; also termed the Steele, Richardson, and Olszewski syndrome) accounts for approximately 4% of patients who exhibit parkinsonian symptoms. Based upon a large clinicopathological study of 103 cases, Williams et al. (2005) divided PSP into two classes which they termed the ‘Richardson Syndrome’ (RS) and ‘PSP-P’. RS accounted for 54% of their cases and is defined by an early onset of postural instability and falls, supranuclear vertical gaze palsy, and cognitive dysfunction. PSP-P accounted for 32% of their patients and is characterized by asymmetrical onset tremor and moderate initial therapeutic response to levodopa. According to these investigators, PSP-P patients are frequently misdiagnosed as classical PD. The remaining 14% of their patients were difficult to assign to these two categories.

Like PD, PSP is associated with widespread accumulation of tau protein in degenerating nerves, although the olfactory bulbs appear to be spared of both tau and  $\alpha$ -synuclein pathology (Tsuboi et al., 2003). Unlike PD, however, the parkinsonian features are less responsive to anti-PD medications (Jackson et al., 1983) and PSP is typically characterized by comparatively more frontal lobe dysfunction, more neuronal degeneration within the basal ganglia and upper brain stem, and less involvement of mesolimbic and mesocortical dopamine systems than PD (Cambier et al., 1985; Jankovic, 1989).

Most patients with PSP have a relatively normal sense of smell, although moderate losses appear to be present in some individuals, conceivably reflecting the PSP-P cohort. In the first study on this topic, the UPSIT and a phenyl ethyl alcohol odor detection threshold test were administered to 21 and 17 PSP patients, respectively. All scored well on a test analogous to the UPSIT in which pictures of the UPSIT odor sources, rather than smells, were presented (Doty et al., 1993). The UPSIT scores were compared to those from equivalent numbers of PD patients and neurologically normal age-, gender-, and race-matched controls. The performance of the PSP patients was markedly superior to that of the PD patients [respective UPSIT means (SD): 31.59 (7.18) and 18.82 (6.94)], with approximately half of the PSP patients scoring within the normal range. While the PSP threshold values tended to be higher than those of controls, the difference was not significant at the 0.05  $\alpha$  level ( $p = 0.086$ ). Similar results have been noted by others (Wenning et al., 1995), with the general conclusion being that PSP-related smell loss, while present on average, is not as great as that seen in PD (Silveira-Moriyama et al., 2010a). Some investigators report not being able to detect any PSP-related olfactory deficits on tests of odor identification, detection or discrimination (Lang et al., 2011). Baker and Montgomery (2001) found 23 relatives of PSP patients to have lower UPSIT scores than 23 matched controls, although both sets of scores were within the normal range.

## 18.11 PURE AUTONOMIC FAILURE

Pure autonomic failure (PAF) is a slowly progressing degenerative disease in which failure of the autonomic nervous system is the sole clinical finding (Hague et al., 1997). Lewy bodies are present in the brain stem and pre- and postganglionic autonomic neurons, as well as in the peripheral sympathetic and parasympathetic nerves (Hague et al., 1997). It is conceivable that this disorder is a precursor to PD, but given its slow progression most patients die before significant PD-related CNS involvement becomes evident (Kaufmann and Biaggioni, 2003). Patients with PAF exhibit UPSIT scores essentially equivalent or only slightly above those of patients with PD (Garland et al., 2011; Goldstein and Sewell, 2009; Silveira-Moriyama et al., 2009a).

## 18.12 SCHIZOPHRENIA

Schizophrenia (SZ) is a complex and debilitating psychiatric disease typically first appearing in late adolescence and early adulthood. Like a number of other diseases discussed in this chapter, SZ is a heterogeneous disorder that is

difficult to completely characterize by current classification systems. Between 1–3% of the population suffers from SZ and related disorders, including those with positive symptoms (e.g., hallucinations, delusions, unusual thought content) and negative symptoms (e.g., alogia, anhedonia, social withdrawal). Many aspects of cognitive functioning can be altered in SZ, including attention, memory, language ability, visuospatial integration, executive function, and perceptual ability (Harvey and Sharma, 2002). While SZ has been typically conceptualized as a neurodevelopmental disorder (Weinberger, 1987), neuropathological changes occur in some cases even after disease onset (Church et al., 2002; Hulshoff Pol and Kahn, 2008). Active psychotic episodes potentially damage the brain, including brain regions associated with olfactory processing, a process most salient early in the disease (de Haan and Bakker, 2004).

Since the time of Kraepelin (1913), olfactory hallucinations, most typically of an unpleasant nature, have been reported in SZ. They are common (11–34%) (Kopala et al., 1995b; Meats, 1988; Mueser et al., 1990; Stevenson et al., 2011), likely depend upon a relatively intact olfactory system (Kopala et al., 1994), and exceed the prevalence of auras of temporal lobe epilepsy (Gupta et al., 1983), a disease that shares with SZ medial temporal lobe pathological substrates (Hayashi, 2004; McAbee et al., 2000). Olfactory hallucinations may be predictive of a poorer prognosis (Kwapil et al., 1996) and earlier age of SZ onset (Lewandowski et al., 2009), underscoring their clinical significance.

Unlike AD, PD, and some other disorders described in this chapter, there is less uniformity of findings regarding the nature of the olfactory deficits observed in SZ when such deficits are measured by tests of odor detection, discrimination, memory, and hedonics (Table 18.4). This may reflect the more modest olfactory dysfunction of SZ and non-olfactory related task demands that differ among such tests (e.g., the ability to attend, discriminate, remember, or identify independent of the ability to smell) (Doty, 2007).

In an early study, *increased* threshold sensitivity to a “sexually relevant” odor was described (Bradley, 1984). However, such hypersensitivity has yet to be replicated, and most investigators find either normal (Geddes et al., 1991; Kopala et al., 1989; Moberg et al., 1995) or elevated (Gross-Isseroff et al., 1987; Serby et al., 1990; Turetsky and Moberg, 2009) thresholds in this disease. Similar inconsistencies have been noted in studies in which nominal measures of odor discrimination have been assessed (e.g., Dunn and Weller, 1989; Rupp et al., 2005b), as well as in studies of hedonic ratings, where there have been reports of impaired (Crespo-Facorro et al., 2001; Hudry et al., 2002; Moberg et al., 2003a; Plailly et al., 2006), enhanced (Becker et al., 1993; Rupp et al., 2005b), or unaltered (Rupp et al., 2005a) hedonic sensations. In one

\*These controls did not receive olfactory testing, only imaging.

case, lower SZ-related hedonic ratings were seen in men, but not in women, adding complexity to this issue (Moberg et al., 2003a). Only one study has assessed odor memory in SZ, reporting impairment in a predominantly male group of SZ patients for whom neuroleptic medications had been withdrawn (Wu et al., 1993).

Unlike the aforementioned test measures, consensus is present for tests of odor identification, conceivably reflecting their higher reliability (see Chapter 11). Thus, impairments in odor identification have been reliably reported in patients with psychotic disorders (Brewer et al., 1996; Compton et al., 2006; Corcoran et al., 2005a; Good et al., 2010; Hurwitz et al., 1988; Malaspina et al., 2002; Moberg et al., 1999). Odor identification in SZ has been shown to correlate with measures of verbal memory (Compton et al., 2006), quality of smooth pursuit eye movements in patients with deficit syndrome SZ (Malaspina et al., 1994; Malaspina et al., 2002), disease duration (Moberg et al., 1997b; Moberg et al., 2006), negative disease symptoms (Brewer et al., 2001; Corcoran et al., 2005a; Good et al., 2010; Strauss et al., 2010), and measures of social drive and intelligence (Corcoran et al., 2005b; Malaspina and Coleman, 2003; Moberg et al., 2006). A more recent study found SZ patients may be impaired in their accuracy for identifying UPSIT odorants that are perceived as pleasant, but not for ones that are perceived as unpleasant, although differences in stimulus intensity could be a mitigating factor (Kamath et al., 2011). Most studies have found the SZ-related deficits to be unrelated to smoking history (Brewer et al., 1996; Houlihan et al., 1994; Kopala et al., 1993), antipsychotic medication treatment (Kopala et al., 1989; Szeszko et al., 2004; Wu et al., 1993), cannabis use (Brewer et al., 1996), or age of symptom onset (Corcoran et al., 2005a).

The data that have emerged regarding specific subgroups of patients with psychotic disorders shed light on the fact that not all patients are impaired on olfactory testing. Depending on the sample composition, rates of olfactory impairment differ. For example, in a sample of antipsychotic drug naïve, first-episode psychosis patients, Kopala et al. (1993) demonstrated that only 30% met criteria for ‘microsmia’ according to standardization data (Doty, 1995). In contrast, in patients with longstanding illness and comorbid polydipsia (water intoxication), 100% of the sample would have been considered impaired (Kopala et al., 1998a) and in those patients who meet criteria for the deficit syndrome, 72% of patients would also be considered impaired (Malaspina et al., 2002).

It is noteworthy that earlier research had noted sex differences in the odor identification test scores of SZ patients and that exposure to estrogen may ‘protect’ the olfactory system from damage (Kopala et al., 1989; Kopala and Clark, 1990). However, it has since become clear that both sexes demonstrate these deficits (for a review, see

Moberg et al. 1999). Nonetheless, women in the general population, as well as women with AD or PD, outperform their male counterparts on numerous olfactory tests (Doty and Cameron, 2009). This sex difference extends to patients with psychotic disorders in general, albeit not beyond the generalized male–female difference (Good et al., 2007; Malaspina et al., 2012). Interestingly, in female patients with psychotic disorders, estrogen deficiency, such as occurs in the menopause, eliminates the female:male disparity in olfactory performance seen in later life (Kopala et al., 1995b). Postmenopausal women, who are otherwise healthy and using estrogen replacement therapy (ERT), reportedly have better olfactory memory skills than postmenopausal women who have never used ERT (Sundermann et al., 2006; Doty et al., 2015a). Such therapy has also been noted to improve psychotic symptoms in both male and female patients with psychotic disorders (Kulkarni et al., 2008; Le et al., 2000).

The aforementioned studies have largely assessed olfaction bilaterally, that is, with both sides of the nose being evaluated at the same time. However, testing each nasal chamber separately, as can be done by occluding the contralateral nostril, makes it possible to examine, to some degree, lateralized pathology since the output neurons of the olfactory bulb project mainly to ipsilateral brain structures (Doty et al., 1997a; Moberg et al., 2003b). There is a suggestion that the right nostril and right hemisphere may be dominant for olfactory processing, in particular for olfactory discrimination (Zatorre and Jones-Gotman, 1990). Nonetheless, a functional lateralization of odor identification ability has not been consistently observed (Hornung et al., 1990) and unilateral testing has not generally found left:right differences in the olfactory function of SZ patients (Good et al., 2002; Roalf et al., 2006; Szeszko et al., 2004). That being said, when Good et al. (2002) divided their male patients into those who were normosmic (normal sense of smell) and those who were microsmic (impaired sense of smell), the microsmic patients were more likely to have relatively poorer left nostril identification, whereas the opposite was true of the normosmics. This finding, which suggests that a specific subgroup of male patients may have significant left hemisphere abnormalities, is in accord with the observation of Szeszko et al. (2004) that patients with left nostril impairment exhibit more problems with personal hygiene.

Reduced olfactory identification performance has been noted in unaffected first-degree relatives of patients with psychotic disorders (Keshavan et al., 2009; Kopala et al., 2001) and in non-psychotic twins of monozygotic twin pairs discordant for SZ (Kopala et al., 1998b; Ugur et al., 2005). These gene-based findings suggest that olfactory processing is a trait marker of psychosis, rather than simply being state-related. Individuals who score highly on schizotypy measures are thought to be genetically similar

to patients with psychosis and share genetic vulnerability. Indeed, olfactory test scores are similar in schizotypy patients when compared with those who are psychotic and are impaired relative to control subjects (Kamath and Bedford, 2008; Mohr et al., 2001; Park and Schoppe, 1997). Further support for a gene-based olfactory deficit in SZ comes from evidence that children with the 22q11 deletion syndrome, who often develop SZ in adulthood, uniformly exhibit olfactory dysfunction (Sobin et al., 2006).

Like olfactory hallucinations, impaired olfactory identification ability may be a marker for poorer outcomes in patients with SZ. Good et al. (2006) have shown that those SZ patients who had higher negative scores on the Positive and Negative Syndrome Scale (PANSS; Kay and Sevy, 1990) after one year of treatment had lower initial (drug naïve) UPSIT scores at baseline assessment. In a subsequent study, these researchers also found that patients with poorer olfactory test scores at first episode had poorer functional outcome than those with normal olfactory function after an approximate four year follow up (Good et al., 2010). Testing olfactory function in individuals who are either at genetic high risk or who are at clinically high risk may allow for the identification of those who are likely to convert to frank psychosis (Brewer et al., 2003; see, however, Gill et al., 2014).

A number of studies have documented structural, electrophysiological, and metabolic alterations, as measured by functional imaging, within the olfactory system of patients with SZ. SZ has been associated with an overall 23% reduction in olfactory bulb volume (Turetsky et al., 2000), smaller nasal cavity volumes (Moberg et al., 2004), and less deep olfactory sulci (Turetsky et al., 2009a). Right olfactory bulb volumes have been reported to correlate positively with UPSIT scores (Nguyen et al., 2011). The 23% reduction of olfactory bulb volume noted by Turetsky et al. is substantially greater in magnitude than what has been demonstrated for generalized brain volumetric changes in schizophrenia. Cell loss, such as what may occur as a result of the interruption of the rostral migratory stream regeneration, has been proposed (Chazal et al., 2000). In an animal model of schizophrenia, secretion of a glycoprotein assumed to be involved in the regulation of neuronal migration (reelin) appears to be compromised in the olfactory bulb (Pappas et al., 2003). Reelin expression has been noted to be significantly reduced in patients with psychotic disorders (Pantazopoulos et al., 2010) and thus may have a bearing on olfactory processing in this patient population.

Olfactory evoked potentials (ERPs) were examined in a group of patients with psychotic disorders by Turetsky et al. (2003a). Increasing concentrations of hydrogen sulfide (an unpleasant odorant) were passively presented while ERPs were measured. Patients demonstrated N1 and

P2 latency prolongation and P2 amplitude reduction, implicating the primary olfactory cortex (N1) and secondary integration regions (P2), respectively. N1 prolongation was associated with olfactory threshold deficits while P2 amplitude reduction was correlated with decreased olfactory identification accuracy. However, these data cannot rule out more peripheral abnormalities that may be at the heart of these findings. Indeed, *larger* summated surface potentials have been recorded from the olfactory epithelia of patients with SZ (i.e., the electro-olfactogram) (Turetsky et al., 2009b), suggesting deficits at either the epithelial or bulbar level, the latter possibly reflecting release of inhibition on the olfactory receptor cells.

The earliest neuroimaging examination of patients with SZ used positron emission tomography (PET) to compare a group of patients with an olfactory agnosia (which the authors defined as normal detection threshold but impaired olfactory identification test scores) with a group of normosmic patients and a group of healthy control subjects (Clark et al., 1991). The combined normosmic and agnosic patient groups had lower rates of frontal metabolism than control subjects. Relative to those with normal olfactory test scores, the patients with olfactory agnosia had hypometabolism in the right thalamus and basal ganglia. A subsequent study that used single photon emission computed tomography (SPECT) found that patients with psychotic disorders exhibited hypometabolism in the right frontal, superior temporal, supramarginal, and angular gyri during an odor matching task (Malaspina et al., 1998). Bertollo et al. (1996) also noted, in patients with psychotic disorders, non-dominant abnormalities in the lateral posterior orbitofrontal cortex, a key odor processing area of the brain.

Wu et al. (1993) examined olfactory function and performed a PET scan on a group of patients with SZ. Significant correlations between UPSIT scores and left hemisphere regional brain metabolism were noted for the middle frontal, inferior frontal, and inferior gyri. Significant correlations between scores on an olfactory match to sample test and metabolism in left temporal regions, including the amygdala and hippocampus, were also observed. Healthy controls, however, did not undergo PET scanning, and, as such, the normal pattern of metabolic correlations is unknown. The regional cerebral blood flow (rCBF) was measured while patients were engaged in a test of attention and monitoring, confusing the interpretation of these findings.

Using odors they deemed pleasant and unpleasant, Crespo-Facorro et al. (2001) found that, for pleasant odors, SZ patients and control subjects demonstrated similar patterns of neural activation. Conversely, for unpleasant odors, patients invoked a compensatory pattern of brain activation that included distributed regions of the frontal cortex instead of the predicted limbic/paralimbic regions.

A PET study performed by these investigators employed numerous odorants to examine the neural substrates of olfactory detection, hedonics, and familiarity. The patients with SZ evidenced reduced odor-induced activation in frontal and temporal regions, including the pyriform and orbitofrontal cortices and insula. Consistent with the findings of Wu et al. (1993), more abnormalities were apparent in the left hemisphere.

Only one fMRI study has been published examining olfactory activation in schizophrenia (Schneider et al., 2007). In this study, male patients with schizophrenia (along with unaffected brothers and healthy controls) were presented with an unpleasant and a pleasant odorant in a block design. Blood oxygen level dependent (BOLD) effects were examined. In patients presented with an unpleasant odor, reduced activation was noted in frontal (middle frontal gyrus) and temporal (middle temporal gyrus) regions, but there was increased activation (compared to controls) in the anterior cingulate. For a pleasant odor, patients demonstrated reduced activation of the thalamus compared with control subjects. A major limitation of this and most extant SZ imaging data is that only males (Clark et al., 1991; Plailly et al., 2006; Schneider et al., 2007) or a disproportionate number of males (Crespo-Facorro et al., 2001; Wu et al., 1993) were tested and only those with a diagnosis of pure schizophrenia.

### 18.13 SPINOCEREBELLAR ATAXIAS

Spinocerebellar ataxias (SCAs) are a heterogeneous group of diseases of the cerebellum and its afferent and efferent connections. Typical symptoms include progressive deterioration of limb movements, gait, and speech. However, a more diffuse neurodegenerative process is present in most instances, as evidenced by autonomic dysfunctions, extra pyramidal signs, sleep disturbances, visual attentional deficits, and impairments of saccades and smooth pursuit movements (Rub et al., 2008). Most forms are inherited, with over 30 genes identified to date. The most common SCA is Machado-Joseph disease (SCA3).

Since the pioneering functional imaging study of Yousem et al. (1997), it has become apparent that the cerebellum is somehow associated with olfactory processing, both in terms of motor and sensory function (Sobel et al., 1998). However, the first evidence for an olfactory deficit in SCAs came from a threshold study by Satya-Murti and Crisostomo (1988). On average, recognition thresholds for seven patients with Friedreich's ataxia (FRDA), an SCA associated with degeneration of the afferent cerebellar pathways, were elevated relative to those of matched controls.

Three studies appeared in 2003 noting olfactory impairment in patients with hereditary ataxias. In the first of these studies, Connelly et al. (2003) administered the

UPSIT to 23 patients with Friedreich's ataxia (FRDA), a disorder associated with degeneration of the afferent cerebellar pathways, and 12 patients with other ataxias associated with cerebellar degeneration. The latter were designated as CNS ataxias (two with Spinocerebellar Ataxia type 2 or SCA2; five with SCA3; one with SCA7; and four whose genetic makeup was unknown). Both of these patient groups, whose scores did not differ significantly from one another, exhibited significant ( $p < 0.001$ ) olfactory deficits relative to matched controls, although the effects were modest (Friedreich ataxia and control UPSIT medians = 36 and 38; CNS ataxias and control UPSIT medians 34.5 and 37). Seventy percent of the 23 FRDA patients scored below their matched controls, whereas 83% of the 12 CNS ataxia patients did so. In FRDA, UPSIT scores did not correlate with the length of the shorter pathological expanded GAA triplet repeat in the FRDA gene, disease duration, or ambulatory ability. In the CNS ataxias, no meaningful correlations were present between the UPSIT scores and disease duration or ambulatory ability.

In the second of these studies, the UPSIT was administered to 12 patients with SCA2, 5 patients with Machado-Joseph disease (SCA3/MJD), 5 patients with autosomal recessive ataxia, and 5 patients with sporadic ataxia (Fernandez-Ruiz et al., 2003). Relative to matched controls, subjects from all groups except the Machado-Joseph disease group exhibited significantly lower UPSIT scores than controls (median scores of all ataxia patients and controls = 26.0 and 34, respectively).

In the third study, Abele et al. (2003) administered tests of odor identification, detection (n-butanol thresholds), and odor discrimination to 19 patients with cerebellar ataxia (8 with multiple system atrophy of the cerebellar type and 11 with late onset sporadic ataxia of unknown etiology. While significant impairment was noted for the odor identification and discrimination tests (74% and 44% of the patients, respectively), this was not the case for the odor threshold test, where only 16% of the patients scored in the abnormal range. No differences in test scores were apparent between the patients with the two classes of ataxia.

Subsequent studies have essentially confirmed the findings of the aforementioned studies, save those for detection thresholds. In a study of 53 patients with spinocerebellar ataxia type 2, Velazquez-Perez et al. (2006) found significant decrements in odor identification, discrimination, recognition, and detection, although like the earlier studies, the magnitude of the deficits were much less than those seen in AD or PD (e.g., the mean UPSIT score for the patients was 27.3 compared to 31.7 for the controls). Weak, but statistically significant, correlations were noted between UPSIT scores and ataxia scores, age, and smoking history ( $r_s < 0.30$ ). However, only the correlation with age remained after omitting scores of patients with MMSE scores below 25. Braga-Neto et al. (2011) tested 41

patients with SCA3 and 46 controls for odor identification and found the expected reduction in function which, as was the case with the Velazquez-Perez et al. (2006) study, was related to the MMSE scores. Moscovich et al. (2012) identified olfactory deficits in a study of 37 genetically determined autosomal dominant ataxia and 31 patients with familial ataxia of unknown genetic basis. When statistically adjusted for cognitive function, however, no significant difference was observed between the ataxia and control groups, suggesting to these authors that previous findings were likely due to general cognitive deficits rather than to specific olfactory problems. This seems unlikely, however, since at least some of the previous studies took cognitive factors into account (e.g., Connelly et al., 2003).

## 18.14 TEMPORAL LOBE EPILEPSY

Although early threshold studies reported heightened overall bilateral sensitivity in patients with temporal lobe epilepsy (TLE), particularly prior to an ictal event (e.g. Campanella et al., 1978; De Michele G. et al., 1976; Dimov, 1973; Santorelli and Marotta, 1964), more recent studies have not observed this phenomenon. In fact, most have failed to observe threshold changes (Eskenazi et al., 1986; Martinez et al., 1993). However, relatively few subjects have been tested and most studies have used threshold tests of questionable reliability, such as the simple ascending method of limits (see Chapter 11). An exception is a recent study of 141 epilepsy patients which employed a single staircase detection threshold test for the rose-like odorant phenyl ethyl alcohol (Doty et al., 2015b). As shown in Table 18.5, a significant threshold *deficit* was found on both the right and left sides of the nose, with a slightly larger deficit on the left. This finding is an example of why it is wrong to infer that olfactory thresholds are a measure of “peripheral” dysfunction, since in epilepsy the lesions are clearly within the CNS.

Suprathreshold deficits in epileptic patients have also been observed. For example, Abraham and Mathai (1983) noted decreased performance on an odor-matching task in 28 epileptic patients with right-sided foci. Interestingly,

patients with left-sided foci did not exhibit the same difficulty in performing the bilaterally-administered olfactory matching task. Eskenazi et al. (1986) found a small bilateral odor identification deficit in 18 epileptic patients relative to 17 normal controls, which was apparently independent of the size of the seizure focus. Carroll et al. (1993) observed a decrease in immediate odor memory to common odorants (e.g., vinegar, coconut, coffee, nail varnish, and garlic) in 10 patients with right-sided, but not left-sided, TLE, seemingly in accord with the findings of Abraham and Mathai. In contrast, Martinez et al. (1993) found no left:right differences in measures odor discrimination, short- and long-term odor memory, and odor naming in 21 patients with epilepsy, although, relative to controls, deficits were observed on all of these measures.

More recently, Haehner et al. (2012) reported that while 13 patients with unilateral epileptic foci (number of left and right side foci not mentioned) tended to have more impaired odor identification deficits on the side of the lesion ( $p = 0.057$ ), this was not the case for odor discrimination and detection measures. However, in the aforementioned Doty et al. (2015b) study, in which 141 epilepsy patients were evaluated along with matched controls, no evidence for lower UPSIT scores on the side of the lesion was evident, despite the fact that, overall, these scores were clearly depressed in the epilepsy patients (Table 18.6). Temporal lobe resection, however, was associated with ipsilateral deficits.

## 18.15 VASCULAR DEMENTIA

Vascular dementia (VD), the second most common form of dementia, is associated with vascular disease and reduced blood flow to the brain. Patients with VD have considerable loss of smell function. In the pioneering study on this topic, Knupfer and Spiegel (1986) found 18 VD patients, relative to 19 normal controls, exhibited elevated thresholds to eucalyptol, citral, and prunolide, and to perform more poorly on tests of odor identification, naming, and recognition. For all tests, however, the degree of dysfunction was less than that observed in 18 patients with probable AD, a finding supported by another study using a three-odor

**Table 18.5** PEA odor detection threshold values with temporal lobe epilepsy and matched normal controls. Threshold values log vol/vol in USP grade light mineral oil. Negative signs are omitted from threshold values, so larger numbers signify greater sensitivity. From Doty et al. (2015b)

Epilepsy Focus	Nostril	Sample Size	Epilepsy Mean (SEM)	Control Mean (SEM)	P-value	Age and Education Adjusted P-value
Left	Left	35	4.51 (0.25)	5.39 (0.19)	0.02	0.06
	Right	35	4.60 (0.30)	5.58 (0.23)	0.04	0.04
Right	Left	36	4.76 (0.24)	5.30 (0.24)	0.13	0.26
	Right	36	4.95 (0.17)	5.72 (0.24)	0.007	0.01

**Table 18.6** UPSIT scores of patients with temporal lobe epilepsy and matched controls. Data from Doty et al. (2015b)

Epilepsy Focus	Nostril	Sample Size	Epilepsy Mean (SEM)	Control Mean (SEM)	P-value	Age and Education Adjusted P-value
Left	Left	35	30.0 (1.35)	35.5 (0.49)	0.0006	0.005
	Right	35	29.0 (1.46)	36.3 (0.49)	0.0002	0.001
Right	Left	36	32.5 (0.87)	35.5 (0.43)	0.006	0.01
	Right	36	30.2 (0.95)	36.1 (0.55)	<0.0001	0.0002

identification test (Duff et al., 2002). Although Gray et al. (2001) found that odor identification performance, as measured by the UPSIT, was lower in 13 VD patients relative to 13 controls, their test scores did not differ significantly from those of the 13 AD patients they tested. Recently, Lee et al. (2010) demonstrated that, on average, 27 patients with a ‘pure’ form of vascular dementia, namely cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), scored below matched normal controls on an odor identification test. The olfactory test scores correlated significantly with scores on the Mini-Mental Status Examination (MMSE;  $r = 0.43$ ) and the Controlled Oral Word Association Test (COWAT;  $r = 0.49$ ).

## 18.16 CONCLUSIONS AND CONSIDERATIONS

In this chapter, we have reviewed a number of studies demonstrating olfactory dysfunction in a wide range of neurological diseases. While the focus has been on those for which the most olfactory data are available, it should be noted that olfactory dysfunction has been observed in a number of disorders not discussed in detail in this chapter. Thus, smell loss is present in frontotemporal dementia (Heyanka et al., 2014; Pardini et al., 2009), hypogonadotropic hypogonadism (Lewkowitz-Shpuntoff et al., 2012), restless leg syndrome (Adler et al., 1998), Korsakoff’s psychosis (Mair et al., 1986), alcoholism (Shear et al., 1992), seasonal affective disorder (Faulcon et al., 1999; Postolache et al., 2002), head trauma (Doty et al., 1997b), attention deficit/hyper-reactivity disorder (Gansler et al., 1998), stroke (Rousseaux et al., 1996), and human immunodeficiency or acquired immune deficiency syndrome (Brody et al., 1991), to name a few (also see Chapter 17). It is noteworthy that a number of neurological disorders are accompanied by no, or only modest, alterations in smell function. In addition to those mentioned earlier in this chapter (e.g., MPTP-P), such disorders include depression (Amsterdam et al., 1987) and panic disorder (Kopala and Good, 1996). However, lack of involvement in neurological diseases seems to be the exception rather

than the rule, as most neurological – particularly degenerative – diseases appear to be associated with at least some degree of olfactory dysfunction.

It is important to note that several studies of AD and SZ patients have reported lack of significant effects on odor detection threshold tests, in contrast to highly significant effects on such tests as the UPSIT. In some such cases, the lack of a threshold effect has been assumed to signify that olfactory system is, in effect, functioning normally and that the deficit on identification reflects a central olfactory agnosia. A case in point for AD is work by Koss et al. These investigators reported, in two publications largely based upon the same set of patients, significant UPSIT, but not pyridine threshold, deficits in AD patients relative to controls (Koss et al., 1987; Koss et al., 1988). They concluded that the olfactory deficit of AD is associated with a “central” rather than a “peripheral” anomaly. While, ultimately, their overall conclusion may be correct (i.e., that the cause of olfactory deficits in AD reflects damage in structures more central than the olfactory neuroepithelium), the basis upon which they arrive at this conclusion is suspect for a number of reasons. First, the vast majority of studies find threshold deficits in AD patients, and even their own data point to this conclusion. Thus, three of their subjects (30%) were either anosmic or hyposmic by their own criteria and, in fact, the average threshold value for the AD patients was higher (i.e., indicative of less sensitivity) than that of the controls, even though statistical significance at the 0.05 level was not achieved. Second, compared to most studies on this topic (see Table 18.1), their sample size was very small, compromising statistical power. In general, single ascending series detection threshold tests, such as those administered in their studies, have test-retest reliability values below 0.40, compared to those of the UPSIT, which are uniformly above 0.90 (Doty et al., 1995b). Hence, the power of such a threshold test to detect a deficit is much less than that of a 40-item odor identification test, and is particularly compromised with small subject samples. Third, the general assumption that threshold tests reflect peripheral damage and identification tests reflect central damage is untenable. Thus, central lesions, in fact, have been associated with threshold deficits (Doty et al., 2015b) and peripheral (i.e., neuroepithelial) lesions are known to

influence both tests of odor detection threshold and odor identification (Deems et al., 1991).

Such issues are important for interpreting divergent findings in the literature (see Chapter 11). Thus, while the test scores of most nominally distinct olfactory tests are positively correlated, olfactory tests differ in terms of their relative reliability and sensitivity, making direct comparisons among them problematic. Moreover, they also differ in terms of the types and number of odorants they employ and in their non-olfactory task demands. Differences in psychophysical paradigms, including instructions to the subject, the time between stimulus presentations, the use or lack of use of forced-choice trials, the differences in odorants used, and the criteria employed for establishing the final test measure (e.g., the number of reversals in a staircase threshold procedure), all can influence the final outcome. This is particularly true in diseases, such as SZ, where the olfactory deficits are comparatively modest (Turetsky and Moberg, 2009). In such disorders, a variety of additional factors can influence the observed effects, including disparities in illness severity from sample to sample (Kopala et al., 1998a) and the involved medications (Sirota et al., 1999a).

## The Olfactory System as a Route of Delivery for Agents to the Brain and Circulation

MARY BETH GENTER, MANSI KRISHAN, and RUI DANIEL PREDIGER

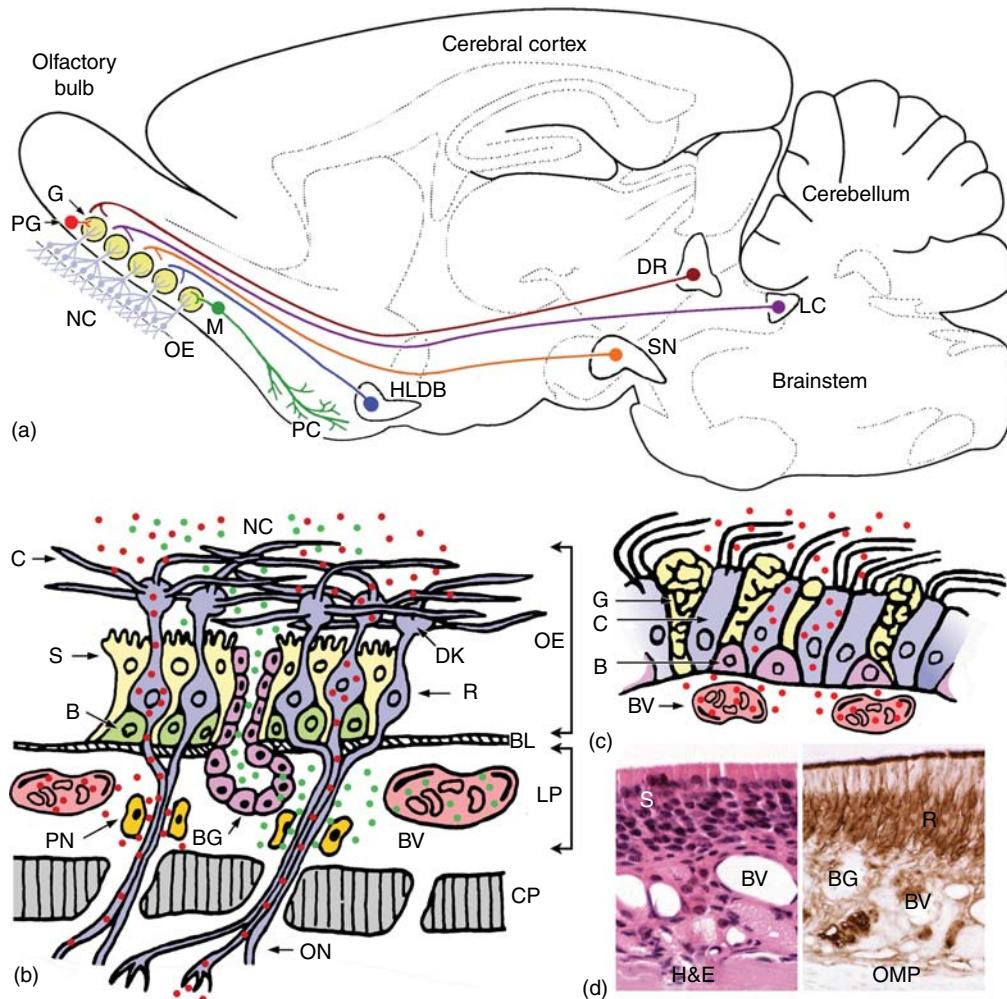

### 19.1 INTRODUCTION

The important role the olfactory system plays in food acquisition and mating behaviors is reflected in the substantial development of this sensory modality in the majority of vertebrate species with, perhaps, the exception of primates. In view of these life-sustaining roles, the common dogma posits that a system as important to survival as olfaction must have mechanisms to protect the sensory cells within the olfactory receptor epithelium from the materials in inspired air, both toxicants and odorants. Also, a means should exist to prevent access of extrinsic substances to the central nervous system (CNS). As discussed below (see also Chapter 3), several mechanisms have been proposed that would protect the epithelium from environmental toxic exposure. Included among these mechanisms are intracellular detoxification of molecules, removal of substances by ligand-specific binding proteins contained in mucosal secretions, surveillance by immune system cells and degeneration and replacement of damaged receptor neurons with new cells derived from basal stem cells. Recent data indicate, however, that these protective mechanisms can be circumvented, resulting in access of xenobiotics from the nares to the CNS and to the systemic circulation.

Figure 19.1 indicates three major routes of entry for agents to the CNS and systemic circulation from the nasal cavity. The first route occurs via internalization of xenobiotics into the receptor neurons of the olfactory epithelium.

Substances are transported into the brain through the axons of olfactory receptor neurons in a process also called the *olfactory nerve pathway* by Mathison et al. (1998). In an older publication, McMartin et al. (1987) referred to both *transcytosis* (uptake of the agent into vesicles with subsequent discharge into interstitial space) and *transcellular transport* (passage of agents via pores or carriers across the cell membrane, diffusion across the cytoplasm, and transport out of the cell to the glomerular region of the olfactory bulb). Within the glomerulus, axodendritic contacts between receptor cells and mitral cells serve as one transport pathway. For some xenobiotics, transneuronal transport has been observed in widespread areas of the brain. Both anterograde and retrograde transport have been reported, the latter perhaps a result of the large centrifugal afferent innervation of the olfactory glomerular region where receptor afferent fibers terminate. Anterograde labeling can then be observed in mitral cell terminal fields such as the piriform cortex. Retrograde transport is also observed in brain regions with projections to the olfactory bulb including the horizontal limb of the diagonal band, substantia nigra, locus coeruleus, and dorsal raphe nucleus.

Xenobiotics also may gain access to the CNS by two other routes as indicated in Figure 19.1. A number of drugs (see below) and metals are hypothesized to reach the subarachnoid space by movement through perineural spaces, a process also called the *olfactory epithelial pathway* or *paracellular transport* (Jackson et al., 1979; Mathison et al., 1998; McMartin et al., 1987). In fact, many drugs

**Figure 19.1** (a). Sagittal view of the rat brain showing olfactory epithelium (OE) receptor cells and their axonal projections to the olfactory glomeruli (G). In the glomerulus, receptor cell axons contact the dendrites of periglomerular (PG) and mitral (M) cells. Mitral cells project to the piriform cortex (PC). Centrifugal afferent innervation comes from the horizontal limb of the diagonal band (HLDB), the substantia nigra (SN), the dorsal raphe (DR) and the locus ceruleus (LC). (b). The olfactory mucosa includes an epithelial cell layer (OE) and the lamina propria (LP) separated by the basal lamina (BL). The OE contains sustentacular (S) and basal (B) cells. Receptor cells have a dendritic knob (DK) from which cilia (C) project into the nasal cavity (NC). Receptor cell axons fasciculate to form the olfactory nerve (ON) that crosses the cribriform plate (CP) to enter the CNS. The axon and nerve are surrounded by a perineurial sheath that forms the perineural space (PN). The lamina propria contains mucus secreting Bowman's glands (BG), axons of receptor cells and numerous blood vessels (BV). Red and green dots depict possible entry pathways through neurons, glands and blood vessels. (c). Respiratory epithelium consists of columnar ciliated (C), goblet (G) and basal (B) cells and is highly vascular (BV). (d). H & E stained section illustrating the layers of the OE and LP showing the numerous blood vessels in the lamina propria. Olfactory marker protein (OMP) immunostained section showing that only mature receptor neurons and their axons, not basal or sustentacular cells, contain OMP (B and C were adapted from Lewis and Dahl, 1995). (See plate section for color version.)

that otherwise would not have access to the brain can be applied intranasally, including antiviral drugs for the treatment of HIV infections that have spread to the CNS. The third route is a consequence of the highly vascular nature of the respiratory and olfactory epithelia. This pathway provides access of intranasally applied agents to the systemic circulation and thus to the brain. Another consequence of the extensive vascularity of the olfactory epithelium is that

some viruses (Charles et al., 1995; Oliver and Fazakerley, 1998) and a variety of organic compounds (Brandt et al., 1990; Brittebo, 1988; Feng et al., 1990) are concentrated in the olfactory epithelium following systemic application. Subsequently, there may be either transport to the brain or destruction of the epithelium (Table 19.1).

Substances that have been reported to be internalized, transported, and accumulated through the olfactory system

**Table 19.1** Substances analyzed for transport from the nasal cavity to the brain

Substance	Species Studied	Application Method	Transneuronal Transport	Reference
<b>Metals</b>				
Aluminum lactate	Rabbit	IN	Indirect pathological evidence	Perl and Good, 1987
Aluminum silicate	Rabbit	Bedding	No	Hayek and Waite, 1991

are quite varied, including lectins, dyes, solvents, metals, viruses, amino acids, and drugs. Table 19.1, a compilation of the range of transported substances, also indicates those for which the evidence suggests transneuronal transport. The consequences of such transport have only begun to be assessed (see below). One hypothesis suggests that the olfactory system may be a route by which some,

as yet undefined, pathogen or toxin reaches the brain to produce degenerative disorders such as Alzheimer's disease (Baker and Margolis, 1986; Crapper McLachlan, 1986) and Parkinson's disease (Prediger et al., 2006, 2010, 2011, 2012; Tjälve et al., 1996), as well as learning and behavioral abnormalities (Becker, 1995). This internalization may have effects reaching through the food chain

as some fish apparently can accumulate materials such as metals found in water by this route (Bazer et al., 1987). Table 19.2 lists compounds that when administered systemically either destroy or produce tumors in the olfactory epithelium. There are, however, benefits to the nasal route of application since in the past two decades, a number of encouraging outcomes have been reported in the treatment of diseases of the brain or CNS through nasal administration of drugs (see Table 19.3). Intranasal drug administration as a non-invasive brain delivery method has developed quickly in terms of safety, efficiency, and convenience. These advantages have made intranasal delivery a hot topic in the exploration of the brain drug delivery.

First to be discussed will be the specific substances and pathogens transported through olfactory receptor cells. Second, the proposed mechanisms of internalization and transport will be reviewed with special reference as to why transneuronal transport occurs only in limited instances. Intranasal application of drugs will be discussed as a means of administering a number of agents for direct entry to the brain. Next, the consequences of xenobiotic access to the brain will be assessed from the disease perspective. Finally, efforts to enhance the delivery of

intranasally-administered drugs to the CNS and systemic circulation will be summarized.

## 19.2 NATURE OF SUBSTANCES TRANSPORTED

### 19.2.1 Metals

Aluminum, cadmium, cobalt, gold, and manganese are among the metals that are internalized in the olfactory receptor epithelium and transported either directly to the brain via olfactory axons or perhaps, as reviewed by Jackson et al. (1979), through either the subarachnoid space or perineurally. The evidence, both direct and circumstantial, for their transneuronal transport to the brain has supported the controversial hypothesis that some of these metals, for example, aluminum and manganese, may be etiologically significant in pathological syndromes such as Alzheimer's and Parkinson's diseases (Crapper McLachlan, 1986; Roberts, 1986; Tjälve et al., 1996). Described below is the method of application and evidence for uptake and transport of each of the metals.

**19.2.1.1 Aluminum.** Several studies have shown that aluminum can reach the CNS after intranasal application (Hayek and Waite, 1991; Perl and Good, 1987; Zatta et al., 1993). Aluminum silicate, presented as a powder in the bedding, was enriched specifically in the rabbit olfactory epithelium and olfactory bulb, but not in cerebellum (Hayek and Waite, 1991). Perl and Good (1987) demonstrated that, following intranasal application of aluminum lactate, granulomas were observed in the olfactory bulb and cerebral cortex. The pathological changes observed in the brain suggested that aluminum reaches these brain regions by transport through olfactory neurons. Inhalation of aluminum acetylacetone resulted in widespread dissemination of the metal complex in diverse brain regions (Zatta et al., 1993). Aluminum was also observed in the neurofibrillary tangles associated with Alzheimer's disease (for review see Crapper McLachlan, 1986; Good et al., 1992), and on intraventricular administration was shown to produce neurofibrillary degeneration in rabbit and rat brain (Kowall et al., 1989; Shigematsu and McGeer, 1992). Additionally, the demonstration that brain

regions having direct connections to the olfactory system are primarily affected in Alzheimer's disease has suggested the provocative hypothesis that transport of aluminum via the olfactory system may play a role in this degenerative syndrome (Roberts, 1986).

Brains from patients with Parkinson's disease have, relative to control brains, elevated levels of aluminum in the substantia nigra, caudate nucleus, and globus pallidus (Yasui et al., 1992). Moreover, increased levels of aluminum have been noted in Lewy bodies of patients with Parkinson's disease. However, whether aluminum plays a causative role is presently enigmatic (Hirsch et al., 1991).

**19.2.1.2 Iron.** Interest in iron as a potential risk factor for Parkinson's disease initially stemmed from reports of heightened accumulation of iron within the substantia nigra in postmortem Parkinson's disease brains (Dexter et al., 1987). In general, evidence for the hypothesis that iron is involved in the etiology of Parkinson's disease is much stronger than that for aluminum, possibly because iron, unlike aluminum, is needed

for cellular metabolism. For example, epidemiological studies suggest that too much dietary iron is a risk factor for Parkinson's disease (Lan and Jiang, 1997; Johnson et al., 1999; Powers et al., 2003, 2009). In animals, iron significantly contributes to oxygen free radical formation during degeneration of nigrostriatal pathways. The neurotoxins 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and 6-hydroxydopamine (6-OHDA), widely used in experimental models of Parkinson's disease, potentiate an increase in iron within the substantia nigra and striatum in mice, rats, and monkeys (Gal et al., 2010). Iron injected directly into the dorsal striatum of rats selectively damages dopaminergic neurons, inducing behavioral and biochemical changes akin to parkinsonism (Yousdim et al., 1993). Moreover, mice fed diets low in iron (4 ppm) for 6 weeks, unlike mice on a normal (48 ppm) or high (400 ppm) iron diets, have increased serum total iron binding capacity and exhibit protection against motor impairments induced by MPTP (Levenson et al., 2004). Iron chelation therapies have restored nigrostriatal dopaminergic neurons in MPTP animal models of PD (Gal et al., 2010). Interestingly, a mutation in the divalent metal transporter-1 (DMT1), which ferries iron across cell membranes, protects rodents from the effects of MPTP and 6-OHDA within the substantia nigra, implying a critical role for DMT1 in the degenerative process in this brain region (Salazar et al., 2008).

**19.2.1.3 Cadmium.** Cadmium transport from the olfactory epithelium to the olfactory bulb has been demonstrated in both fish and rodents. A number of reports suggest an association between cadmium exposure and anosmia in humans, and also accumulation and transport of the metal (Hastings, 1990). In the pike (*Esox lucius*), cadmium appeared to move at a velocity consistent with processing by the fast axonal transport system (Gottofrey and Tjälve, 1991). Cadmium accumulated in anterior regions of the olfactory bulb, but did not appear to move transsynaptically to mitral cell dendrites (Tjälve and Henriksson, 1999; Tjälve et al., 1996). In rats, exposure to both cadmium oxide and chloride, in aerosol form, resulted in accumulation of cadmium in the olfactory bulb (Evans and Hastings, 1992; Hastings, 1990; Hastings and Evans, 1988). Cadmium oxide did not produce anosmia (Hastings, 1990; Hastings and Evans, 1988). Hastings (1990) suggested that the lack of a functional deficit in rodents following cadmium exposure, in view of the purported effects in humans, might reflect a requirement for protracted exposure to produce anosmia.

**19.2.1.4 Cobalt.** Intranasal irrigation with cobalt lysine in king salmon fry (*Oncorhynchus tshawytscha*, Walbaum) resulted in transport of the conjugate to the olfactory bulb as well as to both ventral and lateral regions

of the ventral telencephalon (Bazer et al., 1987). The latter projections may represent transneuronal transport of the metal conjugate (Bazer et al., 1987) as no direct epithelial connections to this brain region have previously been reported. There is evidence that cobalt is able to cross neuronal membranes (Fredman and Jahan-Pawar, 1980).

**19.2.1.5 Gold.** Electron microscopic studies demonstrated that colloidal gold was internalized by olfactory receptor cells within 15 min of intranasal application in squirrel monkeys (DeLorenzo, 1970). Gold was thought to be incorporated into receptor cells by the pinocytotic vacuoles normally observed in the olfactory rod region, more commonly referred to as the dendritic knob (DeLorenzo, 1970). Subsequently, gold particles were observed in the cytoplasm of olfactory axons and within 1 hr in the olfactory glomerulus. Evidence was also presented for transneuronal transport of the gold particles from receptor cell axon terminals within the glomeruli to the dendrites of mitral cells (DeLorenzo, 1970). Within the olfactory bulb the particles were preferentially associated with mitochondria. The rate of appearance in the glomeruli was consistent with the movement of the gold by fast axonal transport (estimated in these experiments at about 2.5 mm/hr). Czerniawska, (1970) also demonstrated uptake of gold into the cerebrospinal fluid, especially in the region of the cribriform plate and the olfactory bulbs, following either mucous membrane or intravenous administration of the metal.

**19.2.1.6 Manganese.** A recent series of papers documents both possible routes of entry of manganese into the CNS and the neurological consequences of exposure. Definitive evidence now exists in rats for transport of manganese from the olfactory epithelium into the brain (Tjälve and Henriksson, 1999; Tjälve et al., 1996). The transport of intranasal administered  $^{54}\text{Mn}$  to the olfactory bulb was significantly reduced by the transection of olfactory nerve fibers (Kinoshita et al., 2008). In contrast to other metals applied by intranasal irrigation (e.g., nickel and cadmium), manganese was transported to all regions of the CNS, including the spinal cord, and could still be detected 12 weeks after initial exposure. Manganism may also reach the CNS when administered by parenteral routes, but in much lower concentrations. Manganism, or manganese toxicity, is associated with a neurological syndrome characterized by features of Parkinson's disease. Interestingly, Lucchini et al. (2009) suggested that acute exposure to high levels of manganese may damage the globus pallidus and induce manganism, whereas chronic low levels of manganese exposure may result in cumulative damage to the substantia nigra and to the expression of Parkinson's disease. Occupational exposure occurs in the mining industry, in steel manufacturing and in welding

and is primarily through inhalation of metal-containing dusts and fumes (Gorell et al., 1999; Tjälve and Henriksson, 1999). Taken together with the widespread CNS distribution following nasal exposure, the association with Parkinson's disease is consistent with specific toxicity towards dopamine neurons. One proposed mechanism (Tjälve and Henriksson, 1999) suggests that the metal may be involved in the formation of free radicals in the presence of catecholamines.

**19.2.1.7 Other Metals.** Several studies investigated the transport of nickel and mercury presented intranasally. Inorganic mercury exhibited limited transneuronal transport restricted to the olfactory bulb following nasal application in rats (Henriksson and Tjälve, 1998). Long term occupational exposure was not associated with increased risk for Parkinson's disease (Gorell et al., 1999). Transneuronal transport of nickel was studied in rats and pike. The transport rate for this metal was 20 times slower than for cadmium and manganese. Nickel could be demonstrated in several forebrain regions suggesting that the metal is transported slowly trans-synaptically (Tallkvist et al., 1998; Tjälve and Henriksson, 1999). Nickel exposure has been associated with cell loss in the olfactory epithelium but did not alter olfactory function as indicated by measurement of either threshold or odor discrimination (Evans et al., 1995). Uptake of thallium along the olfactory nerve is strongly suggested by the observation that the olfactory nerve transection greatly reduces the transport of intranasally-administered thallium into the brain in mice (Kinoshita et al., 2008). Reports that monkeys could be protected against intranasal inoculation with poliomyelitis virus by nasal lavage with solutions of alum, picric acid or zinc sulfate (Armstrong and Harrison, 1935; Schultz and Gebhardt, 1936) led to prophylactic treatment of children with nasal zinc sulfate during poliomyelitis epidemics (Peet et al., 1937; Schultz and Gebhardt, 1937; Tisdall et al., 1937). An undesirable consequence of these treatments was long-lasting anosmia in many individuals (Tisdall et al., 1938) presumably produced by irreversible destruction of the olfactory sensory epithelium; unfortunately, the incidence of polio in the treated children was no different than that in untreated children. More recently, Lim et al. (2009) demonstrated that intranasal administration of Zicam (zinc gluconate; Matrixx Initiatives, Inc), a homeopathic product marketed to alleviate cold symptoms, showed significant cytotoxicity in both mouse and human nasal tissue. Specifically, Zicam-treated mice had disrupted sensitivity of olfactory sensory neurons to odorant stimulation and were unable to detect novel odorants in behavioral testing. These findings were long-term, as no recovery of function was observed after two months (Lim et al., 2009). A causality analysis supported the Bradford Hill criteria and demonstrated that

zinc gluconate therapy caused hyposmia and anosmia in humans (Davidson and Smith, 2010).

### 19.2.2 Lectins

Although native and derivatized lectins have been utilized by a number of investigators to delineate neuronal connectivity, especially in the visual system (Itaya and Van Housen, 1982; Spencer et al., 1982), transport studies of these oligosaccharide-specific proteins in the olfactory system have been limited primarily to concanavalin A (Wiley et al., 1984) and wheatgerm agglutinin (WGA). A number of investigators (Baker and Spencer, 1986; Balin et al., 1986; Broadwell and Balin, 1985; Itaya, 1987; Shipley, 1985; Stewart, 1985; Thorne et al., 1995) have shown that WGA conjugated to horseradish peroxidase (WGA-HRP) is internalized by olfactory receptor cells following binding to surface receptors and transported to the olfactory bulb. Uptake and transport occurred primarily ipsilaterally following intranasal application (Baker and Spencer, 1986; Shipley, 1985). Both anterograde and retrograde transneuronal transport have been observed from the olfactory bulb. Labeled primary olfactory axons containing WGA-HRP reaction product were observed in the nerve and glomerular layers of the main olfactory bulb within 6 hr of intranasal irrigation (Broadwell and Balin, 1985; Itaya, 1987; Shipley, 1985). At longer survival times (four to seven days), labeled neurons and terminals were reported in a number of brain regions known to either receive input from or send axons to the olfactory bulb. Anterograde and retrograde label were observed in the anterior olfactory nucleus (Itaya, 1987; Shipley, 1985). The piriform and entorhinal cortices, as well as the olfactory tubercle, also contained significant label (Baker and Spencer, 1986; Itaya, 1987; Shipley, 1985). Brain regions that send centrifugal afferent innervation primarily to the glomerular region of the olfactory bulb also contained retrogradely labeled cells (Baker and Spencer, 1986; Shipley, 1985). These data indicate the extent of transport that occurs from the olfactory epithelium to those brain regions with connections to the olfactory bulb. More recently, the smallest known lectin, odorrranalectin, was shown to enhance the delivery of a potential Parkinson's disease treatment, urocortin peptide, from the nasal cavity into the brain (Wen et al., 2011).

### 19.2.3 Viruses

From a historical perspective, a neural route of viral invasion of the CNS was postulated as a mechanism for the development of rabies as early as the 18th century and demonstrated in the late 19th century (see Stroop, 1995 for review and references). The nasal route as a site of viral entry to the CNS was established during the 1920s and 1930s (Clark, 1929; Hurst, 1936). Poliomyelitis virus was

subsequently shown to reach the olfactory bulbs through the olfactory neurons following intranasal application in primates (Bodian and Howe, 1941a,b).

Subsequently, transport to the CNS has been reported for several types of viruses following intranasal inoculation, including herpes simplex (Esiri and Tomlinson, 1984; McLean et al., 1989; Stroop et al., 1984), murine coronavirus (Barnett et al., 1993; Perlman et al., 1989; Perlman et al., 1988), Borna disease virus (Morales et al., 1988), Nile virus (Nir et al., 1965), Venezuelan equine encephalitis virus (Charles et al., 1995), vesicular stomatitis virus (Huneycutt et al., 1994), Semliki virus (Oliver and Fazakerley, 1998), sendai virus (Mori et al., 1995) and rabies virus (Astic et al., 1993; Lafay et al., 1991). Olfactory bulb ablation prevented the spread of the neurotropic coronavirus mouse hepatitis virus into the brain (Perlman et al., 1990). Two neurotropic viruses, herpes simplex virus type 1 and mouse hepatitis virus, spread along different neural pathways following intranasal inoculation, suggesting that uptake in specific neurotransmitter systems influences viral distribution in the CNS (Barnett et al., 1993). Selective lesions of neural pathways also contributed to spatial learning deficits (McLean et al., 1993). Learning and behavioral deficits have recently been associated with HSV-1 brain infection, presumably by the olfactory nerve route (Becker, 1995). Olfactory labeling was observed in several instances where the viruses were applied at non-olfactory sites, including intraperitoneal (Monath et al., 1983) and subcutaneous routes (Charles et al., 1995). Virus titers were observed first in the olfactory epithelium (four days) and then in the olfactory bulb (five days) followed by the rest of the brain. Olfactory labeling was observed following corneal inoculation and intradermal application in the mouse (Stroop et al., 1984). In the latter instances the virus may have reached the olfactory epithelium through tears entering the naris or nasopharynx and then entering the nasal receptor epithelium. Applying sensitive immunohistochemical techniques, herpes simplex virus produced Golgi-like, transneuronal labeling in the CNS (Blessing et al., 1994; McLean et al., 1989) and the authors suggested that virus injection may be useful for tracing neuronal pathways. Many recent reports demonstrate that pseudorabies virus also produced significant transneuronal transport and can be used to label CNS pathways (Sams et al., 1995; Strack and Loewy, 1990; Ugolini, 1995). These and many other studies (Table 19.1) demonstrate that the olfactory system may serve as an efficient route of entry of viruses into the brain.

## 19.2.4 Dyes

**19.2.4.1 Procion and Lucifer Dyes.** Several dyes, including procion, lucifer, and Evans blue, were internalized into olfactory epithelial cells. In those species

tested, procion and lucifer dyes specifically labeled olfactory receptor neurons. Two procion dyes, brilliant yellow M4RAN and yellow M4R, labeled the receptor neurons of the catfish, *Ictalurus nebulosus* (Holl, 1980). Similar intravital staining was observed in olfactory receptor neurons of the eel, *Anguilla anguilla* (Holl, 1981). In both the lamprey, *Entosphenus*, and the grass frog, *Rana*, procion yellow MX4R and lucifer yellow VS exhibited internalization specifically by olfactory receptor neurons in contrast to either supporting cells or the glandular components of the epithelium (Suzuki, 1984). Since the stained receptor neurons retained their dye through dissociation procedures, Suzuki (1984) suggested that these fluorescent dyes may be useful cell markers for identifying viable receptor cells in dissociated epithelial preparations. Interestingly, not all dyes showed specific uptake. Lucifer yellow CH stained the receptor epithelium nonspecifically, and procion red H3B at high concentrations resulted in dye aggregations on the surface of the olfactory epithelium. The basis for the difference in labeling between the dyes was thought to reflect binding to specific membranous molecules.

**19.2.4.2 Evans Blue.** Inhalation of a complex of Evans blue dye with albumin resulted in strong red fluorescence within numerous cells of the olfactory epithelium of mice (Kristensson and Olsson, 1971). After 24 hr, the filia olfactoria of the mice exhibited fluorescent label. Although labeling was found in the olfactory bulbs, especially in young mice, there was no evidence of transneuronal transport to secondary neurons such as mitral cells. Evidence for label within the submucosal area and leptomeninges surrounding the olfactory bulb suggested that some of the dye could reach the CNS by other routes in addition to transport through the olfactory nerves (Kristensson and Olsson, 1971).

**19.2.4.3 Trypan Blue.** Trypan blue dye was studied in both the brown bullhead, *Ictalurus natalis* (Holl, 1965) and the mouse (Seki, 1941). The investigations were undertaken to demonstrate the time course and conditions for specific uptake of the dye into olfactory receptor cells and not into other cell types in the olfactory epithelium. Transneuronal transport was not investigated.

## 19.2.5 Amino Acids

**19.2.5.1 Leucine.** The transport of leucine in the olfactory system has been studied by a number of investigators (for review see Weiss and Buchner, 1988). For the most part, uptake, metabolism, and transport of the amino acid were used to characterize the kinetics of protein movement in normal and regenerating nerve fibers. The olfactory system was an ideal model since in many fish species the nerve is long and regenerates

readily. One of the pioneering studies used histochemical techniques to demonstrate axoplasmic transport of labeled proteins following intranasal application of tritiated leucine in the toad, *Bufo americanus* (Weiss and Holland, 1967). Gross and Beidler (1973) studied fast axonal transport in C-fibers of the garfish, *Lepisosteus osseus*. Experiments performed in the pike, *Esox lucius*, demonstrated similar dynamics of fast axonal transport (Gross and Kreutzberg, 1978; Weiss et al., 1978). The long olfactory nerve of this species was used to study temperature dependence of axonal transport, especially slow axonal transport in normal and regenerating olfactory nerve (Cancalon, 1979a,b). The relative uniformity of transport in both the antero- and retrograde direction was shown in the pike olfactory nerve (Weiss and Buchner, 1988). Transport of tritiated leucine was also utilized to analyze the projections of olfactory receptor neurons in the adult rabbit (Land and Shepherd, 1974). In all studies the majority of the leucine was incorporated into amino acids following a short delay. Transport was monitored either autoradiographically or biochemically within dissected nerve segments. Although both slow (Cancalon, 1979a,b) and fast axonal transport (Gross and Beidler, 1973; 1975) were demonstrable using these techniques, transneuronal transport was not observed under the experimental conditions utilized (Land and Shepherd, 1974; Weiss and Holland, 1967).

**19.2.5.2 Alanine.** In the olfactory system the dipeptide carnosine ( $\beta$ -alanyl-L-histidine) may be either a neurotransmitter or neuromodulator of the primary olfactory neurons (Burd et al., 1982). Therefore,  $\beta$ -alanine presented at the mouse external naris was incorporated specifically into carnosine (Margolis and Grillo, 1977). Subsequent experiments in hamsters demonstrated that the radioactivity associated with the  $\beta$ -alanine was converted to carnosine (>82% of the radioactivity was in the carnosine fraction at 24 hr) and transported to the olfactory bulb (Burd et al., 1982). The rate of appearance in the olfactory bulb was consistent with movement of the  $\beta$ -alanine by the fast axonal transport system.

Tritiated  $\alpha$ -alanine exhibited a pattern of transport consistent with a less specific internalization in the olfactory epithelium and incorporation into a number of proteins after intranasal administration. Both sensory and nonsensory cells and the lamina propria were labeled. Peak labeling in the olfactory bulb was less intense and delayed as compared to  $\beta$ -alanine, suggesting that the protein was carried by slow axonal transport. Transneuronal transport was not observed for either  $\alpha$ - or  $\beta$ -alanine (Burd et al., 1982).

**19.2.5.3 Taurine.** Taurine accumulated specifically in the olfactory bulb after intravenous injection (Lindquist

et al., 1983). The ability of the olfactory system to concentrate this amino acid was even more pronounced following intranasal irrigation. An intra-axonal transport mechanism, as opposed to a perineural one, was suggested by the restricted accumulation in the bulb ipsilateral to the application.

### 19.2.6 Drugs

Valproic acid (Hoeppner, 1990), cocaine (Brittebo, 1988), and a number of other drugs (Dahl and Hadley, 1991) were concentrated in the olfactory epithelium following intravenous administration. The relative enrichment of cocaine in the epithelium was maintained for at least 24 hr. The mechanism for the concentration of these drugs in the epithelium is unknown. The presence of dopamine D<sub>2</sub> receptors in the receptor epithelium (Guthrie et al., 1991; Shipley et al., 1991) suggests that cocaine, a dopamine uptake blocker, binds to a specific receptor site in the epithelium. The presence of numerous drug-metabolizing enzymes (Dahl and Hadley, 1991) also may contribute to the bioactivation of drugs in to reactive metabolites in the olfactory epithelium. Transport has not been studied following intranasal administration of the drugs.

Folic acid and its derivatives alone or in combination with other drugs, such as cholinesterase inhibitors and acetylcholinesterase inhibitors, can directly enter the CNS and provide a rapid effect on the prevention or treatment of Alzheimer's disease and stroke (Hussain et al., 2002). However, the transport mechanism of folic acid-mediated nose-to-brain delivery is still under investigation. Intranasal insulin administration improved memory in healthy volunteers and Alzheimer's patients (Benedict et al., 2004; Reger et al., 2008). Intranasal oxytocin administration reduced stress in monkeys (Parker et al., 2005) and intranasal insulin-like growth factor-I (IGF-I) decreased infarct volume and improved neurologic function in stroke models in rats (Liu et al., 2001, 2004).

Dopamine seems also to bypass the BBB when applied into the nose and has been shown to have behavioral and neurochemical effects in rats. For example, intranasal dopamine administration increased dopamine levels in the neostriatum and nucleus accumbens (de Souza Silva et al., 2008). Rodents showed an antidepressant-like behavior in a forced-swimming task and higher locomotor activity in the open field following intranasal dopamine administration (Buddenberg et al., 2008). Intranasal dopamine administration also reduced activity and improved attention in an animal model of attention-deficit-hyperactivity disorder (ADHD) (Ruocco et al., 2009). Interestingly, recent studies demonstrate that intranasally applied dopamine and levodopa alleviate parkinsonian symptoms in rats with unilateral nigro-striatal 6-OHDA lesions, one of the most

used animal models of Parkinson's disease (Pum et al., 2009; Chao et al., 2012).

### 19.2.7 Miscellaneous Substances

**19.2.7.1 Horseradish Peroxidase.** The transport of HRP differed from that observed for the conjugate, WGA-HRP. HRP, like WGA-HRP, was internalized by receptor cells and labeled the olfactory glomeruli (Balin et al., 1986; Kristensson and Olsson, 1971; Meredith and O'Connell, 1988; Stewart, 1985). However, transneuronal transport was not observed. Movement also occurred through the intercellular junctions to label the leptomeninges (Balin et al., 1986). HRP uptake was not observed in the accessory olfactory system unless a large dose of epinephrine was administered to activate the vomeronasal organ pumping mechanism (Meredith and O'Connell, 1988). Mechanistic considerations discussed below may underlie the differences between WGA-HRP and HRP.

**19.2.7.2 Immunoglobulins.** Baker and Maruniak (1990) demonstrated that mouse olfactory receptor neurons internalized IgG molecules from a number of species. Twenty-four hours after intranasal application, receptor neurons, microvillar cells, and nerve bundles in the olfactory mucosa contained IgG, but transport into the olfactory bulb was not observed.

**19.2.7.3 Solvents.** Uptake and metabolism were investigated for several solvents, including benzene, toluene, xylene, and styrene (Ghantous et al., 1990). All the aromatic hydrocarbons were found in the olfactory epithelium, but only toluene, xylene, and styrene were found in the olfactory bulb. Transport of the three solvents in olfactory receptor cells was thought to require conversion to either their aromatic acids or their conjugates. In support of this hypothesis, benzene does not exhibit biotransformation to aromatic acids and was not transported (Ghantous et al., 1990). The cytochrome P-450 enzymes necessary for these biotransformations are known to be present in the olfactory epithelium (Dahl, 1988; Dahl and Hadley, 1991).

### 19.2.8 Olfactory Toxicants Delivered via the Bloodstream

Multiple xenobiotics that are systemically administered (i.e., by non-inhalation routes of exposure) have toxic effects on the olfactory mucosa of experimental animals (Table 19.2). For example, intraperitoneal administration of the analgesic acetaminophen or the anti-hyperthyroid drugs

methimazole or carbimazole to rodents causes degeneration of the olfactory mucosa (Genter, 1998; Genter et al., 1995; Genter et al., 1998; Jeffery and Haschek, 1988). Some anti-hyperthyroid drugs have been associated with impaired olfaction in humans (Schiffman, 1983). The herbicide dichlobenil (2,6-dichlorobenzonitrile) is particularly interesting from the point of view that intravenous (i.v.), intraperitoneal (i.p.), or dermal exposure results in olfactory mucosal degeneration in mice, with dermal exposure representing an occupationally-relevant route of exposure (Brandt et al., 1990; Deamer et al., 1994). In general, there is partial to nearly full recovery of olfactory mucosa which has undergone chemically-induced degeneration (see chemicals labeled "OMD," referring to those causing olfactory mucosal degeneration in Table 19.2). However, a toxicant that destroys the olfactory basal cells and causes persistent metaplasia of the olfactory mucosa has recently been described (Bahrami et al., 2000). A number of drugs (e.g., phenacetin), industrial and agricultural chemicals, for example, (p-cresidine, alachlor) and environmental pollutants (e.g., NNK) are associated with the development of nasal cancer in rodents (Table 19.2). It is interesting to note that humans are exposed to low levels of many of these, or related, agents every day, but none has been linked definitively to human nasal cancer; the most widely-recognized risk factors for human nasal cancer are exposure to wood dust or nickel, both via the inhalation route (Barceloux, 1999; Hayes et al., 1986).

## 19.3 MECHANISMS OF TRANSPORT

### 19.3.1 Uptake

The preceding discussion demonstrates that olfactory receptor cells can internalize many types of substances. The issue is how and why these cells should internalize a wide range of xenobiotics. The answer to both these questions may be the same. Since the olfactory mucosa comes in contact with many substances in inspired air, a means of either elimination or detoxification has likely been developed as a protective mechanism. In fact, the olfactory epithelium contains high concentrations of a wide variety of xenobiotic-metabolizing enzymes, even when compared to levels in the liver (Dahl, 1988; Dahl and Hadley, 1991; Thornton-Manning and Dahl, 1997). A number of enzymes have been found in the olfactory epithelium, including numerous isozymes of P450, monooxygenases, aldehyde dehydrogenases, alcohol dehydrogenase, carboxyesterases, epoxide hydrolases, UDP-glucuronyl transferase, glutathione S-transferase and rhodanese (Dahl and Hadley, 1991) (see also Chapter 1). For some of these enzymes, isozymes have been found that

are specific to the olfactory mucosa (Dahl, 1989; Jones and Reed, 1989; Lazard et al., 1991; Nef et al., 1989; Zupko et al., 1991). Thus, uptake into receptor, supporting, and glandular cells of xenobiotics, including odorants, may serve a detoxification as well as a clearance function. These enzymes also may play a role in defining the characteristic odor of a substance through the production of active metabolites, thereby creating new odorants (Dahl, 1988; Dahl and Hadley, 1983; Getchell et al., 1984).

The specificity of the uptake mechanism has not been established. For WGA-HRP, receptor-mediated processes have been suggested, since the conjugate, which is known to bind to surface membrane oligosaccharides, is found associated with vesicles (Baker and Spencer, 1986; Broadwell and Balin, 1985). Unconjugated HRP, on the other hand, is thought to be internalized via bulk endocytosis (Broadwell and Balin, 1985; Kristensson and Olsson, 1971). Surprisingly, one study reported that some preparations of WGA-HRP were not transuronally transported, suggesting that the method of HRP conjugation may alter the ability of WGA to bind with specific membrane receptors (Russell et al., 1991). The association of gold particles with vesicles suggested that uptake of gold occurred subsequent to the formation of vesicles by pinocytosis (De Lorenzo, 1970). Demonstration of a vesicular association of several intranasally applied tracers indicated that the olfactory epithelium possesses a well-developed system of endocytic vesicles, perhaps as a result of a rapid rate of membrane turnover (Bannister and Dodson, 1992). These authors suggested that materials may be trapped during normal membrane processing. The internalization of materials into the olfactory receptor cells thus may take place by either receptor- or non-receptor-mediated processes. In the former case, internalization may occur at low xenobiotic concentrations, and in the latter, high concentrations may be necessary.

A superfamily of putative odorant receptors was cloned by Buck and Axel (1991), leading to their receiving the Nobel Prize in Physiology or Medicine. The large number of these receptors indicates the presence of cell-type-specific surface molecules that interact with odorants. The binding of odorants to the receptor proteins may result in their internalization. Specific transport of odorant receptor mRNA to the olfactory bulb was used to demonstrate that cells expressing a specific odorant receptor project to a single glomerulus (Ressler et al., 1994; Ressler et al., 1993; Sullivan et al., 1995; Vassar et al., 1994). Olfactory marker protein mRNA shows similar transport to the glomerular layer but no transneuronal transport (Wensley et al., 1995). Interestingly, transneuronal transport was demonstrated for barley lectin (a close relative of WGA) synthesized in olfactory receptor cells of a transgenic mouse expressing the lectin under control of the olfactory marker protein gene promoter

(Horowitz et al., 1999). The function of the intra-axonal mRNA is unknown, but the ability of olfactory receptor neurons to transport numerous other molecules may be a consequence of this endogenous transport capacity. Also, the dopamine D<sub>2</sub> receptors reported in olfactory receptor neurons may play a role in the uptake of molecules that bind to this receptor (Guthrie et al., 1991; Mansour et al., 1990; Shipley et al., 1991). Glycoproteins, as indicated by lectin binding, also have been demonstrated on olfactory receptor cells using both *in vivo* and *in vitro* techniques (Allen and Akeson, 1985; Barber, 1989; Foster et al., 1991; Key and Akeson, 1990; Key and Giorgi, 1986a; Key and Giorgi, 1986b; Lundh et al., 1989; Mori et al., 1985; Polak et al., 1989; Shirley et al., 1983). Uptake of antibodies to IgG into receptor cells has been reported (Baker and Spencer, 1986; Baker and Maruniak, 1990). However, immunoreactivity for constituents of the immune system was not found in receptor cells, but primarily in Bowman's glands, the mucociliary complex, lymphocytes clustered near the basement membrane and scattered in the lamina propria, as well as in mast cells of the human olfactory mucosa (Mellert et al., 1992). A similar distribution of the secretory immune system components was observed in salamanders and rats (Getchell and Getchell, 1991). Monoclonal antibodies also recognize different cell types within the olfactory mucosa (Hempstead and Morgan, 1985), suggesting differences in cell surface constituents that might direct differential binding to olfactory receptors as opposed to either supporting or glandular cells.

Finally, odorant-binding proteins synthesized by mucus-secreting glands of the olfactory and respiratory mucosa have been demonstrated (Baldaccini et al., 1986; Dal Monte et al., 1991; Pevsner et al., 1986). The binding proteins may be necessary for either the transport of odorants to olfactory receptors or their clearance after signal transduction. The odorant specificity of these proteins suggests that a similar binding specificity on the receptor cells may underlie ligand (either odorant or other xenobiotic) uptake into receptor, supporting, and glandular cells. Transfer between these compartments also cannot be ruled out especially since many of the degradative enzymes described above are found in glandular and supporting cells and not receptor cells (Dahl and Hadley, 1991; Thornton-Manning and Dahl, 1997).

### 19.3.2 Transneuronal Transport

Once internalized, transport in the olfactory receptor cells can occur by either the slow or rapid transport systems characteristic of neuronal systems (Weiss and Buchner, 1988). The distinction between molecules transported only to the olfactory bulb and those that are transneuronally transported may lie in the nature of their internalization and thus the organelles with which the molecules are

associated. For example, WGA-HRP, which is internalized by receptor-mediated endocytosis, is transported intra-axonally in tubulovesicular profiles (Baker and Spencer, 1986) and transneuronally following processing in the transmost Golgi saccule (Baker and Spencer, 1986; Broadwell and Balin, 1985). The latter compartment processes vesicles destined for axonal terminals (Broadwell and Balin, 1985). Gold is vesicle-associated and is transneuronally transported (DeLorenzo, 1970). Viruses are transported in axonal vacuoles within receptor cells and appear to move transsynaptically to invade other brain regions synaptically connected to the olfactory bulb (Lavi et al., 1988; Monath et al., 1983). The relative lack of glial labeling for WGA-HRP and some viruses (Baker and Spencer, 1986; Lavi et al., 1988) indicates limited release into the extracellular space and accounts for the restricted transfer to olfactory-related brain regions. In contrast, HRP, which does not exhibit transneuronal transport, is taken up by bulk endocytosis and is not processed through the Golgi saccule. Leucine, which also does not appear to be transported transneuronally (Land and Shepherd, 1974; Weiss and Holland, 1967), is primarily processed into cellular protein components (Weiss and Buchner, 1988). Taken together these data suggest that transneuronal transport requires receptor-mediated uptake into the olfactory sensory cells, followed by vesicular transport of unmodified materials through the axon, with subsequent release and uptake in association with synaptic specializations.

### 19.3.3 Specificity of CNS Transport

As mentioned above, transport from the olfactory bulb to other brain regions occurs along specific pathways. The ability of centrifugal afferents to support specific transport is suggested by data demonstrating selectivity of retrograde axonal transport of radioactive transmitters from the olfactory bulb to their nuclei of origin (Araneda et al., 1983; Bonnet-Font and Bobillier, 1990; Watanabe and Kawana, 1984). Intrabulbar application of radioactive serotonin or norepinephrine results in specific labeling respectively of the dorsal raphe nucleus and the locus coeruleus (Araneda et al., 1983; Bonnet-Font and Bobillier, 1990). Similarly, the receptor-mediated retrograde transfer of nerve growth factor from the olfactory bulb to forebrain cholinergic nuclei indicates the ability of these neurons to transport exogenously applied substances (Altar and Bakhit, 1991).

### 19.3.4 Transporters in Nasal Epithelia

The observation that nucleoside drugs are transported to the CNS following intranasal delivery (Seki et al., 1994; Yajima et al., 1998) prompted the question as to whether the members of the family of transporters known

to transport these drugs (i.e., the equilibrative nucleoside transporters [ENT]) were expressed in nasal epithelia. Branched DNA technology was used to compare the level of expression of nine transporters [ENT1 and ENT2; organic cation transporter (OCT)1, 2, and 3; OCTN1; organic anion-transporting polypeptide (OATP3); and multidrug resistance proteins (MRP)1 and MRP4] in nasal respiratory mucosa, olfactory mucosa, and olfactory bulb. ENT1 and ENT2 expression was relatively high in nasal epithelia and olfactory bulb, which may explain the uptake of intranasally administered nucleoside derivatives observed by other investigators. OATP3 immunoreactivity was high in olfactory epithelium and olfactory nerve bundles, which suggests that substrates transported by OATP3 may be candidates for intranasal administration (Genter et al., 2010). Metal uptake transporters, including divalent metal transporter 1 (DMT1), ZIP8, and ZIP14 are also expressed in the olfactory epithelium (Thompson et al., 2007; Ma et al., 2008; Genter et al., 2009, 2010). Zinc transporters, which either efflux or recompartmentalize cytosolic zinc, are also expressed in olfactory epithelium (Sekler et al., 2002). Amino acid, organic anion, and organic cation transporters have also been shown to be present and functional in olfactory epithelium (Kaler et al., 2006; Eraly et al., 2006; Schnabolka et al., 2006; Bröer, 2006; Chemuturi, 2007).

## 19.4 THE NASAL CAVITY AS A ROUTE OF ADMINISTRATION FOR THERAPEUTIC DRUGS

### 19.4.1 Background

There is currently considerable interest in administration of therapeutic drugs via the nasal cavity for delivery into the brain or into the systemic circulation. This route of administration can be particularly useful for drugs which are readily degraded in the gastrointestinal tract (e.g., small, readily-digestible peptides) or drugs which are extensively inactivated by liver metabolism following oral ingestion. This is not to say that the nasal respiratory and olfactory epithelia are metabolically inert; in fact, there is a vast body of literature documenting the presence of multiple Phase I and Phase II metabolic enzymes in rodent, dog, and human nasal mucosa (Dahl and Hadley, 1991; Gervasi et al., 1991; Sarkar, 1992; Thornton-Manning and Dahl, 1997).

Of the three major routes of entry of drugs from the nasal cavity and into the brain or systemic circulation, the first, “transneuronal transport”, has been dealt with to this point in this chapter. Another putative mechanism for transport of agents from the nasal cavity and into the CNS has been termed the *olfactory epithelial pathway* (Mathison et al., 1998) or *paracellular transport* (McMartin et al.,

1987). Regardless of the designation, the concept is that molecules access the CNS from the nasal cavity via supporting cells, cell-to-cell junctions and/or spaces between cells. A great deal of research effort has gone into our understanding of the factors that are important in this process. For example, molecular weight, lipophilicity and ionization state/pH of the agent are all variables that appear to contribute to the ability of agents to access the CNS from the nasal cavity (McMartin et al., 1987; Sakane et al., 1991a; Sakane et al., 1994; Shimoda et al., 1995). The concentration of sulfonamides in the CSF of the rat resulting from intranasal administration was demonstrated to increase with the lipophilicity of the sulfonamide derivative (Sakane et al., 1991a). In contrast, lipophilicity did not enhance the absorption of a series of peptides from the nasal cavity (Donnelly et al., 1998; Sakane et al., 1991). Using fluorescein isothiocyanate-labeled dextran with molecular weights ranging from 4.4 to 40 kD, it was determined that drugs with a molecular weight of 20 kD or less could reasonably be expected to be transported from the nasal cavity to the CSF (Sakane et al., 1995).

### 19.4.2 Examples of Intranasally-administered Therapeutic Agents

Intranasally-administered drugs can be roughly divided into three main categories: (1) Drugs or other agents administered via the nasal cavity for CNS effects; (2) Drugs administered via the nasal cavity for systemic effects; and (3) Drugs administered via the nasal cavity for nasal and/or respiratory tract effects. Although the development of drugs for treatment of respiratory tract symptoms is undoubtedly the strategy most intuitively associated with intranasal drug delivery, it will not be dealt with in this chapter because of our interest here in transport. The development of drugs administered via the nasal cavity for CNS and/or systemic effects has exploded in recent years (Table 19.3).

#### 19.4.2.1 Drugs and Other Agents Administered via the Nasal Cavity for CNS Effects.

**ANTIMIGRAINE MEDICINES** Therapeutic drugs formulated for intranasal administration for CNS effects include migraine headache treatments, sedatives/anti-epileptics, neuroprotective agents and drugs to suppress cravings for smoking and eating. While some efforts are still largely in the experimental stages, migraine patients using medications administered via the intranasal route have realized significant relief. Due to the high incidence of nausea, vomiting, and visual disturbances during migraine attacks, intranasal administration of migraine medicines

is proving to be superior to pills or self-injections. While ergotamine derivatives have been extensively used in the past (Gallagher, 1996; Lipton, 1997; Marttin et al., 1997), newer generation drugs which act as 5-HT<sub>1D</sub> receptor agonists (e.g., sumatriptan, or Imitrex<sup>®</sup>) are also proving to be potent, highly specific anti-migraine agents when administered via the intranasal route. The bioavailability of intranasally-administered sumatriptan in dogs was equivalent to an oral dose (Barrow et al., 1997). Similarly, BMS-181885, another 5-HT<sub>1</sub>-like receptor agonist, was demonstrated to be quantitatively absorbed from the nasal cavity of cynomolgus monkeys, with the highest observed plasma concentration attained in 30 min (Srinivas et al., 1998). There has also been smaller-scale use of intranasal lidocaine or butorphanol as abortive treatments for migraines, as well as a case study reporting the effectiveness of intranasal capsaicin in migraine relief (Levy, 1995; Melanson et al., 1997; Mills and Scoggin, 1997; Sachs, 1996).

**SEDATIVES AND ANALGESICS** The intranasal route is also a practical alternative to injections/intravenous administration of sedatives and medicines for chronic pain. Midazolam is administered in several medical situations, including induction of anxiolysis and sedation particularly for endoscopic and dental procedures. Midazolam absorption from the nasal mucosa was nearly complete in a study involving adult surgical patients who were administered midazolam in small intranasal doses to preclude swallowing. This study was important in that it revised previous observations that the bioavailability following intranasal administration was approximately 55%, thus reducing the risk of accidental overdoses (Bjorkman et al., 1997). Nasal midazolam also appeared to be safe and effective in treatment of epileptic seizures in children (Jeannet et al., 1999). Intranasally-administered oxycodone and oxymorphone are effectively absorbed from the nasal cavity for treatment of chronic pain (Hussain and Aungst, 1997; Takala et al., 1997). Experiments to investigate the feasibility of administering acetyl salicylic acid by the nasal route have also been conducted in rat with promising results (Hussain et al., 1992). Johnston et al. (2011) discovered that co-administration of inhaled methoxyflurane with intranasal fentanyl improved prehospital management of visceral pain in an Australian ambulance service.

**ANTIVIRALS AND ANTIBIOTICS** Drugs with activity toward the human immunodeficiency virus, namely zidovudine (AZT; 3'-azido-2',3'-dideoxythymidine) and D4T (2',3'-didehydro-3'-deoxythymidine) are absorbed from the rat nasal epithelia and transported into the cerebral spinal fluid (CSF; Seki et al., 1994; Yajima et al., 1998). Under normal administration regimens, these drugs cannot cross the blood brain barrier and therefore are

ineffective against AIDS dementia when administered orally or by injection. The antibiotic cephalexin appeared rapidly in the CSF following intranasal administration (Sakane et al., 1991b). Favorable pharmacokinetics were observed when acyclovir was administered intranasally to rats (Chavanpatil and Vavia, 2004).

### DRUGS TO MODEL PARKINSON'S DISEASE (PD)

**IN LABORATORY ANIMALS** The presence of smell loss and the pathological involvement of the olfactory pathways in the early stages of PD are in accord with the tenants of the olfactory vector hypothesis. This hypothesis postulates that some forms of PD may be caused or catalyzed by environmental agents that enter the brain via the olfactory mucosa. Some compounds, such as rotenone, paraquat, and 6-hydroxydopamine, have limited capacity to reach and damage the nigrostriatal dopaminergic system via the intranasal route (see Prediger et al., 2012). Others, such as MPTP, readily enter the brain via this route in some species and influence the function of the nigrostriatal pathway. Intranasal infusion of MPTP in some rodents elicits a developmental sequence of behavioral and neurochemical changes that closely mimics that seen in PD (Prediger et al., 2006, 2009, 2011). Effects noted included motor deficits that correlated with a progressive and severe depletion of striatal dopamine levels, and loss of tyrosine hydroxylase and dopamine transporter staining in substantia nigra and striatum, as well increased levels of Mn-superoxide dismutase. However, alpha-synuclein aggregation was not observed (Rojo et al., 2006, 2007; Prediger et al., 2012).

### TREATMENT/PREVENTION OF NEURODEGENERATIVE DISEASES AND BRAIN INJURY

Vasoactive intestinal peptide (VIP) is widely distributed in regions of the brain associated with learning and memory. VIP antagonists are associated with learning impairments in experimental systems, and *in vitro* studies have demonstrated that VIP exerts neuroprotective effects, including protection of cortical neurons from the cytotoxic effects of  $\beta$ -amyloid peptide. Intranasal administration of a lipophilic analogue of VIP ( $[St\text{-}Nle^{17}]VIP$ ) to rats has been shown to deliver unmetabolized ( $[St\text{-}Nle^{17}]VIP$ ) to the brain and to prevent impairments in spatial learning and memory associated with cholinergic blockade in rats (Gozes et al., 1997; Gozes et al., 1996). Similarly, dextromethorphan and neostigmine were found to be well-absorbed from the rat and human nasal cavities, with the latter more effective in relieving symptoms of myasthenia gravis as a nasal spray than when administered intravenously (Char et al., 1992; Di Costanzo et al., 1993). Administration of vasopressin to humans to increase brain activity and improve memory has resulted in reports of marginal improvement (Perras et al., 1997; Pietrowsky et al., 1996).

Recent studies have demonstrated that stem cells can migrate to the brain following intranasal instillation. This finding is the basis for great excitement about the possibility of stem cell therapies for treatment of neurodegenerative diseases. Wang et al. (2012) showed behavioral recovery in 6-hydroxydopamine-treated rats following administration of human adult olfactory epithelial-derived neural progenitor cells which had been differentiated into dopaminergic neurons. Human fibroblasts were used as controls and they did not improve parkinsonian endpoints. In addition to behavioral improvement, increased numbers of tyrosine hydroxylase positive cells were detected in the grafted brains; these remained viable for at least six months *in vivo*. Higher dopamine levels were detected in the striatum of behaviorally improved rats than in equivalent regions of rats that did not recover. These results support the hypothesis that human adult olfactory epithelial-derived progenitors represent a unique autologous cell type with promising potential for future use in a cell-based therapy for patients with Parkinson's disease.

High mobility group box-1 (HMGB1) is an endogenous "danger signal molecule" which is released after ischemic injury in the brain and triggers inflammation and apoptosis. Kim et al. (2012) demonstrated that intranasal delivery of a HMGB1-binding heptamer peptide, but not a scrambled heptamer, was extremely effective in neuroprotection following ischemic brain injury, suggesting that this novel approach coupled with the intranasal route, may be an emerging stroke therapy.

Traumatic brain injury (TBI) is receiving heightened attention in light of reports of athletes developing TBI following repeated blows to the head and the prevalence of TBI in soldiers following combat (Kontos et al., 2012; Sahler and Greenwald, 2012). Therefore, therapies to treat this condition once it has developed will be of great interest. Tian et al. (2012) demonstrated in rats that intranasal administration of nerve growth factor ameliorated  $\beta$ -amyloid deposition after traumatic brain injury. Likewise, Won et al. (2012) demonstrated that intranasal delivery of nicotinamide adenine dinucleotide prevented TBI in rats.

### SMOKING CESSATION AND APPETITE

**SUPPRESSION** Nicotine nasal sprays have been evaluated as agents to assist individuals in smoking cessation. It is possible that the sprays are efficacious due both to the direct delivery of nicotine to the brain, as well as maintenance of blood nicotine levels such that the majority of symptoms of withdrawal are avoided. While there have been reports that the irritation associated with nicotine nasal sprays precluded their use to attain therapeutic blood levels (Gourlay and Benowitz, 1997), another study showed that successful "quitters" who most frequently used nicotine nasal sprays as part of a smoking cessation

program had higher blood nicotine and cotinine levels than those using the sprays occasionally or not at all (Jones et al., 1998). Experimentally, cholecystokinin (CCK) agonists show promise as appetite suppressants (Pierson et al., 1997). More recently, Hallschmid et al. (2004) studied the regulation of food intake and body weight in humans treated intranasally with several neuropeptides. Intranasal administration of neuropeptide Y was found to increase food intake (acting as an orexigenic messenger), while prolonged administration of insulin or melanocyte stimulating hormone induced weight loss in healthy humans. Interestingly, the latter treatments did not cause weight loss in overweight subjects.

**BRAIN TUMOR THERAPY** Monoterpene perillyl alcohol (POH), a Ras inhibitor and anti-angiogenic factor with potential capacity to arrest gliomagenesis, was investigated in a phase I/II clinical trial in adults with recurrent malignant glioma. The efficacy of intranasal administration of monoterpene POH upon survival rate of patients with recurrent glioblastoma (GBM) was demonstrated in several trials. One study included 89 adults with recurrent GBM who received daily intranasal administration of 440 mg POH. The prognosis of these patients was compared to that of 52 matched GBM patients as historical control untreated group who received only supportive treatment. Intranasal administration of POH significantly increased the overall survival of patients with recurrent GBM in comparison with historical untreated controls. The side effects of POH treatment were minimal, even in patients treated for over four years (da Fonseca et al., 2008, 2011; Fischer et al., 2008).

In another study suggesting the future importance of intranasally-administered stem cells, Reitz et al. (2012) demonstrated that intranasal administration of neural stem/progenitor cells (NSPCs) led to a rapid, targeted movement of the stem cells toward experimentally-induced gliomas in mice. While most of the NSPCs reached the tumor via the olfactory nerve, some were delivered via blood vessels, but importantly, the cells accumulated with high efficiency in the tumors but not peripheral to the tumors. The goal moving forward is to take advantage of the observed specificity to develop treatment regimens.

**19.4.2.2 Drugs Administered via the Nasal Cavity for Systemic Effects.** There is a similarly long and varied list of therapeutic drugs which are designed for intranasal delivery to achieve a desired systemic effect (see reviews by Jones et al., 1997; Mathison et al., 1998).

**PEPTIDES** Delivery of peptides such as insulin and calcitonin via the nasal route would in theory improve

their bioavailability over oral administration. There have been mixed results with insulin administration via the nasal route (Hilsted et al., 1995), possibly because of peptidases in nasal secretions that have high activity toward insulin peptides. Methods to encapsulate insulin peptides appear promising in the effort to improve systemic delivery of insulin following intranasal administration (Fernandez-Urrusuno et al., 1999). Intranasal calcitonin is a potent agent for reducing bone resorption (Silverman, 1997).

**HORMONE ANALOGUES** Buserelin and nafarelin are being used as nasal sprays for treatment of endometriosis, prostate cancer, and low sperm count, and show favorable results as contraceptives (Bergquist et al., 1979). Oxytocin nasal sprays are associated with high blood levels of the drug and enhanced lactation (Landgraf, 1985; Ruis et al., 1981).

**VACCINES** The intranasal route is also becoming recognized as a route of immunization against agents such as influenza viruses, *N. meningitidis*, diphtheria, and tetanus (Liu, 1998; Maassab and DeBorde, 1985).

**OTHERS** Vitamin B<sub>12</sub> derivatives are well absorbed following intranasal administration, as are drugs for treatment of motion sickness and “bedwetting” (Butler et al., 1998; Kallas et al., 1999; Putcha et al., 1996; Ramanathan et al., 1998; Slot et al., 1997; Swain, 1995).

**19.4.2.3 Enhancement of Delivery of Intranasally-Administered Drugs.** Considerable effort has gone into identifying agents that can enhance the absorption of drugs from the nasal cavity without causing clinically-relevant damage to the mucosal surface of the nasal cavity (Examples are included in Table 19.4). The putative absorption enhancers sodium tauro-24,25-dihydrofusidate (STDHF) and dimethyl-β-cyclodextran (DM βCD) exhibited some epithelial toxicity, whereas ethyleneamine diamine tetraacetic acid (EDTA) was not associated with enhanced absorption or epithelial toxicity (Donnelly et al., 1998). Methylated β-cyclodextrins were less toxic to nasal epithelia than sodium glycocholate, STDHF, laureth-9 (a detergent) and L-α-phosphatidylcholine (Marttin et al., 1998). Free amine chitosans and soluble chitosan salts were evaluated for their efficacy and safety as nasal enhancers of peptide absorption and were found to be comparable in their action, if not more potent, than cyclodextrins (Tengamnuay et al., 2000). Cyclodextrins are believed to enhance absorption of intranasally-administered drugs by transiently opening tight junctions between nasal epithelial cells (Marttin et al., 1998). High concentrations of certain

**Table 19.4** Examples of strategies to increase delivery of intranasally-administered drugs

Molecule/Drug Treatment	Enhancer	Disease	Species	Ref.
Acyclovir	Hydroxypropyl b-cyclodextrin > sodium deoxycholate > sodium >caprate > sodium >tauroglycocholate > EDTA	Herpes simplex, varicella zoster, cytomegalovirus, and Epstein Barr virus infections	Rat	Chavapati and Vavia, 2004
AT1002, a six-amino acid fragment of Zonula occludens toxin	Carrageenan as bioadhesive polymer and dextrose as stabilizer	Proof of concept	Rat	Song and Eddington, 2012
Calcitonin	N- acetyl-L-cysteine	Proof of concept	Rat, rabbit, dog	Matsuyma et al., 2006b
Cannabidiol	Polyethylene glycol 400	Chronic and breakthrough pain	Rat	Paudel et al., 2010
Erythropoietin, human growth hormone, and salmon calcitonin	Lipoamino acids	Proof of concept	In vitro	Bijani et al., 2012
Exendin-4	Polyethylene glycol	Type 2 diabetes	Mouse	Kim et al., 2012
Fentanyl	Pectin, chitosan and chitosan-poloxamer 188	Proof of concept	Human	Fisher et al., 2010
Fexofenadine	Chitosan-coated liposome	Allergic rhinitis	In vitro, rat	Qiang et al., 2012
Fluorescein	Sodium hyaluronate	Proof of concept	In vitro, rat	Horváth et al., 2009
Fluorescent isothiocyanate-labeled 4 kDa dextran (FD-4)	N-acetyl-L-cysteine + nonionic surfactant, polyoxyethylene lauryl ether (laureth-25)	Proof of concept	Rat	Matsuyma et al., 2006a
Galanin-like peptide ( <sup>125</sup> I-GALP)	Cyclodextrins	obesity and related conditions	Mouse	Nonaka et al., 2008
Gemcitabine	Polybutylcyanoacrylate nanoparticles coated with polysorbate-80	Anti-tumor	Rat	Wang et al., 2009a
Gemcitabine	Papaverine	Proof of concept	Rat	Krishan et al., 2014
Gransetron	Hydroxypropyl-cyclodextrin and sodium carboxymethylcellulose	Treatment of nausea and vomiting following chemotherapy	Primary human nasal epithelial cells in vitro	Cho et al., 2010
Growth differentiation factor 5	Lipid microemulsion of olive oil and phosphatidylserine	Parkinson's disease	Rat	Hanson et al., 2012
Indomethacin	Polyvinylpyrrolidone, citric acid, sodium taurocholate	Anti-inflammatory effects	In vitro, ex vivo, rat	Karasulu et al., 2008

Insulin	Oligoarginine-linked poly (N-vinylacetamide-co-acrylic acid)	Diabetes/obesity	Mouse	Sakuma et al., 2010
Insulin	Starch nanoparticles with sodium glycocholate	Streptozotocin-induced diabetic rats	Rat	Jain et al., 2008
Insulin	Aminated gelatin	Proof of concept	Rat	Seki et al., 2005
Insulin	PEG-grafted chitosan nanoparticles	Proof of concept	Rabbit	Zhang et al., 2008
Insulin	Chitosan-N-acetyl-L-cysteine nanoparticles	Proof of concept	Rat	Wang et al., 2009
Insulin	Polysaccharide nanoparticles consisting of chitosan and cyclodextrin (CD) derivatives-(sulfobutylether- $\beta$ -CD or carboximethyl- $\beta$ -CD)	Proof of concept	Rabbit, in vitro	Teijeiro-Osorio et al., 2009
Isosorbide dinitrate	Poloxamer 188	Angina pectoris	Rat	Na et al., 2010
Lorazepam	Vinyl polymer-coated microparticles	Maximize speed of onset and minimize carry-over sedation	Rabbit	Zhao et al., 2012
Lysozyme	Hydroxypropyl-methylcellulose, hydroxypropyl-cyclodextrin, d-alpha-tocopheryl polyethylene glycol 1000 succinate	Delivery of therapeutic proteins	Human nasal epithelium in vitro	Cho et al., 2011
Midazolam	Cyclodextrins and chitosan	Proof of concept	Human	Haschke et al., 2010
Morphine	Nanoparticles consisting of a polysaccharide core surrounded by a lipid bilayer	Analgesia	Mice	Betbeder et al., 1998
Morphine, fentanyl	Pressurized olfactory delivery device	Analgesia	Rats	Hoekman and Ho, 2011a
Nelfinavir, mannitol	Pressurized olfactory delivery device	Proof of concept	Rat	Hoekman and Ho, 2011b
Nerve growth factor	Mutation at residue R100	Neurodegenerative diseases	Mouse	Capsoni et al., 2012
Olanzapine	Peppermint oil Poly(lactic-c-glycolic acid) nanoparticles	CNS disorders	Rat Ex vivo	Vaka and Murthy, 2010 Seju et al., 2011

(continued)

**Table 19.4 (Continued)**

Molecule/Drug Treatment	Enhancer	Disease	Species	Ref.
Ondansetron HCl	Solid lipid nanoparticles	Management of chemotherapy induced postoperative nausea and vomiting	In vitro	Joshi et al., 2012
Peptide YY 3–36 (PYY3–36)	Novel tight junction modulating peptide (PN159)	Proof of concept	Rabbit	Chen et al., 2006
Pituitary adenylate cyclase activating polypeptide Recombinant hirudin-2 (rHV2)	Cyclodextrins Chitosan	Alzheimer's disease Anticoagulant, antithrombotic activities	Mouse Rat, in vitro	Nonaka et al., 2012 Zhang et al., 2005
Recombinant human growth hormone (rhGH)	<i>N</i> -trimethyl chitosan chloride and a patented fatty acid-based delivery system	Proof of concept	Rat	Steyn et al., 2010
Recombinant iduronidase (IDUA; in the form of laronidase)	Adeno-associated virus vector encoding IDUA	Lysosomal storage diseases	Mouse	Wolf et al., 2012
Rivastigmine (RHT)	Chitosan nanoparticles	Alzheimer's disease	Rat, in vitro	Fazil et al., 2012
Pituitary adenylate cyclase activating polypeptide <i>Streptococcus equi</i> proteins	Cyclodextrins Poly (L-lactic acid) and glycol-chitosan nanospheres	Alzheimer's disease Strangies	Mouse Mouse	Nonaka et al., 2012 Florindo et al., 2009
Tacrine	Mucoadhesives (albumin, cyclodextrins)	Alzheimer's disease	In vitro, proof of concept	Luppi et al., 2011
Thymopentin (TP5)	Chitosan and bacitracin	Modulator for immunodeficiencies	Rat	Wang et al., 2006
Urocortin peptide	Odorranalactin	Parkinsonism	Rats	Wen et al., 2011

cyclodextrins are associated with ciliary damage, an endpoint also associated with benzalkonium chloride, which has been used as a preservative in many nasal formulations (Bernstein, 2000; Uchenna Agu et al., 2000). Luppi et al. (2011) used mucoadhesives (albumin, cyclodextrins to improve delivery of intranasally-administered tacrine. Wen et al. (2011) took advantage of prior knowledge of lectin biology and the olfactory system to enhance the delivery of urocortin peptide, a potential Parkinson's disease therapeutic, using odorrranalectin, a very small lectin molecule.

## 19.5 CONSEQUENCES OF TRANSPORT

One of the early changes associated with several neurodegenerative disorders, including Parkinson's and Alzheimer's diseases, is a substantial deficit in olfactory function of a discriminatory nature (Doty et al., 1988; Doty et al., 1991; Doty et al., 1987). These data in conjunction with recent findings of pathological changes in the olfactory epithelium (Tabaton et al., 1991; Talamo et al., 1989) and olfactory bulb (Esiri and Wilcock, 1984; Ohm and Braak, 1987), as well as brain areas with close synaptic relationships to the olfactory bulb (Ferreya-Moyano and Barragan, 1989; Saper et al., 1987), formed the basis for the hypothesis that the olfactory system may be a route of entry for either a toxic agent or a virus that is important to the etiology of these diseases.

For most substances, the evidence is at best circumstantial. Several reviews have outlined the data suggesting that environmental aluminum could contribute to the loss of olfactory functioning and the ensuing disease process in Alzheimer's disease. The findings of high levels of aluminum in plaques and the ability to produce lesions following inhalation of aluminum support this hypothesis. The data could reflect, however, other abnormalities in Alzheimer's disease, such as changes in the blood-brain barrier that permit accumulation of this metal in neurons (Crapper McLachlan, 1986; Roberts, 1986). Recent studies have provided anatomical demonstration of transport to the CNS of intranasally applied manganese (Tjälve and Henriksson, 1999) as well as epidemiological evidence for a Parkinson's-like syndrome following environmental exposure to the metal (Gorell et al., 1999). While there is no definitive evidence that the olfactory system serves as a route of entry for metals and other toxic agents in humans, there is strong support for an environmental role in sporadic Parkinson's disease (Langston, 1998; Tanner and Langston, 1990).

Currently, there is no evidence for viral involvement in neurodegenerative disorders such as Alzheimer's or Parkinson's disease. To postulate that the olfactory system

serves as a route of entry for a virus in these diseases is only conjectural. The fact that in some degenerative disorders the affected neuronal populations appear to be restricted to interconnected pathways has been clearly established (Saper et al., 1987), and transneuronal transport of viruses does occur along some of these routes especially in the olfactory system. Trophic substances also were shown to be transported along these same pathways. In the cholinergic system, for example, which innervates the olfactory bulb, nerve growth factor is retrogradely transported (Altar and Bakheit, 1991). Thus, an abnormality in transport of a trophic factor, either inborn or toxicant (viral?) induced, could result in neuronal degeneration. Alterations in peripheral afferent innervation of the olfactory bulb, both denervation and odorant deprivation, produce profound anatomical and biochemical consequences. Both neonates and adults show reductions in bulb size (Maruniak et al., 1989a,b; Meisami, 1976), granule cell spine densities (Benson et al., 1984), number of granule cells (Frazier and Brunjes, 1988), and neurotransmitter expression, including substance P and dopamine, in juxtaglomerular cells, (Baker et al., 1983; Kream et al., 1984). The latter changes occur without apparent cell death indicating the presence of phenotypic plasticity (Baker et al., 1984; Cho et al., 1996; Stone et al., 1991; Stone et al., 1990). These data indicate the importance of afferent innervation as a trophic regulator of bulb function and suggest that either exogenous agents or viral internalization may alter this trophic balance and result in the loss of olfactory function with eventual consequences in synaptically interconnected brain regions.

On a positive note, recent successes in the treatment of human CNS disorders using intranasally-administered agents continues to justify expanding the use of this route of exposure, as well as further studies into transiently and safely increasing the permeability of the route between the nasal cavity and the brain.

## 19.6 CONCLUSIONS

The intensive study of the olfactory mucosa over the years has done much to expand our knowledge in many seemingly-unrelated areas. The ill-advised intranasal zinc treatments of the 1920s and 1930s, intended as a polio prophylactic treatment, helped us refine our knowledge of the natural course of polio infection and ultimately lead to the development of an effective vaccination. The original identification of the putative structure of olfactory receptors by Buck and Axel culminated in their winning the Nobel Prize in Physiology or Medicine in 2004. Studies by Brunet et al. (1996) in a knockout mouse model determined that cyclic nucleotide gated channels subserve excitatory olfactory signal transduction and suggested

that cAMP is the critical second messenger in olfaction. Still unsolved is the mystery underlying the ‘plasticity’ of the olfactory epithelium. While many investigators have identified patterns of gene expression that make the olfactory mucosa unique (e.g., Genter et al., 2003), the definitive answer as to why these neurons not only have a basal level of turnover, but can regenerate after toxicant- (and some injury-) mediated damage is still unknown; yet this answer is still highly sought after, with the hope that this understanding could improve our ability to treat injuries in other regions of the nervous system. Important observations that many neurodegenerative diseases are associated with functional and structural alterations of the olfactory system (e.g., Doty et al., 1988; Talamo et al., 1989) have led to testable hypotheses about the possibility that causative agents for neurodegenerative diseases, particularly Parkinson’s disease, may attack the brain from the nasal cavity. Convincing evidence has been provided earlier in this chapter with MPTP, an important model of toxicant-induced Parkinson’s disease in rodents (e.g., Prediger et al., 2006, 2009, 2010, 2011, 2012). With regard to the topic of this chapter, the nose as a route of exposure/delivery, our knowledge continues to expand. Intranasal vaccinations are becoming more routine. Abundant recent experimental and clinical data show that the nasal route may provide an ideal route for delivery of drugs and even stem cells to the CNS for treatment of brain injuries, neurodegenerative diseases, and brain tumors. The story of the intranasal, mechanism-based treatment for patients with recurrent, inoperable glioblastomas (Fischer et al., 2008; da Fonseca, 2008, 2011) should serve as an inspiration to all of us as we attempt to take our bench research to the bedside. The nose knows a lot—it is up to us to ask the right questions!

## ACKNOWLEDGMENTS

Dr. Harriet Baker was a major contributor to the previous version of this chapter, and given that much of her content has been kept in this version, we acknowledge these contributions.

# Chapter 20

---

## Influence of Toxins on Olfactory Function and their Potential Association with Neurodegenerative Disease

LILIAN CALDERÓN-GARCIDUEÑAS

### 20.1 INTRODUCTION

Olfactory impairment significantly affects many facets of well-being, including safety, quality of life, and social behavior. As noted throughout this volume, smell dysfunction is common in a significant proportion of the population and can reflect numerous factors, including epithelial damage or airway blockage from local nasal disease, neurotransmitter alterations, metabolic derangements, exposures to environmental hazards and toxins, brain lesions, trauma, tumors, neurodegeneration, and occlusion of the foramina of the cribriform plate through which the olfactory receptor cell axons pass from the nose into the brain. In practice, the three most common causes of smell disorders are upper respiratory infections, sinonasal diseases, and head trauma (Deems et al., 1991). Although up to half of patients presenting with chemosensory dysfunction exhibit some return of smell function over time, less than 12% of those with anosmia return to normal age-related function. Prognosis is better for those with some initial function, with over 20% regaining normal age-related function (London et al., 2008).

Of importance to this chapter is the fact that large segments of the population are exposed to a myriad of toxic substances on a daily basis that have the potential for harming the olfactory system and, in some cases,

penetrating the brain via the olfactory epithelium (OE) (Tjälve et al., 1996, 1999; Dorman et al., 2006; Wang et al., 2011). Extreme instances of such exposures include the massive dust cloud following the September 11th, 2001, terrorist attack in New York City, smoke and debris from wildfires, dust and particulate matter encountered in desert storms, exposures to airborne herbicides and pesticides in farming communities, and pollutants from vehicle exhaust and manufacturing enterprises in major metropolitan areas. Nearly all people in industrialized societies are exposed, on a cumulative basis, to such airborne agents.

The amount, that is, dose, of xenobiotics that reaches the nasal passages depends upon their concentration in air, the volume of the inhaled air, the chemical nature of the xenobiotic (e.g., diffusivity, solubility), airflow characteristics of the nose, and the absorption and metabolic properties of the nasal lining (Kimbell et al., 2006). The inhaled air traverses the complex and highly variable nasal passages, that is, the folds and protrusions of the nasal walls and the inferior, middle, and superior turbinates, where its contents are largely deposited (Chapter 2). The volume of inhaled air is variable and depends on such subject factors as age, gender, weight, height, metabolic activity, and health (Becquemin et al., 1991; Vearrier and Greenberg, 2011). The integrity of the nasal and olfactory epithelia can further predispose them to damage and, as discussed later in this chapter, a

disrupted or “sick” epithelium may increase the likelihood of xenobiotics penetrating the brain.

## 20.2 THE OLFACTORY EPITHELIUM: A KEY TARGET FOR DAMAGE FROM TOXIC XENOBIOTICS

The olfactory epithelium (OE), which is described in detail in Chapter 4, is particularly susceptible to damage from environmental agents given its rather direct exposure to the inhaled air and associated outside environment. Thus, cellular damage to this neuroepithelium, including its stem cells near the basement membrane, has been repeatedly documented following exposure to various environmental pollutants, toxic gases, nanoparticles, and even chemotherapeutic agents (Féron et al., 2001; Steinbach et al., 2009; Faure et al., 2010; Chen et al., 2012; de Gabory et al., 2011; Inthavong et al., 2011; Holbrook et al., 2011; Altman et al., 2011; González-Pérez et al., 2011; Girard et al., 2011; Prediger et al., 2012; Nazarenko et al., 2012).

Computer models of airflow during normal respiration predict that approximately 3% of the inhaled air reaches the OE of most adults (Kimbell et al., 2006; see Chapter 16). Sniffing dramatically increases this percentage. While children inhale less air than adults, their nasal surface is smaller, resulting in essentially the same degree of epithelial exposure. However, their noses are not as efficient filters as those of adults, even though both groups exhibit similar patterns of nasal vapor uptake (Becquemin et al., 1991; García et al., 2009). For some toxic agents (e.g., formaldehyde), most nasal absorption occurs in the mid-septal area. For others (e.g., ozone), the major impact occurs elsewhere. Importantly, the toxic effects do not affect the same anatomical regions of each individual.

Nanoparticles are very effective in reaching the OE (Oberdorster et al., 2004). Deposition of particulate matter (PM) depends upon a number of factors, including access to the nasal region, speed of particle diffusion from the air stream, and particle size (see Chapter 16). Even slight geometric differences in the nasal passages can have significant effects on nasal deposition (Schroeter et al., 2011a), a factor to take into account when comparing nasal exposures among individuals and when attempting to extrapolate animal data to humans. Human nasal computational fluid dynamic models using size particles in the range of 5–50  $\mu\text{m}$  and volumetric flow rates of 7.5, 15, and 30 L/min have found a 3% maximum PM deposition efficiency in the olfactory region (Schroeter et al., 2006). For micrometer-sized PM, inertia is a key factor influencing deposition, while for nano size PM ( $<100 \text{ nm}$ ) Brownian diffusion is a critical factor (García and Kimbell, 2009). Estimates of nanoparticle deposition

in the rat olfactory region based on anatomically accurate fluid dynamic models of the nasal passages have shown maximal olfactory deposition of 6–9% with a size particle from 3 to 4 nm (García and Kimbell, 2009). PM  $<3 \text{ nm}$  deposits predominantly in the anterior nose, while PM  $>30 \text{ nm}$  distributes more uniformly throughout the nasal passages.

To protect against cellular damage, as well as the entrance of some xenobiotics into the brain via the nose, the OE is equipped with Phase I and Phase II metabolizing enzymes and Phase III transporters (see Chapter 3). The Phase I mixed-function oxidases include members of the cytochrome P450 family, aldehyde dehydrogenases (ALDHs), and epoxide hydrolases (EPHXs). Among the Phase II enzymes found in the OE are UDP-glucuronosyl-transferases (UGTs), sulfotransferases (SULTs), and glutathione-S-transferases (GSTs) (Su et al., 1996; Ding and Dahl, 2003; Su and Ding, 2004; Genter et al., 2009, 2010; Heydel et al., 2010; Thiebaud et al., 2011). Transport proteins that facilitate Phase III xenobiotic metabolism, thus allowing conjugates and their metabolites to be excreted from cells, play a critical role in the OE and olfactory bulb (OB). Metal transporters, multidrug resistance P-glycoproteins (MDR), multidrug resistance-related proteins (MRP), and organic anion and cation transporters are the most transcriptionally expressed transporters in the OE (Genter et al., 2010; Thiebaud et al., 2011). Many of the detoxification proteins are located at the apical part of the olfactory mucosa, olfactory cilia, and in sustentacular and Bowman cells. Given that excreted metabolites of odorants and other xenobiotics are disposed of within the nasal mucus (a further elimination step), a significant change in the nasal mucus amount and alterations under pathological circumstances (e.g., squamous metaplastic changes) can serve to decrease the mucus concentration and, hence, maximize the impact of the deposited xenobiotics.

## 20.3 MOVEMENT OF XENOBIOTICS INTO THE BRAIN AND GENERAL CIRCULATION FROM THE NOSE

It has been known for nearly a hundred years that viruses and microorganisms can be transported via olfactory neurons to the OB glomeruli, where movement can occur across synapses to dendrites of second order neurons (Doty, 2008). Among the documented mechanisms by which xenobiotics enter the brain via the OE are paracellular transport, axonal movement, and uptake through specific transporters (Thiebaud et al., 2011). Metal transporters, such as those with divalent cation transport function, play a critical role in cases where exposures to metals are prevalent, as in polluted urban environments

and in certain occupational settings (Lewis et al., 2005; Genter et al., 2010; Prediger et al., 2012).

Additional uptake of xenobiotics into the brain can occur through the nasal vasculature. The nasal cavity is lined with capillaries from the ethmoid branches of the internal carotid arteries and the facial and internal maxillary divisions of the external carotid arteries. Such capillaries serve a primary role in the transport of substances from the nose to the systemic circulation. From there, such transport can occur to all sectors of the body (Turker et al., 2004). In fact, nasal drug delivery of hormones and nano-size particles have been found to be an effective means for accessing both the circulatory system and the brain (Ali et al., 2010; Craft et al., 2012). The long-term effects of such delivery on nasal (e.g., ciliary transport) and olfactory (e.g., sensitivity) function, however, has not been thoroughly assessed.

It has only recently been appreciated that damage to the OE in a prion host can result in a substantial increase in the release of prion infectivity into the nasal mucosa. Such prion shedding may, in fact, further infect intranasal neural pathways (Bessen et al., 2012). In a hamster prion model, infected brain homogenates are transported paracellularly across the respiratory, olfactory and follicle associated epithelia of the nasal cavity. Prions cross the nasal mucosa via multiple routes and quickly enter lymphatics where they can spread systemically via lymph draining the nasal cavity (Kincaid et al., 2012). Axonal pathways from the nasal region to the brain include the trigeminal nasal branches (V1 ophthalmic and V2 maxillary branches) and their transganglionic projections to the trigeminal brain-stem nuclear complex (Anton and Peppel, 1991; Allavena et al., 2011). The drainage of lymphatic nasal turbinate channels to the CSF through the perineural olfactory nerve space (Zakharov et al., 2004; Walter et al., 2006; Koh et al., 2006) also provides a further connection between the nose and the brain.

The second order olfactory system neurons, namely the mitral and tufted cells, project to allocortical regions, most notably the anterior olfactory nucleus and the piriform and entorhinal cortices, as well as to sectors of the amygdala (Kalinke et al., 2011). The observation that the piriform and entorhinal cortices share with the OE and the OB the presence of specific metabolizing enzymes, that is, UGTs (Heydel et al., 2010), is particularly important and may be associated, in part, with the olfactory deficits observed in some neurodegenerative diseases. Subjects with mutations in the P450 cytochrome CYP2D6-debrisoquine hydroxylase gene have an increased risk of developing Parkinson's disease (PD), in accord with hypotheses that impairment in local metabolism can aid xenobiotic toxicity, facilitate penetration of toxins into the brain via the nasal/olfactory pathway, and produce neuronal damage in the brain beyond

the initial nasal route (Iskan et al., 1990; Ding et al., 1992; Xie et al., 2010).

## 20.4 CRITICAL NEURONAL RESERVE AREA IN THE SUBVENTRICULAR ZONE AND ITS IMPACT ON OLFACTION

The neuronal reserve area of the subventricular zone (SVZ) is critical when discussing the influence of toxins and neurodegenerative diseases on olfactory function and pathology. Some toxins may damage this reserve early in life and alter its capacity to generate neuroblasts which, in turn, are responsible for development of new OB neurons, such as periglomerular and granule cells (Conover and Shook, 2011). Although the human SVZ is small, recent studies have shown there are clusters of heterogeneous cells along the anterior horn and body of the ventricular surface. Critical to this chapter, a ventral extension of the anterior horn has the potential to generate neuroblasts capable of reaching the OB along the rostral migratory stream (Curtis et al., 2007; Guerrero-Cázares et al., 2011). The rostral migratory stream itself plays a key role in intranasal delivery of drugs into the CNS and is a potential pathway for the access of hazardous materials and organisms into the brain (Scranton et al., 2011).

## 20.5 IMMUNOLOGICAL RESPONSES TO XENOBIOTICS WITHIN THE OLFACTORY SYSTEM AND THEIR LIKELY ROLE IN DAMAGING THE SYSTEM

The immune system plays a critical role in thwarting the penetration of unwelcome organisms or xenobiotics into the brain via the OE. An excellent model of immunological responses that occur in the olfactory system is the system's responses to neurotropic viruses reaching the nose (Huneycutt et al., 1993; Reiss et al., 1998; Detje et al., 2009; Kalinke et al., 2011; Harberts et al., 2011). Intranasal vesicular stomatitis virus (VSV) rapidly spreads throughout the olfactory system of mice whose functional interferon (IFN) system has been genetically compromised. In contrast, in wild-type mice of the same strain the virus stops at the interface between glomerular structures and periglomerular cells (Detje et al., 2009; Kalinke et al., 2011). These observations are relevant to humans and suggest the OB offers an effective barrier to restrain the passage of microorganisms through a Type I IFN pathway (Kalinko et al., 2011).

The fact that viruses cross into and stay within the olfactory bulb for long periods of time has been shown

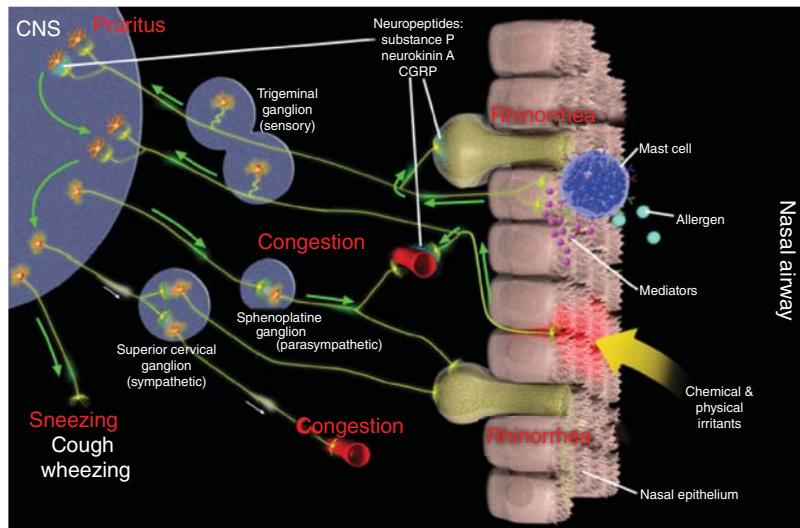

in human autopsy specimens. For example, human herpes virus 6 (HHV-6) exhibits a high prevalence in OBs and the nasal cavity, as assessed in human cadavers (Harberts et al., 2011). HHV-6 is capable of replicating in olfactory-ensheathing cells *in vitro*. Of utmost importance is that olfactory-ensheathing cells guide the connections between the OE and the OB and have relevant neuroregenerative properties (Chapter 4). In consequence, any pathology affecting olfactory-ensheathing cells could potentially alter their critical functions.

The bridge between the OE and the immunologic system is shown by the dual presence of the TAC4 gene that encodes a tachykinin related to substance P in both the OE and in B cells (Kurtz et al., 2002; Tran et al., 2011). The inhibitory role on developing B cells and the role of TLR4 in inducing differentiation to mature B cells would be relevant in human pathological processes involving upregulation of TAC4 in the olfactory region. Moreover, inflammatory mediators and infiltration of inflammatory cells can contribute to olfactory loss. In the setting of inflammation, a significant number of cytokines and chemokines participate in cell proliferation, survival, migration, and differentiation of neural stem cells, including ones that repopulate the olfactory bulbs. Thus, an imbalance of inflammatory mediators can have an impact on neurogenic niches (González-Pérez et al., 2010; Sultán et al., 2011).

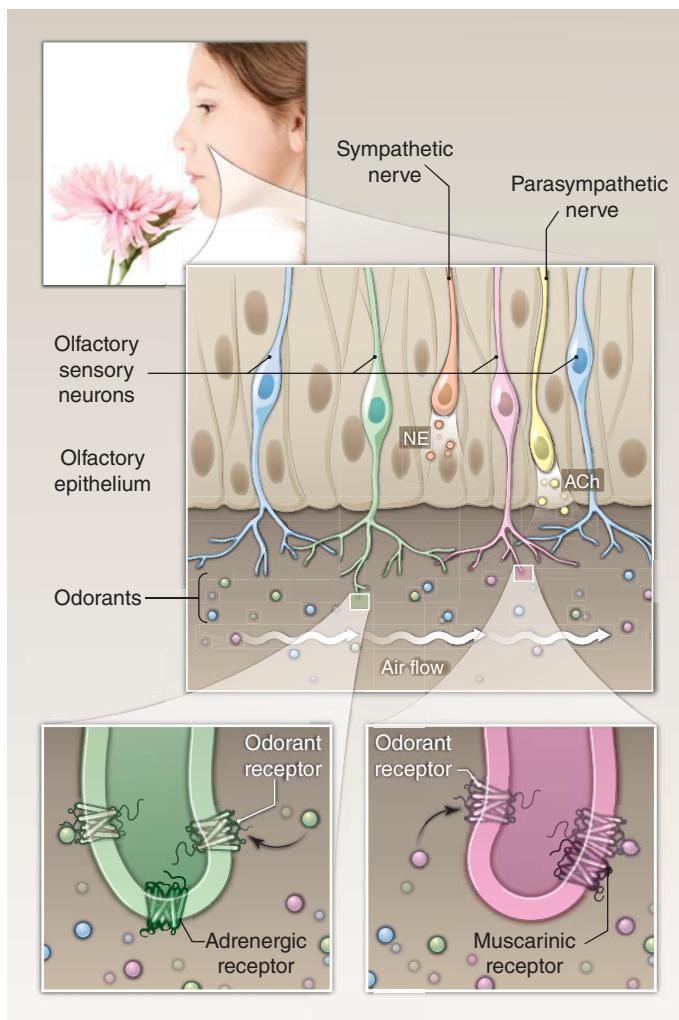

## 20.6 NEUROGENIC INFLAMMATION AND THE IMPACT OF AUTONOMIC MODULATION ON THE OLFACTORY EPITHELIUM

The sensory, sympathetic, and parasympathetic nerves within the olfactory neuroepithelium are highly responsive to environmental and endogenous stimuli (Sarin et al., 2006). Inflammatory processes trigger neural hyperresponsiveness with the release of neuropeptides (i.e., tachykinins) by sensory nerve endings and their resultant vasodilatation, leukocyte recruitment, and immune cell activation in a process known as neurogenic inflammation (Baraniuk and Kaliner, 1990; Sanico et al., 1997; Sarin et al., 2006; Jornot et al., 2008). Nerve activity is transmitted to the CNS and can further travel to secondary synapses to activate efferent motor and autonomic neurons (Figure 20.1) (Sarin et al., 2006).

The aforementioned scenario is important in pathological states such as allergic rhinitis and is potentially relevant to the nasal (including olfactory) responses to xenobiotics. Vascular dilation – an intrinsic part of neurogenic inflammation – may aid in facilitating the transport of toxic substances into the vascular network. The sensory nerves can act as carriers for the transport of nanoparticles to the sympathetic, parasympathetic, and trigeminal ganglia. Further, inflammatory nasal responses, including

**Figure 20.1** Neural pathways and nasal symptoms. Sensory nerves can be stimulated by products of allergic reactions and by external physical and chemical irritants. Action potentials traveling through parasympathetic efferent nerves can lead to glandular activation and rhinorrhea, as well as to vasodilation. Suppression of sympathetic neural output results in vasodilation and nasal congestion. Antidromic stimulation of sensory nerves with release of tachykinins and other neuropeptides at the nasal mucosa contributes to symptom development with glandular activation, vasodilation, and plasma extravasation. Neuropeptide release can also lead to leukocyte recruitment and activation. Collectively, events generated by the antidromic stimulation of sensory nerves constitute the phenomenon of “neurogenic inflammation”. From Sarin et al. (2006). Reprinted with permission. (See plate section for color version.)

**Figure 20.2** Autonomic nervous system modulation of the earliest steps of olfactory signaling. Norepinephrine (NE) released by sympathetic nerves and acetylcholine (ACh) released by parasympathetic nerves both can modulate the responses of olfactory sensory neurons to odorants. Stimulation of adrenergic receptors, in either the cilia or cell body, results in downstream changes in ion channel activity and olfactory sensory neuron output, whereas muscarinic acetylcholine receptors can form complexes with odorant receptors in the olfactory cilia to directly control odorant receptor activity. From Hall (2011). Reprinted with permission. (See plate section for color version.)

the production of inflammatory cytokines, can affect the OE with an enhanced sensory neuropeptide release, a phenomenon that has been described following exposure to asphalt fumes in a study by Sikora et al. (2003). These investigators found that the activation of sensory C-fibers in the nasal cavity was followed by increases in the levels of substance P and calcitonin-gene-related peptide in trigeminal ganglia neurons innervating the nasal mucosa.

The importance of the autonomic system is evident in the modulation of the responses of olfactory sensory neurons to odorants and in diseases such as Parkinson's (PD), where autonomic imbalance and olfactory deficits precede the motor symptoms by years (Bohnen et al., 2008, 2010; Dickson et al., 2009a, b; Hall, 2011; Doty, 1988a, b, 2012a, b). A recent review describes the extensive innervation of the OE by sympathetic and parasympathetic nerve endings that release norepinephrine and acetylcholine, respectively, which can subsequently modulate the responses of the olfactory sensory neurons to odorants (Figure 20.2) (Hall,

2011). It is conceivable that the olfactory deficits observed in the early pre-motor stages of PD (Braak stages I and II) reflect disturbances in the autonomic nervous system's innervation of the olfactory system. From the toxicological point of view, any drug, chemical agent, or pathological process which produces a dysbalance and/or directly damages the autonomic system could result in olfactory dysregulation (Anderson et al., 2012; Balali-Mood et al., 2011; Hall, 2011; Liu et al., 2011; Doty, 2008, 2012b).

## 20.7 AIR POLLUTION, OLFACTION, AND NEURODEGENERATION

### 20.7.1 Urban Air Pollution and Olfaction

Air pollution is a complex mixture of particulate matter (PM), gases, and both organic and inorganic compounds that are present in outdoor and indoor air. Urban outdoor

pollution is a well-documented global health problem (Molina et al., 2007). The role of indoor air pollution (e.g., cooking with biomass) is widely recognized to adversely affect the health of millions of people, particularly in underdeveloped countries. Both short and long-term exposure to air pollutants produce respiratory and cardiovascular morbidity and mortality (Brook et al., 2010; Coneus and Spiess, 2011; Rückerl et al., 2011; Anderson et al., 2012). It is now evident that the CNS is also a target of air pollutants (Calderón-Garcidueñas et al., 2004, 2008a, b; 2011a, b; Block and Calderón-Garcidueñas, 2009; Levesque et al., 2011; Guxens and Sunyer, 2012).

PM is broadly defined by the diameter of the aerodynamic particles, being classified into coarse particles ( $<10\text{ }\mu\text{m}$ ;  $\text{PM}_{10}$ ), fine particles ( $<2.5\text{ }\mu\text{m}$ ;  $\text{PM}_{2.5}$ ), and ultrafine particles ( $<100\text{ nm}$ ; UFP). Fine and ultrafine PM are of particular interest given their capability to reach the brain. Their major sources in the environment are fires, industrial processes, metals, biological materials, and the combustion of gas, oil, and coal (Brook et al., 2010). The smaller the particle, the greater its penetration, diffusion, and deposition into the respiratory tract and its direct translocation into the brain. Man-made nanoparticles  $<100\text{ nm}$  are a significant threat given their increased availability. It is not widely appreciated that nano-sized materials are present in many consumer products to which large segments of the population are exposed (e.g., toothpastes, cosmetics, sunscreens, food additives, and laser printer emissions) (Tang et al., 2011; Fröhlich and Roblegg, 2012).

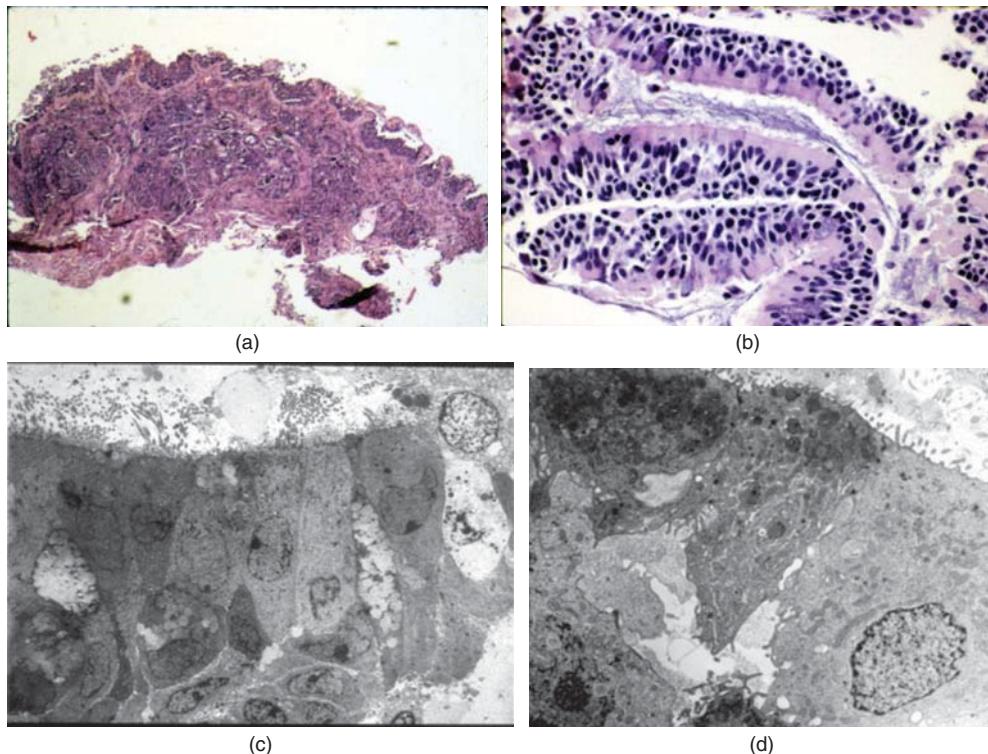

Chronic inflammation is the link between air pollution and brain damage, including damage to the olfactory pathway. Such inflammation can involve the upper and lower respiratory tracts and can induce the production of inflammatory mediators capable of reaching the brain. Continuous expression of inflammatory mediators in the CNS promotes the formation of reactive oxygen species (ROS). The uptake of ultrafine particulate matter associated with lipopolysaccharides (PM-LPS) and metals can take place through olfactory neurons, cranial nerves such as the trigeminal and vagus, the systemic circulation, and macrophages loaded with PM from the lungs (Calderón-Garcidueñas, 2002, 2003a, b, 2004, 2008a, b, 2010, 2011a, b, 2012a, b). Activation of innate immune responses within the brain may follow the interactions between circulating cytokines and the constitutively expressed cytokine receptors of brain endothelial cells. Such responses may, in turn, be followed by activation of cells involved in adaptive immunity (Simart and Rivest, 2006; Calderón-Garcidueñas, 2012a). Monocytes are the main innate immune response mediator cells, producing and secreting TNF- $\alpha$ , interleukin-6 (IL-6), and IL-1 $\beta$ , which in turn recruit and increase the activity of other immune cells. Thus, in the sustained respiratory tract chronic inflammatory process elicited by air pollutants

in megacities such as Mexico City, fine and ultrafine PM likely serve as the first falling dominos, initiating a chain of events leading to brain endothelial cell activation, disruption of the neurovascular unit, altered response of the innate immune system, neuroinflammation, and neurodegeneration (Neuwelt, 2004; Calderón-Garcidueñas, 2012 a, b).

The nasal epithelia, including the olfactory region, are prime targets of exposures to complex mixtures of urban air pollutants. The nasal respiratory pathological changes are critical since they prevent the respiratory epithelium from executing its normal protective functions, including the formation of a protective barrier for the OE. Pathological nasal changes seen in some Mexico City urbanites only a few months after arrival include severe loss of the normal ciliated pseudostratified respiratory epithelium, prominent basal cell hyperplasia, squamous metaplasia, and submucosal vascular proliferation (Figure 20.3a). Such effects are evident even in children (Figure 20.3b and 20.3d) and dogs, where progressive pathology has been noted (Figure 20.4). The end result is the easy access of particles and toxins through the broken epithelial barrier and a compromised OE.

The severe pathological changes in the nasal respiratory epithelium go hand and hand with a marked decrease in olfactory neurons, significant changes in Bowman's glands, and pathologic changes within the olfactory bulbs (OBs). In one study, the OBs of 35 young Mexico City residents and 9 controls (average ages  $\sim 20$  years) from a minimally polluted control city were examined. The Mexico City residents exhibited ill-defined and fragmented organization of the olfactory bulb layers, including small acellular glomeruli (Figure 20.5b, c). In contrast, the basic laminar OB organization of the glomerular, external plexiform, mitral cell, internal plexiform, and granular cell layers of the controls was generally intact (Figure 20.5a). Mexico City residents, but not controls, exhibited neuronal periglomerular accumulation of particulate material (Figure 20.6a) and immunoreactivity to alpha-synuclein, amyloid beta  $A\beta_{42}$ , and hyperphosphorylated tau (Figure 20.6b–d). Interestingly, the disruption of the olfactory bulb architecture was more severe in the Mexico City APOE 4 allele carriers than in the non-carriers (Figures 20.5d and e).

The finding of PM in the glomerular OB region of the Mexico City residents suggests that air pollution-related particles are readily transported from the nasal cavity into the brain via the olfactory nerves. It seems plausible that PM is largely responsible for the accumulation of  $A\beta$  and  $\alpha$  synuclein within their olfactory bulbs and other olfaction-related brain structures (Cedervall et al., 2007; Dell'Orco et al., 2010). Interactions between PM and normally soluble  $A\beta$ , tau, and  $\alpha$  synuclein, conceivably changes their conformation and, thus, their function.

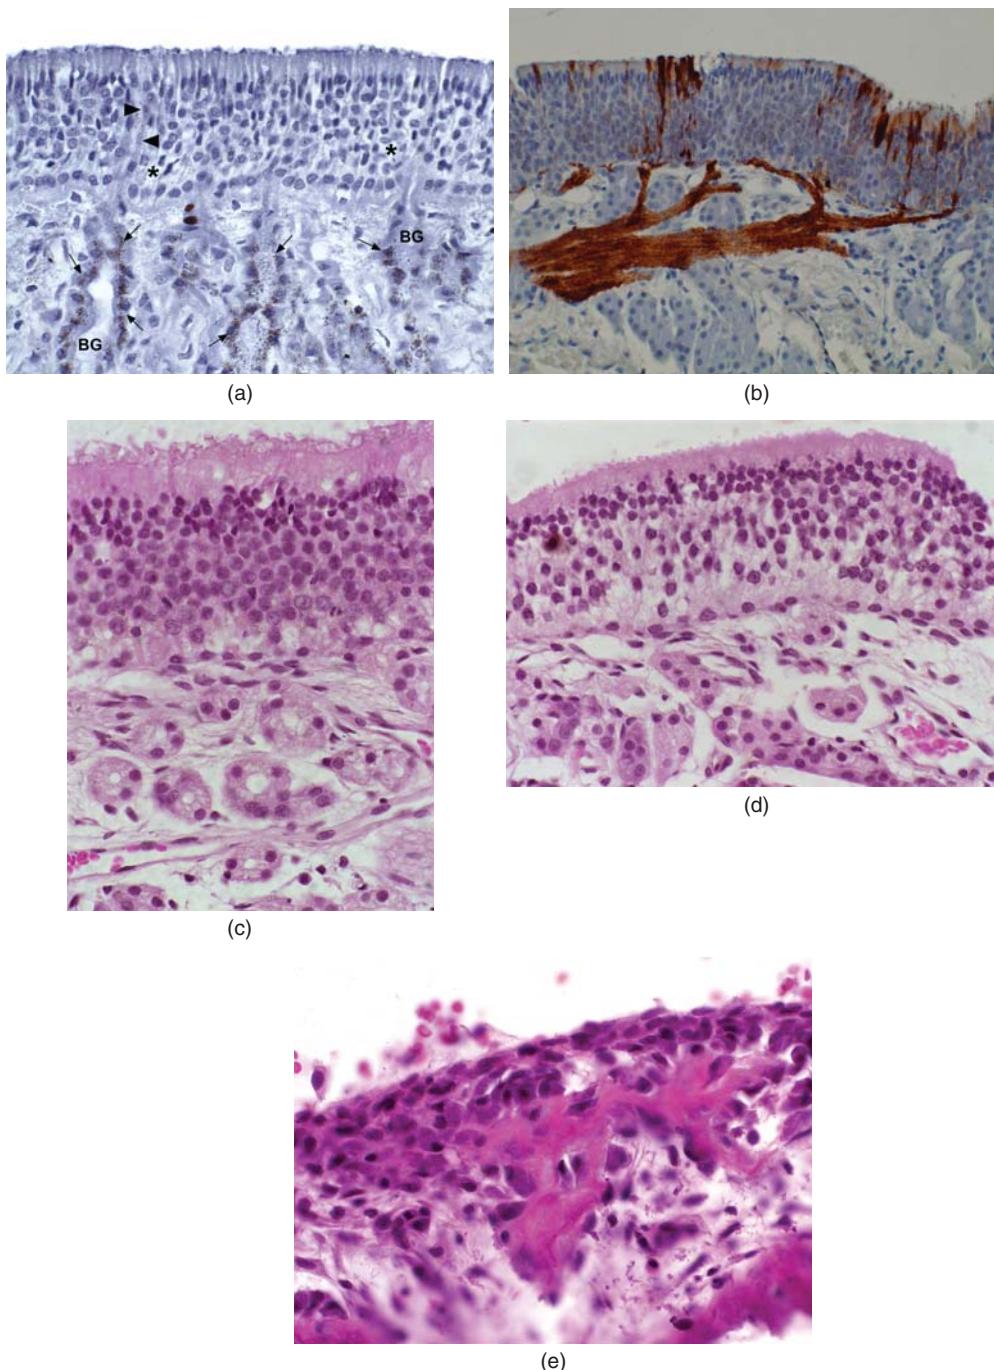

**Figure 20.3** (a) Nasal biopsy from a 30-year-old male who had been residing in MC for 3 months. The normal pseudostratified ciliated columnar epithelium has been replaced by a squamous metaplastic epithelium sitting on an abnormally thick basement membrane and accompanied by an extensive submucosal chronic inflammatory infiltrate. This subject has lost all normal nasal mucosa properties, i.e., secretion of mucus, cilia movement, the capacity to warm or cool the passing air within one degree of his body temperature, the inhaled air is no longer humidified, and a strong mucosal barrier is no longer present. (b) This biopsy comes from an 11-year-old Mexico City boy. A moderate basal cell hyperplasia is present, along with a reduction in the number of cilia. (c) An electron micrograph of a child resident in a low polluted city shows an intact nasal epithelium with abundant intact cilia. (d) In sharp contrast, this Mexico City boy shows an abnormal epithelium with wide intercellular spaces (that are synonymous with a severe breakdown of the epithelial barrier) and a severe reduction in the number of cilia. (*See plate section for color version.*)

Alpha-synuclein – an abundant brain 140 residue protein – is the main culprit in PD, while hyperphosphorilated tau is a key feature of both PD and Alzheimer’s disease (AD) (Jellinger, 2012; Braak et al., 2011a, b). The scenario of neuron-to-neuron transmission and trans-synaptic transport of tau protein aggregates, A $\beta$  and other proteins, has been contemplated as a major pathogenic mechanism in AD and PD. These mechanisms could be playing a critical role in the OB pathology of exposed urbanites (Jellinger, 2012; Doty, 2012b; Prediger et al., 2012).

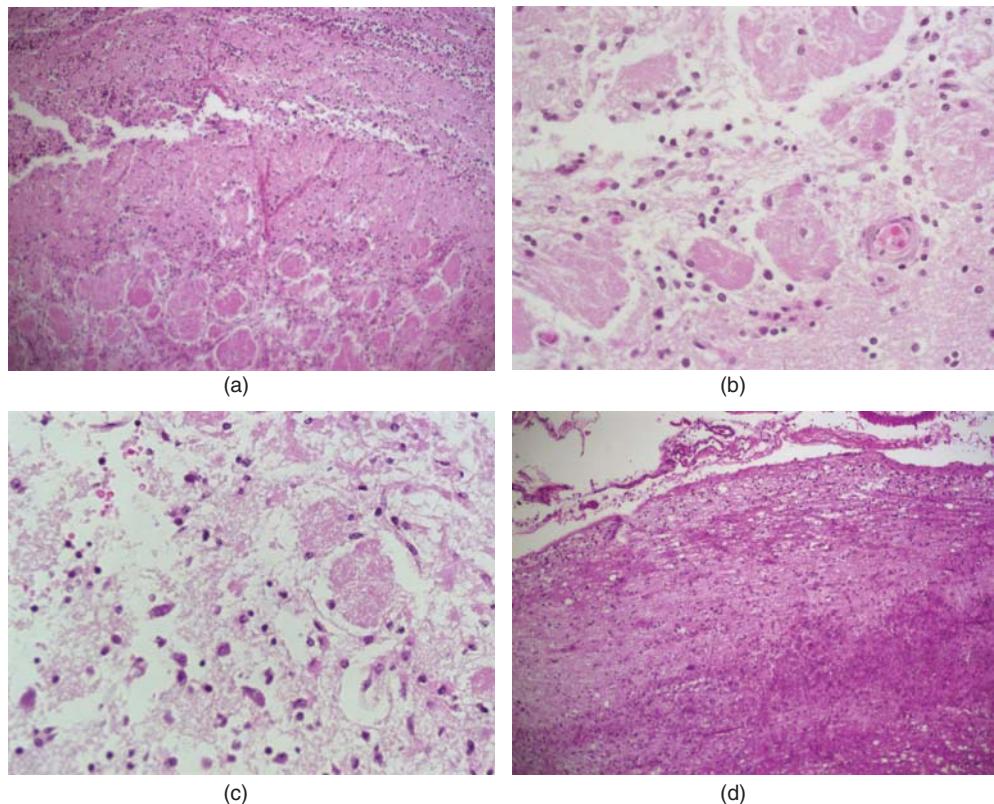

It is important to note that, in Mexico City residents, we have observed elevation of indices of neuroinflammation and oxidative stress, AD and PD-associated pathology, and down-regulation of the PrP(C) not only in their olfactory bulbs, but also in their frontal cortices. The inducible regulation of critical genes suggests they are evolving different mechanisms in an attempt to cope with the constant state of inflammation and oxidative stress related to their environmental exposures. The down-regulation of the PrP(C) is

key given its important roles for neuroprotection, neurodegeneration, and mood disorder states.

Our data and those of others suggest that exposure to PM can activate pathogen sensors, and that signaling by ROS can drive inflammatory processes (e.g., Martinon, 2010). Asbestos and silica activate the NALP 3 inflammasome and NALP3 deficient mice have a significant reduction of their lung inflammatory responses (Dostert et al., 2008). The innate immune system rapidly detects invading pathogenic microbes and eliminates them. It is biologically plausible that PM with lipopolysaccharides reaching the brain initiates an inflammatory response, resulting in detrimental effects. Toll-like receptors sense “extracellular microbes” (e.g., PM-LPS) and trigger anti-pathogen signaling cascades (Martinon, 2010). Both LPS responses and systemic inflammation are important for the understanding of how the sensing of “microbial invaders” could translate into signaling pathways that culminate in the transcriptional regulation of immune responsive genes and how the activation of inflammasomes could be a contributing factor

**Figure 20.4** (a) The olfactory epithelium of a 6-month-old Mexico City dog shows the presence of particulate material in the cytoplasm of numerous Bowman's glands (arrows), while particles are also seen in the glands' ducts (arrow heads). In addition, there are scattered areas where cellular elements are missing (\*), including neurons and sustentacular cells. (b) The olfactory epithelium of a 5-month-old Mexico City dog exhibits a marked expression of metallothionein I-II in sensory neurons and sustentacular cells. The olfactory axons in the lamina propria are also strongly stained. Sequestration of heavy metals by metallothioneins is an important olfactory defense mechanism employed to minimize adverse effects caused by heavy metal contaminants in polluted air (Tallkvist et al., 2002). (c) The olfactory epithelium from a 3-year-old dog living in Mexico City. Note the moderate decrease in thickness and several areas devoid of viable cells, both neurons and sustentacular cells. The Bowman glands are smaller than those of the 6-month-old dog denoted in Figure 4a. (d) The olfactory epithelium of a 12-year-old Mexico City dog showing a severe decrease in thickness and extensive areas devoid of viable cells, both neurons and sustentacular cells. This dog likely had significant olfaction deficits. (e) Same dog as in D, showing an abnormal nasal respiratory epithelium with an area of metaplastic bone replacing the normal ciliated pseudostratified epithelium. (See plate section for color version.)

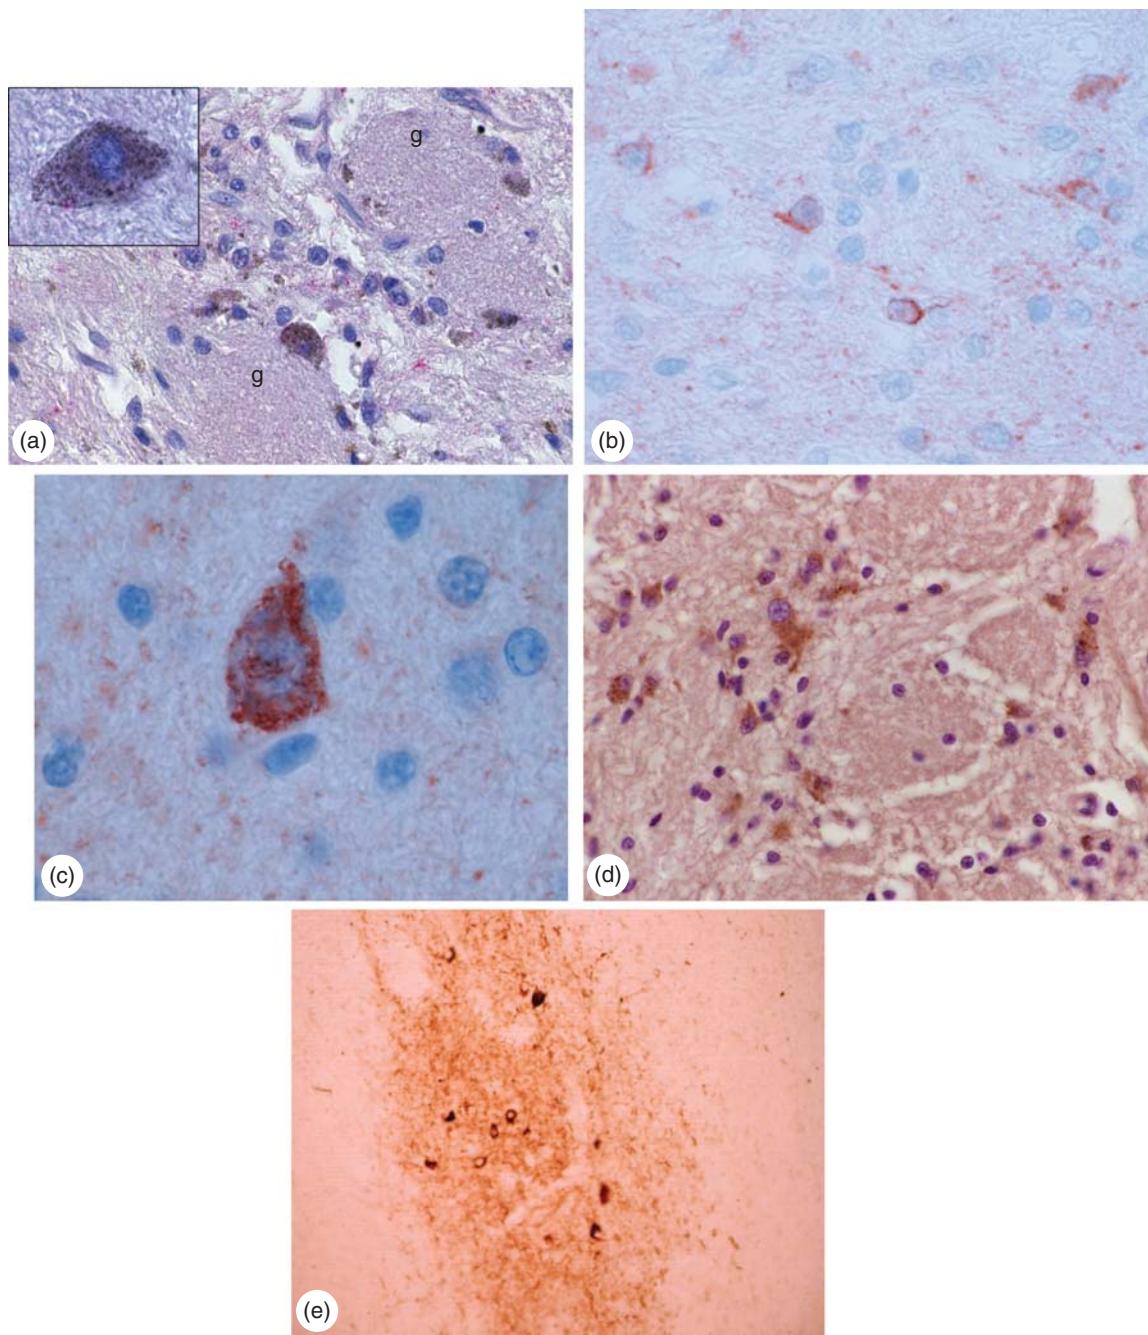

**Figure 20.5** (a) Olfactory bulb from a 21-year-old control male. The laminar organization is intact and there are abundant glomeruli. (b) Olfactory bulb from a 19-year-old Mexico City woman showing small glomeruli and arteriolar vessels with thick walls. (c) Olfactory bulb from a 26-year-old Mexico City woman with few remaining acellular glomeruli, scarce periglomerular cells, and an extensive fragmentation of periglomerular neuropil. (d) The olfactory bulb from a 23-year-old woman with an APOE 3/4 haplotype. There is premature accumulation of abundant corpora amylacea (lower right corner). Glycoproteinaceous inclusions in astrocytic processes play an important role in the sequestration of toxic cellular metabolites. (See plate section for color version.)

for CNS inflammatory responses. The inflammasome activation results in caspase 1 activation, leading to processing and secretion of pro-inflammatory cytokines like IL1 $\beta$  to engage innate immune defenses (Latz, 2010).

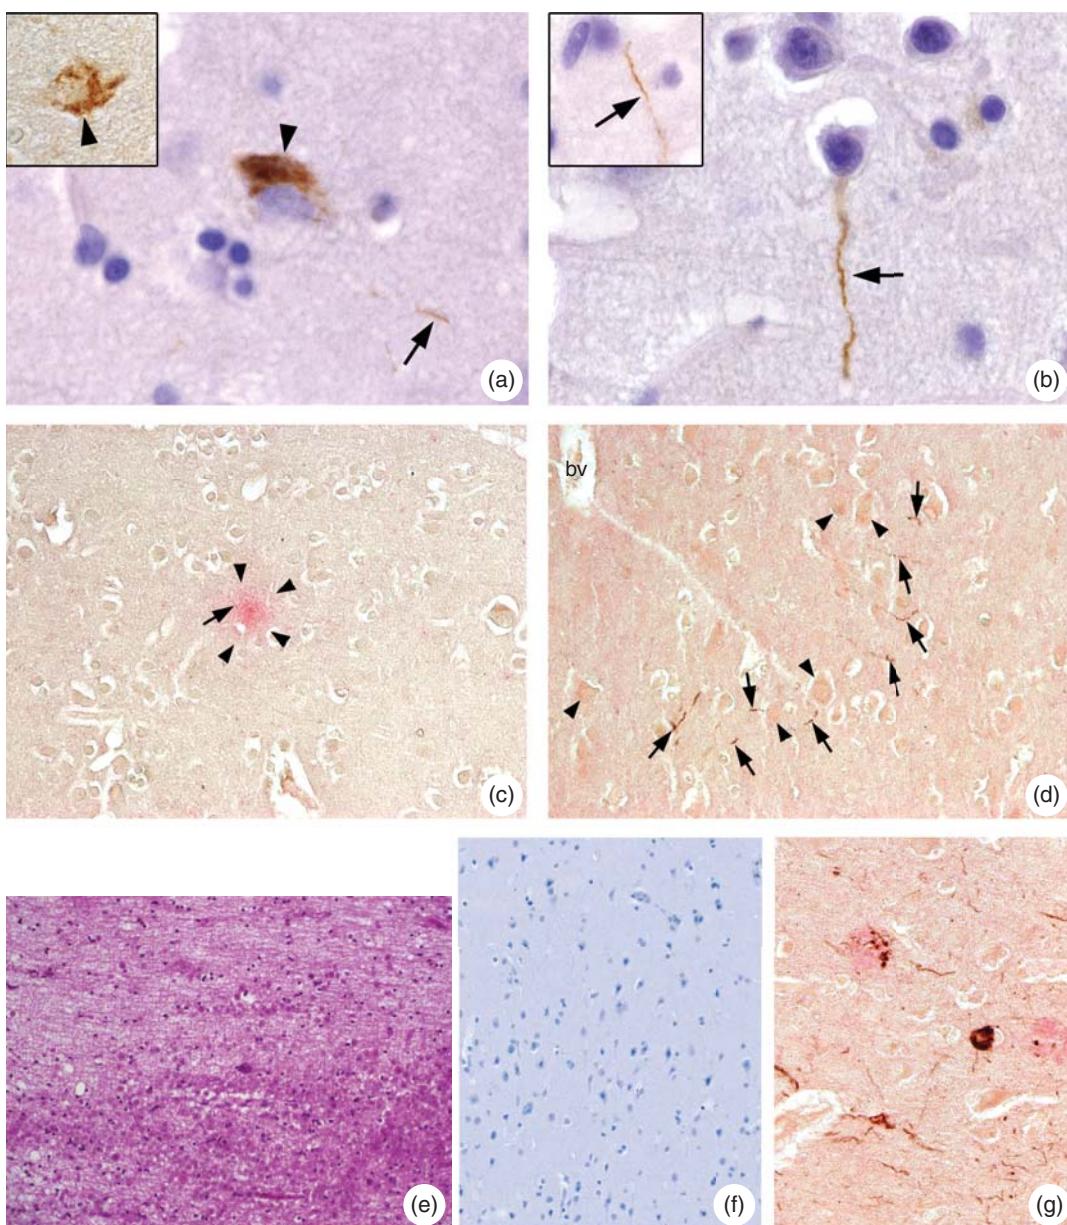

In keeping with the neuropathological findings, olfactory dysfunction was recently documented in 62 young persons (average age 21 years) who were living in a highly polluted area of Mexico City (Calderón-Garcidueñas et al., 2010). Abnormal UPSIT scores were present in 35.5% of the highly exposed subjects and in only 12% of controls of similar age who lived in a less polluted control city. Moreover, the influence of the APOE epsilon 4 genotype was related to the test scores of the Mexico City residents. Thus, highly exposed APOE epsilon 4 carriers failed, on average, 2.4 of the 10 UPSIT items identified in one study as being most strongly related to AD (Tabert et al., 2005), while APOE 2/3 and 3/3 subjects failed only 1.36 such items ( $p = 0.01$ ).

In our studies, the early olfactory deficits appear to be associated with the aforementioned presence of

beta amyloid, alpha synuclein, and hyperphosphorylated tau in the olfactory bulbs and the frontal cortices. The extensive olfactory bulb pathology likely affects proteins with critical functions. Recently, Fernández-Irigoyen et al. (2012) have characterized 1466 human olfactory bulb proteins. Proteins with catalytic and nucleotide binding activities were over-represented and the identification of a subset of proteins mainly involved in axon guidance, opioid signaling, neurotransmitter receptor binding, and synaptic plasticity were in evidence. In a study of the frontal cortices (Figure 20.7), 35 high pollution-exposed and 8 low-pollution exposed children and young adults, the exposed cohort displayed differential (>2-fold) regulation of 134 genes. Up-regulated gene network clusters included IL1, NF $\kappa$ B, TNF, IFN, and TLRs. A 15-fold frontal down-regulation of the prion-related protein [PrP(C)] was also present. Forty percent of the exposed individuals exhibited tau hyperphosphorylation with pre-tangle material and 51% had A $\beta$  diffuse plaques compared with 0% in controls. In keeping with the OB findings, APOE4

**Figure 20.6** (a) Olfactory bulb from a 14-year-old boy living in Mexico City. Neurons in the glomerular region exhibit abundant intracytoplasmic particulate matter. The inset shows a close-up of a PM-loaded neuron with a positive immunoreactivity to beta amyloid<sub>42</sub> (red product). (b) Olfactory bulb from an 11-year-old living in Mexico City with a APOE 3/3 haplotype. Note neuronal granular positive immunoreactivity for  $\alpha$  synuclein (red product). (c) A close-up of an olfactory bulb neuron with abundant granular  $\alpha$ -synuclein, a marker of Parkinson's disease (red product). (d) Olfactory bulb from a 23-year-old woman with an APOE 3/4 haplotype. There are abundant neurons, glial cells and endothelial cells positive for  $\beta$  amyloid (4G8 monoclonal antibody reactive to amino acid residues 17–24 of beta amyloid). (e) Same 23-year-old woman as in d. Olfactory neurons with immunoreactivity to tau 8 PHF-Tau-8 (Innogenetics, Belgium, AT-8). AT8 reacts with tau only when multiple sites around Ser202, including Ser199, Ser202, and Thr205, are phosphorylated. (See plate section for color version.)

**Figure 20.7** (a) Sample from frontal cortex of a 15-year-old Mexico City APOE 3/3 boy. Note that the cortex exhibits abnormal tau protein immunoreactivity in the neuronal body (insert and head arrow) as well as in neurites (arrow). Immunohistochemistry for AT8 counterstained with hematoxylin x 100. The insert has no counterstaining. (b) Sample from frontal cortex of a 15-year-old Mexico City APOE 3/4 boy. Small varicosities are visible in the IR abnormal neuritic tau (arrow). IHC for AT8 counterstained with hematoxylin. (c) Same boy as 3C. HP  $\tau$  + neurites (arrow) were associated with diffuse amyloid plaques (surrounded by head arrows) in dual stained HP  $\tau$  and A $\beta$  sections. (d) Sample from frontal cortex of an 18-year-old Mexico City APOE 3/4 male. Clusters of HP  $\tau$  + neurites up to 12 per 20x field (arrows) are seen in a dual HP  $\tau$  and A $\beta$  stained sections. IR for A $\beta$  is seen in neuronal cytoplasm (head arrows). IHC for AT8 (brown product) and A $\beta$  6E10 antibody (red product). (e) Frontal one micron toluidine blue section from the white matter in a 14-year-old Mexico City woman. Arterioles exhibited numerous macrophage-like perivascular cells (arrow) and prominent expansion of the Virchow-Robin spaces (\*), along with lipid deposits. The insert shows an arteriolar white matter vessel in a control 17-year-old boy. WM (white matter), (a) axons, and bv is the lumen of the blood vessel. Stain: Toluidine blue. (f) Frontal cortex from a control 17-year-old man stained with A $\beta$  6E10 antibody and counterstained with hematoxylin. The frontal cortex is unremarkable and no diffuse plaques were identified. (g) Frontal cortex from a 75-year-old Mexican woman with a diagnosis of Alzheimer's disease. HP  $\tau$  + neurites and tangles surrounding A $\beta$  positive mature senile plaques are seen in a dual HP  $\tau$  and A $\beta$  stained sections. IHC for AT8 (brown product) and A $\beta$  6E10 (red product) x 40. (See plate section for color version.)

carriers had greater hyperphosphorylated tau and diffuse A $\beta$  plaques versus E3 carriers ( $p = 0.005$ ).

The observations noted above are in potential accord with the tenants of the olfactory vector hypothesis (Doty, 2008; 2009b; Prediger et al., 2012). This hypothesis posits that intranasal exposure via the olfactory pathways to environmental agents, including viruses, toxins, agricultural chemicals, dietary nutrients, and metals, may lead to the development of some neurodegenerative diseases. Whether the olfactory loss is due to the transit of such agents or is secondary to the disease processes themselves is unknown. As discussed in detail in Chapter 18, olfactory dysfunction is among the earliest ‘pre-clinical’ features of AD and PD, occurring in ~90% of early onset cases (Doty, 2012a, b). Importantly, equivalent smell loss is evident in Down syndrome, non-Down mental retarded individuals, the PD-Dementia complex of Guam, and, most recently, myasthenia gravis (Leon-Sarmiento et al., 2012). Such observations have led Doty to suggest that a common pathological substrate may be involved (Doty, 2012a, b). There are, in fact, significant correlations of olfactory dysfunction with decreased numbers of neurons in structures such as the locus caeruleus, the raphe nuclei, and the nucleus basalis of Meynart (Doty, 2012a). In the case of PD, the involvement of the autonomic nervous system in numerous PD-related symptoms suggests that deficits in cholinergic, noradrenergic, and serotonergic function may contribute to the olfactory loss (Doty, 2012b). It is not known to what extent damage to such neurotransmitter/neuromodular systems contributes to neurodegenerative disease pathology.

## 20.7.2 The Effect of World Trade Center Exposures on Olfaction

The September 11th, 2001, terrorist attack on the World Trade Center exposed more than 50,000 people to an intense dust cloud with massive amounts of chemicals, xenobiotics (including dioxins, furans), asbestos, plastics, and construction debris (Betts, 2010; Wisniveskyn et al., 2011). These exposed subjects are currently at higher risk for heart disease, systemic inflammation, airflow obstruction, mental health symptoms, asthma, cancer, and chronic lung disease including “sarcoid-like” granulomatous pulmonary disease (Wisniveskyn et al., 2011; CDC, 2012). Airborne dust contaminants recovered from the WTC surrounding area 24–48h after the act demonstrated direct cytotoxicity to airway epithelial and smooth muscle cells, airway cell types most directly exposed to dust (Xu et al., 2011).

Two studies have evaluated olfactory function in rescue, demolition, and cleanup WTC workers. Many of these workers were not properly protected with gas masks or ventilators. In the first study, the prevalence of decreased olfactory and trigeminal sensitivity was found to be higher in

102 workers than in a similar number of non-exposed controls (Dalton et al., 2010). Testing took place, on average, two years after the exposures. WTC responders exposed directly to the dust cloud from the collapsed buildings exhibited the most serious trigeminal loss. Chronic nasal inflammation was a key finding in exposed subjects. In the second study, UPSIT scores of 99 WTC subjects were compared to controls obtained from a large normative database (Altman et al., 2011). The mean UPSIT scores were significantly lower in the WTC exposed cohort (30.05 vs. 35.94;  $p = 0.003$ ). Fifteen percent of the exposed subjects had severe microsmia, but only 3% anosmia. The authors concluded that exposure to severe massive air pollution impacts the capacity to identify odors in a manner similar to that found in Mexico City residents (Calderón-Garcidueñas et al., 2010). Based on the clinical and neuropathological findings in such residents, the most highly exposed WTC subjects with the most olfactory deficits and genetic risk factors (e.g., APOE 4 allele) may be those at higher risk for the future development of AD- and/or PD-related pathology (Calderón-Garcidueñas et al., 2012a).

## 20.7.3 The Olfactory Effects of the Gulf War Syndrome

There is a significant amount of information in the Gulf War Syndrome (GWS) literature to suggest that physiological, psychological, and environmental factors play a role in the presentation and severity of the illness (Iannacchione et al., 2011; Li B et al., 2011; Li X et al., 2011; Chao et al., 2010; Fiedler et al., 2004; Ferguson et al., 2001/2002, 2004). Given that impaired metabolism of toxic chemicals is a postulated mechanism underlying multiple chemical sensitivity (MCS), it is important to record patients’ war exposure history (Fiedler et al., 2004; McKeown-Eyssen et al., 2004). Interestingly, one study of 72 GW US veterans and 33 military personnel activated during the GW, but not deployed to the war zone, showed no evidence that performances on olfactory or neurocognitive measures were related to war-zone duty or to self-reported exposure to GW toxicants (Vasterling et al., 2003). In relation to such findings, it should be pointed out that empirical studies have found no evidence that patients complaining of MCS evidence altered smell function (Doty et al., 1988; Hummel et al., 1996; Dalton and Hummel, 2000).

Also relevant to this subject are reports of hippocampal neurophysiological and volume changes in Gulf War veterans (Li X et al., 2011). It remains to be seen if the available quantitative olfaction tests exhibit differences between the three target GWS groups: impaired cognition, confusion-ataxia, and central neuropathic pain. The hippocampal dysfunction could be a part of an immunoexcitotoxicity setting to explain the evolving pathological

changes in patients with GWS (Blaylock and Maroon, 2011). The interaction between immune receptors within the CNS and excitatory glutamate receptors trigger a series of events, including ROS/RNS generation, accumulation of lipid peroxidation products, and prostaglandin activation, which then leads to dendritic retraction, synaptic injury, damage to microtubules, and mitochondrial suppression.

## 20.7.4 Metals and Olfaction

Metal ions are readily transported from the OE to the brain (Tjälve et al., 1996; Tjälve and Henriksson, 1999; Divine et al., 1999; Sundermann, 2001; Persson et al., 2003a, b; Bondier et al., 2008; Jia et al., 2010). The issue of metals and toxicity to the olfactory system and neurodegeneration has been discussed in epidemiological and occupational studies, in the olfactory vector hypothesis, and in fish models where emerging evidence shows very low sub-lethal levels of metal ions can adversely affect the sense of smell (Doty, 2008; 2009a, b; Flynn and Susi, 2009; Sriram et al., 2010; Tierney et al., 2010; Kiaune and Singharaman, 2011; Tilton et al., 2011; Prediger et al., 2012). The issue of metals and olfaction is particularly relevant to the field of occupational medicine. Despite the fact that OSHA works to assure safe working conditions by setting and enforcing standards and by providing training, and both outreach education and assistance, occupational exposures still remain harmful for millions of US workers (Rose et al., 1992; Bowler et al., 2011). Listed below are the major metals to which exposures are common in the workplace and their realized or potential influences on the olfactory system.

**20.7.4.1 Cadmium (Cd).** Cadmium is a heavy metal widely used in industry and is a widespread environmental pollutant. Exposures to Cd include the ingestion of contaminated cereals and vegetables, inhalation of cigarette smoke, and airborne exposures within occupational and contaminated environmental settings. Cd has been associated with fatalities and adverse health effects, including cancer, kidney damage, low bone mineral density and fractures, hearing loss, and impaired olfaction (Tallkvist et al., 2002; Mascagni et al., 2003; Gobba, 2006; Bondier et al., 2008; Sharogorodsky et al., 2011; Hossain et al., 2012; Chang et al., 2012). The association between Cd and impaired olfaction was well established in the 1950s (reviewed in Gobba, 2006). Workers in alkaline battery factories, welders, smelters and brazing workers were found to be at high risk for olfaction dysfunction (Adams and Crabtree, 1961; Ahlström et al., 1986; Rose et al., 1992; Sulkowski et al., 2000; Mascagni et al., 2003).

**20.7.4.2 Chromium (Cr).** Chromium is used in the manufacture of steel and non ferrous alloys, dyes and pigments, leather tanning, photographic processing, wood fabrication, and in various medical applications, including prostheses in surgery (hip, knee). Hexavalent chromium is the form with the greatest occupational and environmental health concern (Pellerin and Booker, 2000). Chronic exposures can result in nasal septum perforations, nasal ulcers, and olfaction deficits (Lin et al., 1994; Kuo et al., 1997; Kitamura et al., 2003; Gouillé et al., 2012). In the United States, industrial exposure to hexavalent Cr via inhalation of fume dusts is the most likely basis for reported nasal and olfaction deficits. Cr is the primary contaminant of over 50% of Superfund hazardous waste sites. Numerous waste sites are found near chromate factories. Although OSHA and NIOSH have established permissible exposure limits (PELs) and recommended exposure limits (RELs) for Cr in the workplace, thousands of workers are likely exposed to higher levels of Cr in welding and other workshop operations in places lacking adequate ventilation, while their family members are exposed through contact with contaminated clothes, shoes, and other items.

**20.7.4.3 Manganese (Mn).** Manganese is an essential trace element. Distinct pathways are known to contribute to Mn influx into the brain and to Mn olfactory neurotoxicity (Tjälve and Henriksson, 1999; Aschner et al., 2007; Leavens et al., 2007; Dorman et al., 2006, 2008; Erikson et al., 2008; Bouchard et al., 2007, 2008; Burton and Guilarte, 2009; Guilarte, 2010; Kim et al., 2011; Bowler et al., 2011; Schroeter et al., 2011b; Racette et al., 2012). Mn occupational neurotoxicity is very common worldwide (Antonini, 2003; Criswell et al., 2011). It was first described in the 19th century in two workers with high exposures to Mn oxide (Couper, 1837).

There are presently ~466,000 full-time welding and soldering workers in the US. More than a million workers perform welding as part of their job requirements (Antonini, 2003; Criswell et al., 2011). Although current human Mn exposures are usually below the current NIOSH recommended exposure limit (REL) of 1 mg/m<sup>3</sup> and the American Conference of Governmental Industrial Hygienists (ACGIH) Threshold Limit Value (TLV) of 0.2 mg/m<sup>3</sup>, there are common examples of high exposures in the occupational setting (Bowler et al., 2011; Racette et al., 2012).

Mn homeostasis is critical in light of the fragile relationship between its essentiality and toxicity. Movement abnormalities are found in non-human primates exposed to moderate levels of Mn – abnormalities associated with the inability of dopaminergic neurons to release dopamine (Guilarte, 2010). In addition to subtle deficits in motor function, deficits in working memory and neurodegenerative changes are seen in the prefrontal cortex (Guilarte

et al., 2008; Guilarte, 2010; Racette et al., 2012; Nelson et al., 2012). Manganism – a disorder characterized by bradykinesia, masked facies, and gait impairment – is the most common syndrome associated with Mn neurotoxicity, although PD, *per se*, may also result from long-term low-level exposure to this metal.

Olfactory deficits are a critical early finding in idiopathic PD and in Mn-associated toxicity (Ansari and Johnson, 1975; Doty, 1988a, 2008, 2009b, 2012a, b; Lucchini et al., 1997, 2012; Antunes et al., 2007; Bowler et al., 2007, 2011; Bohnen et al., 2008, 2010; Dickson et al., 2009b; Baba et al., 2011). Bowler et al. (2007) studied 43 welders working at the San Francisco-Oakland Bay bridge under confined spaces with little protection equipment (see also Antunes et al., 2007). Workers, who were on average 43.8 years of age, had spent on average of 16.5 months working on the bridge. The mean time weighted average of Mn in air ranged from 0.11 to 0.46 mg/m<sup>3</sup>, while Mn in blood was 9.6± 2.5 µg/L. Significant cognitive impairment and mood disturbances and a high number of days with poor health were found, with 80% of the welders with lower scores than their matched controls p<0.001. In their 2011 follow-up study and after 3.5 years of cessation of welding in a confined space, there was some improvement of their cognitive function, but olfactory, extrapyramidal, and mood disturbances remained unchanged (Bowler et al., 2011). Thus, in spite of an overall decrease of Mn exposure, some workers continued to have higher concentrations of Mn in blood and exhibited higher than normal tremor intensity on the CATSYS (quantifies coordination ability, reaction time, tremor and postural stability). The lack of improvement in neurological functions involving the olfactory pathway and the limbic system (olfaction and mood), basal ganglia (neuromotor and movement alterations), in conjunction with improvement of frontal cortex and the hippocampus (short term memory), strongly suggest the presence of intrinsic brain Mn vulnerabilities and the potential problem that after a certain level of exposure, the Mn neurotoxicity reaches a point of no return (Bowler et al., 2011).

Non-primate studies have provided invaluable insights into the CNS effects of Mn (Eriksson et al., 2008; Burton and Guilarte, 2009; Schneider et al., 2009; Guilarte, 2010). A spectrum of cognitive deficits have also been described in children exposed to Mn in drinking water and living in the proximity of a ferro-manganese alloy plant, as well as in occupationally exposed workers (Bouchard et al., 2007, 2008; Menezes-Filho et al., 2011). Children are a susceptible population, as shown by Lucchini in their 11–14-year-old cohort in Valcamonica, Italy, a region that had high ferro-alloy plant emissions for a century before 2001 (Lucchini et al., 2012). Impairment of motor coordination, hand dexterity and odor identification were associated with the measures of soil manganese. Tremor

intensity was positively associated with blood and hair Mn. This study illustrates a very important aspect of Mn toxicity in children with high exposures: olfactory deficits are readily detected along with motor dysfunction.

**20.7.4.4 Nickel (Ni).** Nickel (Ni) is an environmental pollutant with an impact in the occupational setting mainly through inhalation and in dietary exposures secondary to water and food chain-induced bioaccumulation (Liapi et al., 2011). Ni is actively transferred across the blood-placenta-barrier into the fetus. The placenta has a high affinity for nickel and the placental barrier does not confer the fetus protection from Ni exposure (Hou et al., 2011). Children are at risk as well, especially those exposed to polluting steel mills in industrial areas (Kasper-Sonnenberg et al., 2011). Also critical is the Ni ion bioavailability as a key factor determining toxicity (Schaumlöffel, 2012; Henderson et al., 2012).

The altered olfaction and anosmia resulting from Ni exposures are well known in occupational medicine and in studies of experimental animals (Tjälve and Henriksson, 1999; Evans et al., 1995). Jia et al. (2010) exposed adult mice to intranasally instilled NiSO<sub>4</sub> or saline followed by ATP, purinergic receptor antagonists, or saline. Location-dependent atrophy of the OE was found to be associated with sustentacular cell loss and apoptosis of OSNs. This study illustrates the selective susceptibility of sustentacular cells to local damage from NiSO<sub>4</sub>. The location of the sustentacular cell somas in the apical portion of the epithelium forms a protective barrier for the rest of the OE – a barrier crucial for mitigating the effects of toxins. Menco (1980) had observed a zone of tight junctions close to the apical surfaces of sustentacular cells that prevents paracellular diffusion of lipophobic compounds. Ni<sup>2+</sup> induces the formation of hydroxyl radicals which can produce single DNA strand breaks and DNA-protein cross-links consistent with Jia et al.'s (2010) observations of DNA fragmentation in sustentacular cells one day following the instillation of NiSO<sub>4</sub> (Torrielles and Guerin, 1990; Patierno and Costa, 1985). Evans also suggested the mechanism of NiSO<sub>4</sub>-induced sustentacular cell loss could be attributed to the expression of metabolic enzymes given that biotransformation enzymes are preferentially expressed in sustentacular cells (Evans et al., 1995; Banger et al., 1994).

Other olfactory neuronal damage mechanisms related to Ni toxicity include apoptosis via activation of death receptor 3 and caspase-8, leading to activation of caspase-3 (Zhao et al., 2009). Ni<sup>2+</sup> reduces odorant-induced calcium transients in the dendritic knob, the dendrite, and the soma of OSNs via inhibition of T-type Ca<sup>2+</sup> channels (Gautam et al., 2007). Ni's inhibition of the T-type channels may result in inhibition of odorant signal transduction that ultimately leads to hyposmia and anosmia (Jia et al., 2010).

**20.7.4.5 Zinc (Zn).** There is an extensive literature on the loss of smell function resulting from intranasal exposure to zinc ions (Tisdall et al., 1938; McBride et al., 2003; Seidman, 2006; Alexander and Davidson, 2006; Slotnick et al., 2007; Lim et al., 2009; Davidson and Smith, 2010; Duncan-Lewis et al., 2011). Recently the potential association of zinc with olfactory dysfunction has come to the fore as a result of claims that a popular zinc-based intranasal agent, Zicam (Matrixx Initiatives, Inc), causes hyposmia or anosmia (e.g., Alexander and Davidson, 2006). Considerable contention has arisen around this issue, in part because (a) it is not entirely clear how much of the zinc preparation, particularly from gels, actually reaches the OE, (b) the most frequent cause of smell loss is the common cold for which Zicam is often employed, and (c) many of the clinical reports specific to this agent have been driven by litigation. Moreover, some animal studies have found that olfactory deficits secondary to Zn exposure of their olfactory epithelia are largely reversible (Slotnick et al., 2007) and that low doses of zinc nanoparticles actually enhance physiological measures of olfactory function (Viswaprakash et al., 2009; Moore et al., 2012). Systemic zinc has been used for years to treat human olfactory dysfunction. Except in cases of frank zinc deficiencies, however, such treatments are generally viewed as ineffectual (Price, 1986). In light of the numerous reports that intranasal application of zinc ions is toxic to olfactory epithelia, the use of nasal preparations containing zinc is not generally recommended.

**20.7.4.6 Aluminum (Al).** The neurotoxicity of aluminum has been well known for years (Dollken, 1897; Klatzo et al., 1965). Exposure to Al is accompanied by oxidative stress, apoptosis, and the perikaryal accumulation of tangles of phosphorylated neurofilaments (NFs). A prolonged interaction induced among phospho-NFs by the trivalent Al impairs axonal transport and promotes perikaryal aggregation (Bharathi et al., 2008; Kushkuley et al., 2010). Olfactory deficits have been observed in rabbits who received intraventricular injections of aluminum chloride (Polonskaia et al., 1990). In a *Drosophila* model with chronic dietary Al overloading, Wu et al. (2012) observed general neurodegeneration and a number of behavioral changes. These authors indicated that the Al toxicity is likely mediated through ROS production and iron accumulation and suggested a remedial route to reduce Al toxicity. Al neurotoxicity is important to consider in this chapter because the reports dealing with olfaction deficits associated with glue sniffing (glues and their containers often have high Al content) in teenagers who inadvertently expose themselves to such metals and other neurotoxic chemicals with the intent of feeling high (Akay et al., 2008).

## 20.8 INFLUENCES OF ALCOHOL, TOBACCO, CHEMOTHERAPY, AND DIALYSIS ON OLFACTION

### 20.8.1 Alcohol

Alcohol, particularly during development, has multiple negative effects on the brain, including the olfactory system (Vent et al., 2004; Bragulat et al., 2008; Youngentob and Glendinning, 2009; Middleton et al., 2009; Eade and Youngentob, 2010; Akers et al., 2011; Maurage et al., 2011; Huang et al., 2012; Balaraman et al., 2012; Munner et al., 2012; Valenzuela et al., 2012). Prenatal alcohol exposure can result in abnormal olfactory bulb development, as reflected by smaller bulbs, fewer bulbar cells, and fewer neural precursory cells within the sub-ependimal zone. In later life, prenatal exposure to alcohol is associated with impaired odor discrimination and altered olfactory bulb expression of neurotransmission genes, in addition to general alterations in learning, memory, motor coordination, social behavior, and stress responses (Youngentob and Glendinning, 2009; Middleton et al., 2009; Akers et al., 2011; Valenzuela et al., 2012). This is an issue of relevance to healthcare providers since approximately 1% of children in the US exhibit symptoms of Fetal Alcohol Spectrum Disorder (FASD) (Sampson et al., 1997).

It is of interest that the effects of alcohol on the fetal brain can result in life-long increased vulnerability to substance abuse and impairments in neurotransmitter systems, neuromodulators, and/or synaptic plasticity in numerous brain regions (Valenzuela et al., 2012). Although acute exposure to alcohol in healthy subjects has no effect on odor identification, alcohol ingestion to the level of legal intoxication markedly and selectively alters olfactory sensitivity to ethanol, and depresses scores on a match-to-sample odor discrimination/memory test (Patel et al., 2004). In chronic alcoholics, brain structures critical for the secondary “cognitive” processing of odors are frequently damaged (Maccioni et al., 2007; Maurage et al., 2011), and irreversible smell loss is common in the alcohol-related Wernicke-Korsakoff syndrome – a loss secondary to poor nutrition and the lack of adequate thiamine in the diet (Mair et al., 1987).

The concept of *in utero* chemosensory plasticity has been recently proposed (Youngentob and Glendinning, 2009; Middleton et al., 2009). The olfactory bulb's sensitivity to ethanol exposure depends on the dose and time of the exposure (Barron and Riley, 1992), with large effects occurring prior to when the sensory axons reach the olfactory bulb and prior to when the fetal olfactory sensory neurons begin to transduce sensory information. Alcohol causes selective effects on GABAergic and glutamatergic neurons, as well as genes involved in synaptic transmission, synaptic development, and cell fate (Middleton et al.,

2009). Specifically, *in utero* exposure to alcohol results in a significant decrease in the OB expression of the GABA B1 receptor and the mGluR2 receptor, as well as increased expression of calcium/calmodulin-dependent protein kinase IV and potassium channel. Long-term changes in the OB expression of a gene subset temporally associated with an enhanced unconditioned sniffing response to ethanol odor have been reported (Middleton et al., 2009).

It is well known that fetal ethanol exposure is highly predictive of the propensity to consume ethanol in adulthood. Indeed, the smell of alcohol in later life among early exposed individuals can lead to the development and maintenance of alcoholism, including, in some instances, to stronger alcohol craving responses and desires to drink. Presently there are 17.6 million people in the United States who abuse alcohol or who are alcohol dependent, which translates into 1 in every 12 adults. Since alcohol intake is usually associated with tobacco consumption, it is important to keep in mind the synergistic effects of both toxins to the olfactory system (Vent et al., 2004).

## 20.8.2 Tobacco

Tobacco is the best example of a legal substance whose addiction affects millions of people around the world (Talhout et al., 2011; Dorman et al., 2012). Cigarette smoking causes considerable morbidity and mortality by inducing cancer, chronic respiratory disease, cardiovascular disease, and nasal and sinus disorders. The effects of tobacco on children and fetuses are well known and second-hand smoke (SHS) exposure has long been correlated with disease processes (Röösli, 2011). The term third-hand smoke (THS) applies to the residual tobacco smoke-related pollutants that remain on surfaces and in dust which can be reemitted in the gas phase and can interact with other compounds. THS poses adverse health risks, particularly for children (Tillett, 2011; Matt et al., 2011). Among the mix of more than 5,000 chemicals in cigarette smoke, a number have well documented effects on the OE, including acrylic acid, acrolein, acetaldehyde, and Cr (VI) (Matt et al., 2011). Active components of tobacco smoke such as lipopolysaccharides (LPS) add significant contributions to OE damage (Yagi et al., 2007). Apoptosis within the olfactory epithelium as a result of exposure to tobacco vapors is well documented and is a plausible explanation for the olfactory deficits observed in smokers (Nageris, et al., 2001, 2002; Vent et al., 2004).

The inflammatory nasal response elicited by tobacco exposure is another likely cause of damage within the olfactory epithelium. De et al. (2011) found increased concentrations of matrix metalloproteinase (MMP) 9, a gelatinase associated with tissue remodeling, in the nasal

secretions of children exposed to second-hand smoke. Passive smoking might alter the inflammatory response within the nasal mucosa in a similar way to allergy. Smoking is clearly associated with a significant dose-related decrease in olfactory function that affects both current and previous smokers. Current smokers are twice as likely as non-smokers to have olfactory deficits, reflecting, in part, the fact that cessation of smoking can reverse its detrimental effects over time (Frye et al., 1990).

## 20.8.3 Chemotherapy

Millions of people undergo chemotherapeutic treatments each year. Among the main clinical goals are to identify, delay, and relieve chemotherapy-induced side effects and optimize the quality of life, especially after first-line therapy (Doty and Bromley, 2004; Steinbach et al., 2009, 2010, 2012). Some chemotherapy cocktail combinations are particularly bothersome for patients, such as carboplatinum-containing chemotherapy for ovarian cancer (Steinbach et al., 2012). Among 136 chemotherapy outpatients from Kanazawa University, 55% complained of a gustatory and 19% of an olfactory disorder. Olfactory alterations were significantly greater in patients who also had gustatory disorders. Complaints of taste disorders were significantly higher among those taking docetaxel (85%) than those on other regimens (Suga et al., 2011).

In advanced terminal patients, the most common complaints include persistent bad taste in the mouth, taste distortion, and heightened sensitivity to odors. Patients with severe chemosensory complaints show substantially lower energy intakes (by 900–1,100 kcal/day), higher rates of weight loss, and lower quality of life scores compared to subjects with mild or moderate chemosensory complaints (Hutton et al., 2007). Although such symptoms are common side effects of chemo- and radiotherapy, their physiological basis remains mostly unexplained (Faure et al., 2010). Unfortunately, self-reports of taste and smell function are notoriously inaccurate (Soter et al., 2008), and a large number of patients confuse altered flavor sensations with taste disorders (Deems et al., 1991).

Some chemotherapy patients report experiencing only smell disturbances, including increased sensitivity to one or several odors, without apparent decreases in general olfactory sensitivity (Bernhardson et al., 2009, 2012). In the 2009 Bernhardson et al. survey, those patients who reported experiencing only smell problems also reported gaining weight and having fewer oral problems. Reports of increased olfactory sensitivity during chemotherapy were often unpredictable and were commonly associated with emotional sequelae. Many chemotherapy patients report having specific complaints related to eating (Bernhardson et al., 2012).

Difficulties in recognizing tastes, particularly sweet tastes, occur in about 33% of patients undergoing chemotherapy and taste thresholds, as assessed by electrogustometry, are often elevated (Berteretche et al., 2004; DeWys, 1979; Ovesen et al., 1991). Taste dysfunction can result in food avoidance and, consequently, can negatively impact the nutritional status and quality of life of patients (Bartoshuk, 1990; Berteretche et al., 2004). Many cancer patients complain that taste is “abnormal, bad, or new” during and for some months after termination of chemotherapy treatments.

It is possible that such changes in taste or flavor makes the affected foods “novel” and susceptible to conditioned taste aversions (CTAs), that is, unpleasant and nausea-associated aversions to foods that often develop in children and adults undergoing chemo- or radio-therapy (Scalera and Bavier, 2009). As noted in detail in Chapter 37, CTAs arise from the delayed pairing of the flavor of a meal with the nausea induced by the therapy (Bernstein, 1978; Bernstein and Webster, 1980). Fortunately, many CTAs can be mitigated by presenting a novel and distinctive flavored food that is rarely or never before been encountered (e.g., a root beer Lifesaver) after a meal but before the initiation of the chemo- or radio-therapy. For some unknown reason, this flavor becomes the “scapegoat” for the CTA, minimizing treatment-associated aversions and hypophagia (Broberg and Bernstein, 1987; Mattes et al., 1987). As noted above, one school of thought assumes that the cancer itself causes the flavor of foods to be distorted or “novel”, making them particularly susceptible to such conditioning. By presenting an even more novel or distinct food, the CTA focuses on the more novel flavor and less on the more familiar flavor. In most cases, chemotherapy related food aversions last only a few weeks or months after cessation of treatment (Mattes et al., 1992). Perhaps their transience is due to the reversal of the taste or smell dysfunction and consequently the disappearance of the “novel” food.

#### 20.8.4 Anesthetics

The effect of anesthetics on olfactory function remains an obscure topic and no double blind study has been performed on the potential influences of anesthetics on such function. Anesthetic drugs could adversely affect olfaction at either central or peripheral levels, including direct toxicity to the olfactory neuroepithelium, nasal vasodilatation, or mucus hypersecretion (Doty and Bromley, 2004). An already compromised olfactory epithelium could explain rare cases where anesthetics have been reported to alter chemosensory function.

Different mechanisms apply for the associations between local anesthetics and smell impairment. Salvinelli reported the case of permanent olfactory dysfunction

after endonasal local anaesthesia with lidocaine 4% that was due to direct contact of the anesthetic with the OE (Salvinelli et al., 2005). Johnson et al. (2004) has shown that mitochondrial dysfunction with activation of apoptotic pathways could be the key factor associated with lidocaine neurotoxicity (Johnson et al., 2004).

It is hard to determine with certainty the causative role of specific anesthetics in the development of olfaction impairment (Konstantinidis et al., 2009). Kostopanagiotou compared the effects of general and regional anaesthesia on olfactory acuity and memory in the immediate post-operative period. In this study, olfactory memory deficits were accompanied by a significant post-operative reduction of plasma melatonin levels in the sevoflurane patients, suggesting that the misinterpretation of odors in the immediate post-operative period by sevoflurane could be mediated by the decreased levels of melatonin (Kostopanagiotou et al., 2011). It is important to note, however, that sevoflurane, as well as propofol, affect subcortical and cortical *c*-aminobutyric acid (GABA) receptor ligand binding (Salmi et al., 2004). Since GABA is a neurotransmitter present at many areas of the olfactory system, any alteration of the GABA dependant pathways could potentially impair olfactory transmission within the CNS (Levy and Henkin, 2004). However, it is not clear why such effects should lead to chronic dysfunction.

#### 20.8.5 Dialysis

More than 485,000 Americans are being treated for end stage renal disease, including 341,000 dialysis patients. Each year, 90,000 new patients with kidney failure are registered (Krishnan and Kiernan, 2009). One of the main problems of dialysis patients is their low quality of life, with malnutrition and anorexia being key contributors. Uremic anorexia and olfactory dysfunction are at the core of their nutritional problems (Schiffman et al., 1978; Raff et al., 2008; Bomback and Raff, 2011).

In the setting of renal insufficiency, impaired olfactory function may serve a dual role: First, as an easily quantifiable measure of neurological dysfunction and second as an indicator of detrimental effects of uremia (Bomback and Raff, 2011). The OE, as well as higher olfactory processing pathways, are potential urea targets. The constant turnover of olfactory neurons throughout the life span presents with an easy target for systemic toxins (Schiffman et al., 1978; Conrad et al., 1987; Suzuki and Farbman, 2000; Raff et al., 2008).

Studies in hemodialysis, peritoneal dialysis, transplanted patients, and patients with varying degrees of renal insufficiency have shown a significant negative correlation between odor perception and serum concentration of urea and protein catabolic rate (Griep et al., 1997). Frasnelli et al. (2002) found reduced olfactory function in

chronic renal failure patients. Raff et al. (2008) demonstrated a critical association between impaired olfactory function (UPSIT) and poor nutritional status in such patients.

## 20.9 SUMMARY

Olfactory dysfunction disrupts people's lives and can, in some instances, be an early sign of an ominous disease. Different components of the olfactory system may be involved in the pathological process and the list of toxics and xenobiotics is a long one. Olfactory bulb pathology relates to significant smell loss and carries a significant risk of a neurodegenerative process. The role of air pollution in the production of olfactory system pathology is enigmatic; however, current knowledge points towards a significant impact of air pollutants – especially particulate matter – in the induction of olfactory system pathology, neuroinflammation, and subsequent neurodegeneration. The issue is a serious one, since millions of people are exposed to concentrations of air pollutants above current standards and young residents of highly polluted cities are showing early olfaction deficits associated to the hallmarks of diseases such as AD and PD. Gene-environmental influences are at play in olfaction disorders, as illustrated by the significant impact of air pollutants upon the CNS in APOE 4 carriers.

### 20.9.1 Summary of Things to Remember on the Subject of Air Pollution and Olfaction

1. Smell deficits are seen in highly exposed young urbanites, including children. Such deficits appear to be most profound in those that spend significant amounts of time outdoors.
2. The lesions seen in children and young adults involve the nasal respiratory mucosa, the olfactory epithelium, and the olfactory bulb.
3. The olfactory bulb neuropathology associated with urban exposures is very similar to that described in early stages of AD and PD (Jellinger et al., 1991; Jellinger, 2012; Braak et al., 1991, 2003a, b, 2011a, b, c). The neuropathological hallmarks of AD (e.g., hyperphosphorilated tau and amyloid plaques) are present in the frontal cortex of children as young as 10 years, and these children already have evidence of olfactory and cognitive deficits, prefrontal white matter hyperintensities, and white matter volumetric changes (Calderón-Garcidueñas et al., 2012a, b).
4. The brunt of the inflammatory brainstem changes in Mexico City young residents involves the medulla

oblongata, as well as accumulation of  $\beta$  amyloid and alpha synuclein in key olfactory nuclei, the dorsal motor nucleus of the vagus, the nucleus of the solitary tract, arcuate nucleus, raphe midline, and extra-raphe medial and lateral tegmentum neurons. These lesions are very similar to the PD stages I and II of Braak (Braak et al., 2003a, b).

5. Olfactory deficits in highly exposed young urbanites must be kept in mind by clinicians. Such deficits are worse in APOE 4 carriers.
6. Air pollution plays a key role in the development of CNS damage and has detrimental effects upon the developing brain. Pollution potentially plays a role in the etiology of AD, PD, and mood disorders, although direct evidence for this is currently lacking.
7. Subjects exposed to massive air pollution, such as occurred in the aftermath of the WTC tragedy, may be at higher risk for the future development of AD and/or PD. Those at greatest risk may be the most highly exposed subjects with the most olfactory deficits and genetic risk factors (e.g., APOE 4 allele carriers).

### 20.9.2 Summary of Things to Remember Regarding Occupational Settings where Exposure to Ionized Metals is Prevalent

1. Adverse effects on olfaction in workers exposed to metals is dose-related and the duration of exposure is critical.
2. Early toxic effects of the metal can occur at low levels, underlying the importance of olfactory tests for identifying early effects.
3. Metal toxicity mechanisms include oxidative stress, interactions with sulphydryl groups, dysregulation of DNA methylation, mitochondrial damage and direct neuronal effect to release neurotransmitters.
4. Welding fumes contain heavy metals with aerodynamic diameters  $<10\mu\text{m}$ , such as chromium, manganese, and nickel. Such fumes can be toxic. Compliance of established exposure limits should be enforced.
5. A word of caution should be raised for the use of Mn nanoparticles as contrast probes for magnetic resonance imaging (Zhen and Xie, 2012) based on the occupational and non-primate Mn literature.

As is clear from the material described in this chapter, much more research is needed to elucidate the olfactory toxicity mechanisms of a variety of everyday health hazards, including exposures to nanoparticles and environmental xenobiotics. Unfortunately, until such hazards

are better understood and appropriate environmental safeguards are in place, many people will continue to be exposed to xenobiotics that potentially have long-lasting effects on their health, including the brain and the olfactory pathways.

## Microbial Chemical Sensing

JUDITH VAN HOUTEN

### 21.1 INTRODUCTION

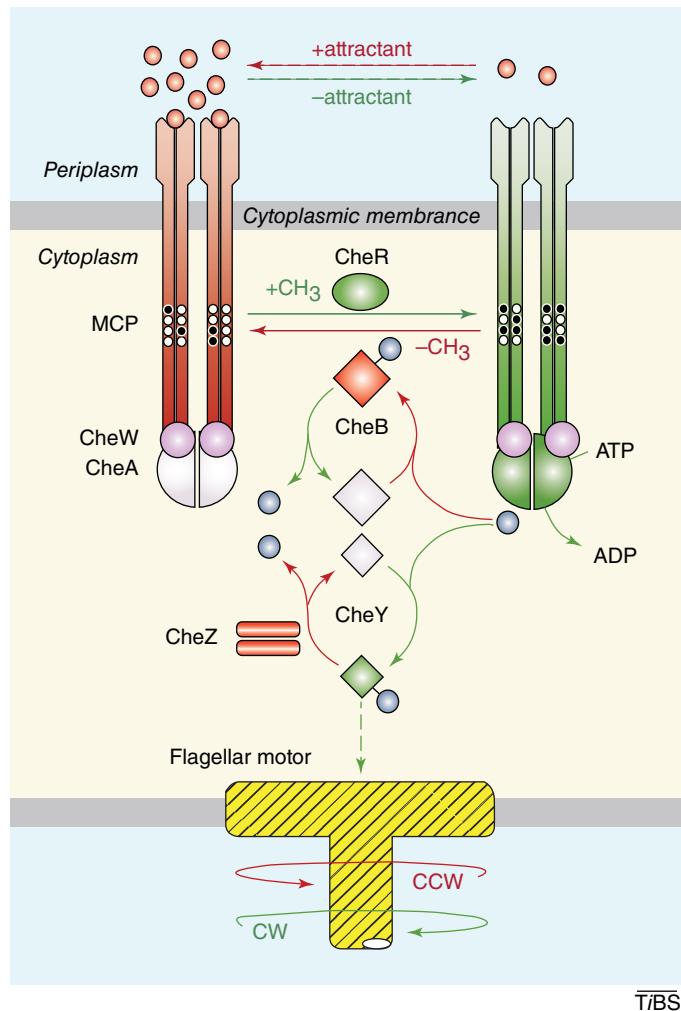

Microorganisms are capable of detecting a host of chemicals in their environments and they display a very wide range of responses. If the chemicals are nutrients, the cells transport and use them for growth in size and number. However, many cues signal the quality of the environment, that is, the presence of oxygen, attractants, optimal pH, toxins or conditions that inhibit growth. The means by which microbes use their motility to accumulate in or disperse from the areas of these cues is the subject of this review. Using this latter narrow definition of microbial chemical sensing and response still leaves an enormous variety of systems to explore from bacteria to protozoa.

### 21.2 BACTERIAL CHEMOTAXIS

Because our current understanding of bacterial chemosensory transduction developed over more than 40 years, it is extremely detailed and deep. While bacterial chemoreponse has been observed since the 1880s (Adler, 1975; Berg, 1975), genetic and cell biological studies began in the 1960s with genetic dissections of how motile *Escherichia coli* move up gradients of attractants like aspartate or down gradients of repellents like acetate, and provided a host of very useful mutants (Armstrong and Adler, 1969; Hazelbauer et al., 1969). The field has matured to our current understanding of chemosensory transduction of several bacterial species in addition to *E. coli* (Porter et al., 2011; Rao and Ordal, 2009) and how they use chemical sensing in pathogen colonization and interaction with the host immune system, quorum sensing for parasitic life styles and virulence regulation, and biofilm formation (Wadhams and Armitage, 2004).

*E. coli* or *Salmonella typhimurium* swim by rotating their 5–8 flagella that arise from the sides of the cell. Unlike eukaryotic flagella, bacterial flagella are in a fixed helix. When moving counterclockwise, the flagella form a bundle at a pole and propel the cell forward. Spontaneously there will be a switch of rotation to clockwise, making the flagellar bundle fly apart and the cell to tumble for a short time. When the sense of the rotation returns to counterclockwise, the cell moves forward again but on a different trajectory (Berg, 2008). Chemical stimuli bias this process so that what is a random walk of smooth runs with random turns becomes a biased random walk (Berg, 1975). Movement up a gradient of attractant results in long runs with few tumbles until the cell eventually arrives at the attractant. Repellents bias the walk in the opposite direction, causing more frequent tumbles and net movement away from the repellent. While other bacteria move by rotating the flagella at their poles or glide with no flagella at all, their chemosensory transduction pathways that modulate motility have many components in common (Adler, 1975; Berg, 1975; Porter et al., 2011; Wadhams and Armitage, 2004). Although the field refers to these behaviors as chemotaxis, they qualify as biased random walks (Berg, 1975) or kinesis because the cells do not orient in the gradient. We will see true chemotaxis in the later example from *Dictyostelium discoideum*.

Bacteria respond to spatial gradients as they swim and also to temporal changes in chemical stimuli, making it possible to see the change in flagellar rotation as stimuli are abruptly introduced into the solution surrounding the cells. Runs of smooth swimming and tumbles can be seen in the rotation and reversal of rotation of bacterial cell bodies that are tethered to slides by antibodies against flagellar proteins (Adler, 1975). Similarly the tracking microscope allowed visualization of the cells in three dimensions (Berg, 1975) as stimuli were applied.

**Figure 21.1** The chemoreceptor signaling pathway in *E. coli*. Components and reactions in red promote counter clockwise (CCW) flagellar rotation; those in green promote clockwise (CW) flagellar rotation. Components in grey represent inactive forms. Solid lines represent enzymatic reactions; broken lines indicate binding interactions. CheA-derived phosphoryl groups are shown as blue spheres. Receptor modification sites are shown as white (unmethylated) and black (methylated) circles. (See plate section for color version.)

In *E. coli* the five transmembrane receptors for attractants and repellents are called methyl-accepting proteins (MCPs) (Grebe and Stock, 1998) because methylation is part of their adaptation process (discussed below). The most abundant MCP is Tar that binds the ligand aspartate directly and another ligand, maltose, indirectly through a periplasmic binding protein (Figure 21.1). It also functions as the MCP for repulsion by nickel and cobalt. Other MCPs Trg, Tsr, Tap, and Aer mediate responses to ribose and galactose, serine, peptides, and oxygen respectively. The crystal structures of the receptors, their multimeric structures and ligand binding pockets have been established in great detail (Hazelbauer et al., 2008). Upon ligand binding, the transmembrane MCPs signal through the lipid bilayer to the cell interior by a piston-like molecular movement that has been described on a detailed level (Hall et al., 2011). The conformation changes in the transmembrane helices that link the binding domain to the domains involved in the intracellular signal cascade are still under investigation.

The signal transduction cascade for *E. coli* chemotaxis is outlined in Figure 21.1. At first glance, the pathway looks like that found in eukaryotic signaling with proteins interacting and becoming phosphorylated by kinases. In bacteria the phosphorylation cascade starts with ATP bound to the kinase domain in one protein of a dimer (e.g., see CheA Figure 21.1), and the  $\gamma$  phosphate of ATP is transferred to the other subunit of the dimer. However, the amino acid phosphorylated is histidine and the same protein goes on to transfer this same phosphate to an aspartate on a response regulator protein (e.g., see CheY in Figure 21.1). This is a two component system (sensor histidine kinase and response regulator) that is well represented in bacteria for detecting environmental signals (Krell et al., 2010) but can also be found in eukaryotes such as yeast, protozoa, and plants (Schaller et al., 2011).

In the cytoplasm CheW couples the histidine kinase CheA to the receptors that influence CheA's phosphorylation state. The autophosphorylation of CheA is critical

in determining whether the signal to the flagellar rotor will cause clockwise or counterclockwise rotation, that is, tumbling or smooth swimming that underlie repulsion and attraction. In the presence of repellents or the removal of attractants (right side of Figure 21.1), the kinase domain of CheA that binds ATP auto-phosphorylates a histidine residue in a regulatory domain of the other member of the dimer. This phosphorylated form of CheA-P in turn transfers its phosphate to response regulator CheY. The phosphorylated form of CheY (CheY-P) interacts with the proteins of the flagellar motor and promotes clockwise movement. A phosphatase CheZ turns over the CheY-P to allow continual response to gradient sensing.

Binding of an attractant to the receptor accomplishes the converse of this transduction pathway for repellents (left side of Figure 21.1). Receptors bound with attractant do not allosterically activate the auto-phosphorylation of CheA and there is no subsequent phospho-relay to CheY. The flagellar motor consequently turns counterclockwise and the cell swims smoothly.

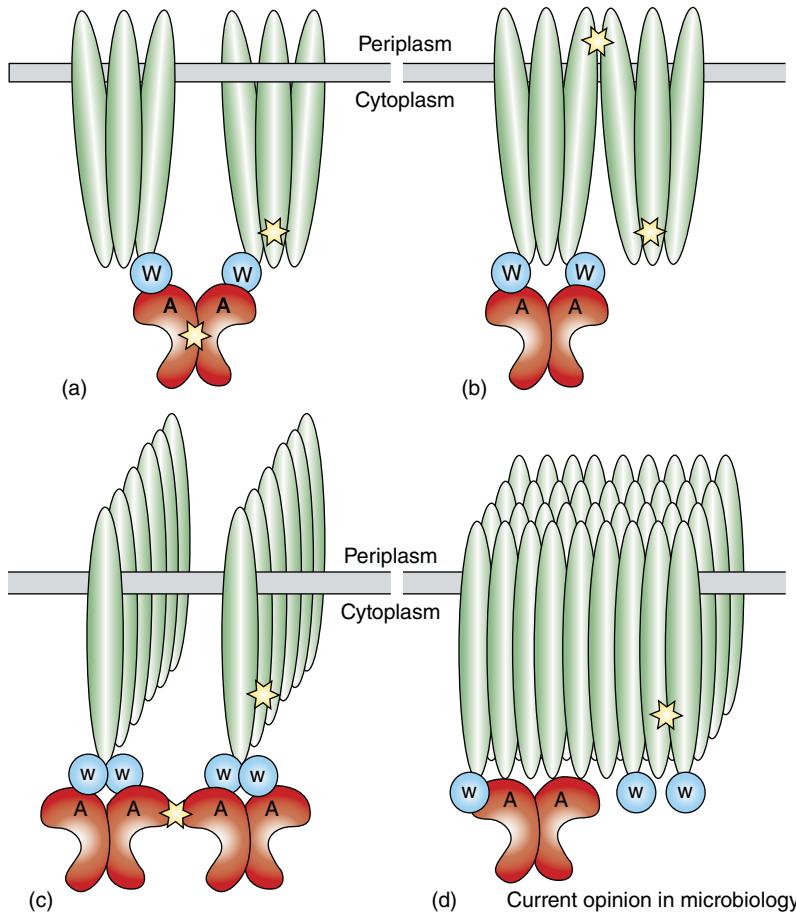

In addition to this phospho-relay signaling pathway, there is an adaptation process of addition and removal of methyl groups on glutamates of the receptors. Addition of the methyl groups is catalyzed by CheR and removal by CheB-P. CheA-P transfers a phosphate from its histidine to the CheB protein; CheB-P in turn removes methyl groups from the receptors. The methylation level of the receptor reflects the recent past of the cell's exposure to attractants and repellents. Methylation of the cytoplasmic domain of a receptor by CheR increases the ability of the receptor to activate CheA; the CheA-P form promotes clockwise rotation and tumbling through CheY-P. CheB-P opposes bias toward tumbling by removing methyl groups; CheB activity increases about 100-fold after phosphorylation by CheA-P. Interestingly, CheB also catalyzes the deamidation of glutamines to glutamates which can then be methylated. Thus there is a feedback system: methylation of receptors by CheR promotes tumbling through the receptor activation of CheA-P and CheA-P in turn reduces methylation by activating its phospho-relay substrate CheB-P. Adaptation is thought to reset the pre-stimulus receptor and rotor bias very precisely back to the pre-stimulus levels. In this way, the cell continues to respond over a large dynamic range of stimulus concentrations that it encounters in a gradient.

Chemoreceptors of bacteria exhibit “exquisite sensitivity, extensive dynamic range and precise adaptation” (Hazelbauer et al., 2008). These characteristics arise in part from the physical arrangement of the receptors in large arrays primarily at a pole of the cell. A large gain is achieved in part by linking one receptor to multiple CheA molecules, allowing for large amplifications of the signaling to the kinase (Li and Hazelbauer, 2005). Additional gain and sensitivity are achieved from aggregation of the cell's 7,500 or so receptors into several large

patches of trimers of homodimers (Figure 21.2 (Bray, 2002; Kentner and Sourjik, 2006), see (Hazelbauer et al., 2008) for review). The activation of a receptor in a cluster appears to influence its neighbors and amplify the signal, explaining in part why a 1% change in receptor occupancy can result in a 50% change in motor response. There is thought to be a conformational spread of allosteric interactions and cooperativity among the receptors that account for sensitivity to small changes in concentration over several orders of magnitude of background stimulus concentration (Keymer et al., 2006). Rao and Ordal (Rao and Ordal, 2009) provide an excellent description of the role of the signaling arrays in which the receptors are highly cooperative at low ligand concentration and act as solitary receptors at high concentration thereby contributing to high sensitivity and also large dynamic range. They also discuss the coupling of mixtures of receptors in arrays that allow for integration of signaling information and tuning of receptor output to the concentration of attractant.

Networking of multiple receptor types contributes to signal integration in clusters as described above (Keymer et al., 2006) and can also be seen in the adaptation process that must reset the motor bias back precisely to pre-stimulus levels in order for the cells to respond in the presence of persistent stimuli. In the receptor clusters of trimers of dimers (Endres, 2009) there can be mixtures of homodimers of more than one receptor type in a trimer, such as Tar receptor homodimers with Tsr receptor homodimers (Li and Hazelbauer, 2005). The high abundance receptors such as Tar or Tsr have the sequence NWETF that is required for efficient adaptation modification by methylation, demethylation, and deamidation to create the glutamate methylation sites. Low abundance receptors like Trg lack this sequence and are inefficiently modified, and, similar to mutants lacking this sequence, are also defective in adaptation. However, in mixtures of the high and low abundance receptors, the modifications for both receptors and adaptation are timely and efficient because the high abundance receptors provide assistance to the low abundance receptors in “assistance neighborhoods” (Endres and Wingreen, 2006; Li and Hazelbauer, 2005). The neighborhoods are five to seven near-by interacting receptors, subsets within the clusters composed of many more interacting receptors (Kentner and Sourjik, 2006; Li and Hazelbauer, 2005).

Adaptation at the level of the flagellar motor has been suspected for some time, and now has been demonstrated by Berg and co-workers (Yuan et al., 2012). Methylation and demethylation clearly are the major mechanisms for adaptation, but mutants that lack these enzymatic activities can still adapt slowly. The motor of the flagellum is extremely sensitive to levels of CheY-P, the diffusible protein that binds the receptor and the FliM proteins of the motor. Recent studies have uncovered the signal-dependent

**Figure 21.2** Models of cluster organization. Crucial interactions are marked with a yellow star. (a) Trimers of receptor dimers, formed by interactions at the cytoplasmic receptor tip, bind CheA through CheW and are connected by CheA dimerization. (b) Trimers-of-dimers interact at the periplasmic side. (c) Receptors form one-dimensional hedgerows through lateral interactions between their cytoplasmic domains. CheA dimers bind receptors via CheW and connect adjacent hedgerows through interactions between the P5 domains. (d) Receptors self-organize into a two-dimensional lattice through lateral interactions between their cytoplasmic domains. CheW and CheA bind with a variable stoichiometry and stabilize clustering. (See plate section for color version.)

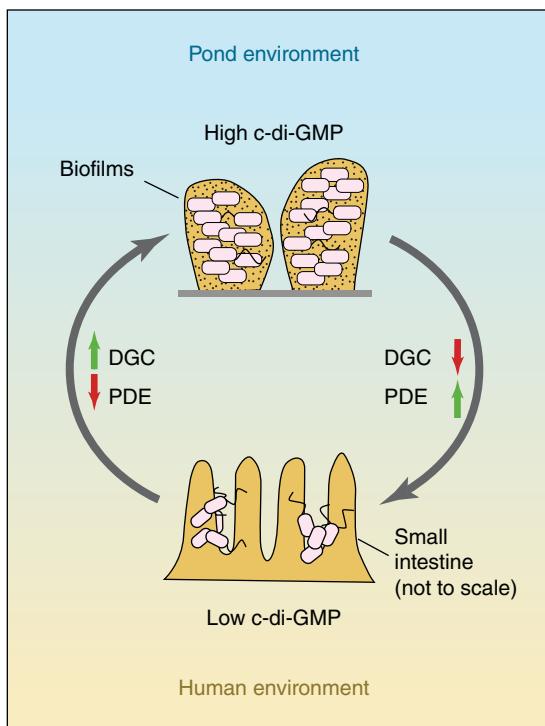

turnover of the FliM protein that remodels the target of signaling. More FliM allows more sensitivity to the decrease in CheY-P from repellents or reduction in attractants that promote smooth swimming from counterclockwise flagellar rotation. The process of adaptation by adjusting levels of FliM to adjust sensitivity is a much slower process than the adaptation by methylation levels.

While the focus above has been on *E. coli*, other bacteria have been thoroughly studied, such as *Bacillus subtilis*, *Rhodobacter sphaeroides*, and *Myxococcus xanthus* (see (Porter et al., 2011; Rao and Ordal, 2009; Wadhams and Armitage, 2004) for broader views beyond *E. coli*). The role of chemotaxis of *Rhizobium* for symbiosis that is beneficial to plants, likewise, has been documented (Miller et al., 2007).

Bacteria make use of a second messenger not shared with eukaryotes or Archaea, cyclic di-GMP (see (Hengge, 2009; Ryan et al., 2012; Schirmer and Jenal, 2009) for reviews). This signaling molecule is of interest to this overview of chemical sensing because it is a regulator of processes like virulence and biofilm formation that also depend upon bacterial motility and chemotaxis signaling systems (Jenal and Malone, 2006; Tamayo et al., 2007;

Williams et al., 2007). Cyclic di-GMP is a ubiquitous second messenger in bacteria and controls a large and diverse range of targets that have a PilZ or one of three other domains. Cyclic di-GMP binds to these domains it acts allosterically to promote protein-protein interactions or binding to DNA elements. Remarkably, it is known to regulate at transcriptional, translational, and posttranslational levels. Motile cells generally have low levels of unbound c-di-GMP that at high levels serve as second messengers in the switch between planktonic motile and sedentary behavior through controlling flagellar synthesis (Tamayo et al., 2007). The switch to sedentary life style is critical for biofilm formation, as is promotion of biofilm matrix synthesis by cyclic di-GMP (Figure 21.3 shows an example of *V. cholera* (Tamayo et al., 2007)). This second messenger is implicated in quorum sensing, biofilm formation, exopolysaccharide production, attachment to surfaces, and attenuation of motility and virulence (Jenal and Malone, 2006).

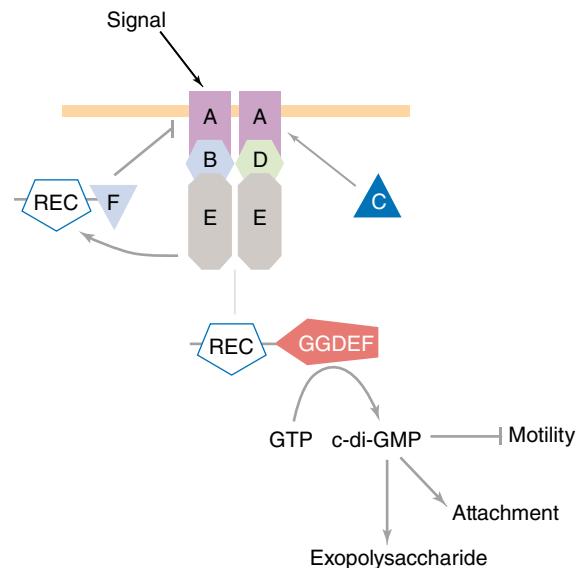

Bacteria regulate the synthesis and degradation of the second messenger cyclic di-GMP with diguanylate cyclases and specific phosphodiesterases by allosteric effectors, phosphorylation, transcription control, and

**Figure 21.3** Model of the role of c-di-GMP in the transition of *V. cholerae* from persistence in aquatic reservoirs to survival in the human host. C-di-GMP is predicted to be high in *V. cholerae* existing in biofilms attached to biotic and abiotic surfaces in the pond environment. Upon entry into the human host, induction of PDE and/or repression of DGC activities can lower c-di-GMP and allow dispersion from the biofilm and maximal expression of the virulence genes. Conversely, c-di-GMP must be elevated once again through activation of DGC and/or repression of PDE to resume the biofilm lifestyle.

restriction to microdomains (Tamayo et al., 2007). Because cyclic di-GMP is thought to transmit and integrate information about environmental stimuli to the cell, it is presumed that cyclic di-GMP synthesis pathway is regulated by environmental signals, but the mechanisms of this regulation are far from clear. There is only a small list of environmental signals that affect the levels of cyclic di-GMP including oxygen, blue light, nutrient starvation, and mucin (Jenal and Malone, 2006). Where the cyclic di-GMP pathway intersects most clearly with bacterial chemotaxis is in *Pseudomonas fluorescens* and *P. aeruginosa* that are pathogens in lung infection in patients with cystic fibrosis. The pathway in Figure 21.4 (Jenal and Malone, 2006) shows the signal transduction pathway from the *Pseudomonas* chemoreceptor that is homologous to those in *E. coli* for the cyclic di-GMP pathway that controls motility and attachment. However, the external ligands for the receptor for *Pseudomonas* are not known.

Cyclic di-GMP promotes the adhesion of pathogenic bacteria to intestinal cells and expression of virulence

**Figure 21.4** The Wsp chemosensory pathway. The Wsp chemosensory pathway is homologous to the chemosensory system in *E. coli*. In this model, WspE kinase activity is activated via signal-dependent conformational changes in the WspA/WspB or WspA/WspD complex. WspE phosphorylates WspR leading to downstream signal propagation. Adaptation to external signals is mediated by the phosphorylation-dependent methylesterase activity of WspF and the methyltransferase WspC. Intracellular information transfer is indicated by arrows (25, 50, 88).

factors in *Vibrio cholerae* and *Clostridium difficile* by regulating riboswitches (Hengge, 2009; Ryan et al., 2012). Since cyclic di-GMP is so ubiquitous in bacteria it is not surprising that it is recognized by the mammalian innate immune sensor STING and serves as a microbial signal of infection (Burdette et al., 2011; Yin et al., 2012). There are still more variations on the cyclic di-nucleotide signaling in bacteria as cyclic di-AMP is found as a recognition signal in the mammalian innate immune system and a mixed cyclic di-AMP-GMP regulates *V. cholerae* virulence (Davies et al., 2012).

We have discussed bacteria as though they live in pure cultures, but that is clearly not the case when one examines the recently delineated microbiomes of every human surface (skin, gut, vagina, mouth, nares) (Balter, 2012; Relman, 2012). In the gut alone, our microorganisms interact with host cells in very complex and important ways. The microbes are involved in the regulation of our metabolism, nutrition, and immune-inflammation systems (Hooper et al., 2012; Nicholson et al., 2012). As we saw with cyclic di-GMP, the microbes interact with our immune system through signal transduction pathways that should be better understood in the near future if we are to comprehend our relationship with our own microbes (Kau et al., 2011; Rak and Rader, 2011).

Bacteria of our human biome and other ecosystems interact in communities with other bacteria and other microbes (Little et al., 2008; West et al., 2007). Two social activities that have already been mentioned in this review are quorum sensing and biofilm formation that are described in more depth below.

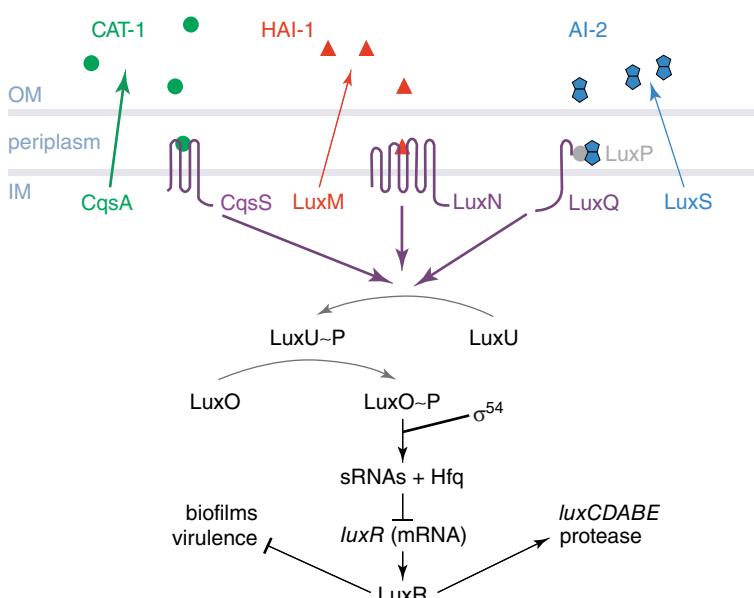

### 21.3 QUORUM SENSING

Bacteria monitor the density of their populations through the process of quorum sensing (Federle, 2009; Jayaraman and Wood, 2008; Little et al., 2008; Waters and Bassler, 2005). The bacteria communicate and coordinate among themselves through secreted cues called Auto Inducers (AIs) that allow the bacteria to act in unison in transcription or motility when the population density has reached the appropriate level. Quorum sensing is very specific, allowing bacteria to communicate among cells of the same species when in mixtures of microbes. Gram positive bacteria utilize a variety of homoserine lactones called AI-1s; Gram negative bacteria utilize a variety of peptides called AI-Ps. These AIs are specific for intraspecies communication, in contrast to a relatively newly discovered autoinducers (AI-2) that allow inter-species communication among Gram positive and negative bacteria. AI-2 synchronizes transcription and behavior so that the bacteria may act in unison in biofilm formation or virulence in pathogenesis. The outcomes of quorum sensing also include bioluminescence, antibiotic production, and sporulation, but key to all of these very varied outcomes is the communication among bacteria that allows them to respond only when their secreted signals and population densities

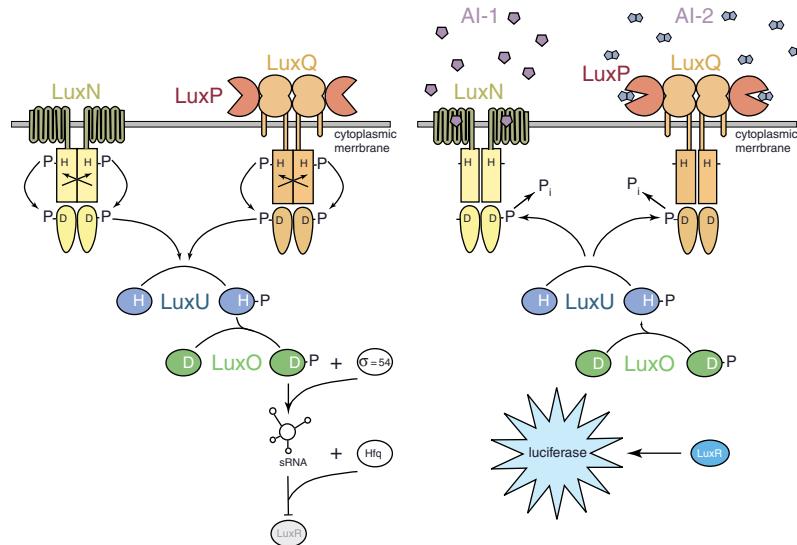

reach critical levels. (For some exceptions to intraspecies specificity that allow for cross-talk see (Jayaraman and Wood, 2008).

Frequently, the *Vibrio* species are used to illustrate the principles of quorum sensing signaling and also the means by which bacteria integrate multiple signal inputs (reviewed by (Federle, 2009; Jayaraman and Wood, 2008; Waters and Bassler, 2005)). *V. fischeri* colonize the Hawaiian squid light organ where they benefit from the concentration of nutrients. The squid benefits from the bioluminescence of the bacteria that makes its shadow harder to see by predators below the squid. The *V. fischeri* do not transcribe the genes for the bioluminescence pathways until they reach an adequate cell density, which is monitored from the concentration of the AI-1 secreted by these bacteria. The AI-1 diffuses into the cells and binds to an intracellular receptor protein LuxR that acts as the transcription factor for the luciferase operon.

*V. harveyi* also shows density dependent luciferase expression and expression of about 100 other genes. *V. harveyi* utilizes three AI systems that all converge on the same pathway at the LuxO protein that acts as coincidence detector. Three AIs that are secreted by *V. harveyi* include two different acyl homoserine lactones (HAI-1 and CAI-1), and a furanosyl borate diester autoinducer-2 (AI-2) (Jayaraman and Wood, 2008). Each binds to a surface receptor histidine kinase or a periplasmic protein that in turn binds to the receptor kinase (Figure 21.5 (Waters and Bassler, 2005)). The most detail of the signaling pathways is known for the HAI-1 and AI-2 pathways that utilize the two component histidine receptor kinases LuxN and LuxQ, respectively (Figure 21.6 (Neiditch et al., 2006)). One notable difference from the chemotaxis histidine kinases is

**Figure 21.5** *Vibrio harveyi* produces and responds to three distinct autoinducers. The sensory information is fed into a shared two-component response regulatory pathway. The arrows indicate the direction of phosphate flow in the low-cell-density state. CAI-1, HAI-1, and AI-2 are respectively represented by green circles, red triangles, and blue double pentagons. OM, outer membrane; IM, inner membrane. (See plate section for color version.)

**Figure 21.6** The *Vibrio harveyi* Quorum-Sensing Signal Transduction Circuit Under conditions of low cell density (i.e., in the absence of appreciable concentrations of autoinducers; left), LuxN and LuxPQ act as kinases that catalyze histidine (H) phosphorylation, presumably across dimer pairs (arrows). Phosphate is subsequently transferred to a conserved aspartate (D) in the receiver domains of LuxN or LuxQ and then to histidine and aspartate residues on LuxU and LuxO, respectively. LuxO-phosphate, in conjunction with the sigma factor  $\sigma^{54}$ , promotes transcription of genes encoding small regulatory RNAs (sRNAs). The sRNAs, together with the chaperone Hfq, destabilize the mRNA encoding the transcription factor LuxR. Under high cell density conditions, (i.e., in the presence of high concentrations of autoinducers; right), LuxN and LuxPQ bind their respective autoinducer ligands (AI-1; pentagons; AI-2: double pentagons) and are converted from kinases to phosphatases. Phosphate is stripped from LuxO and LuxU and is hydrolyzed to inorganic phosphate ( $P_i$ ). Because dephosphorylated LuxO is inactive, LuxR is produced and activates the expression of the luciferase operon. As a result, the bacteria produce light. (See plate section for color version.)

the periplasmic binding protein for AI-2 called LuxP. LuxP interacts in turn with LuxQ, the transmembrane receptor kinase. At low concentration of either AI-1, the receptors are active histidine kinases that auto-phosphorylate across dimer pairs and, through phosphor-relay, transfer the phosphate to an aspartate of the receiver domain of the same protein. The phosphates from both receiver response domains are then transferred to histidines of LuxU and LuxO where the pathways converge. Phosphorylated LuxO with a specific sigma factor for production of sRNA and a chaperone Hfq represses LuxR synthesis by destabilizing its mRNA, thus repressing transcription of the luciferase operon. At high AI concentrations, the sensor kinases switch from being kinases to phosphatases. The result is that LuxO and LuxU are no longer phosphorylated, LuxR is produced, and the genes for bioluminescence among others are expressed. The same basic principles of signaling also apply to the CAI-1 pathway.

The quorum sensing pathways of *V. harveyi* converge on the same protein, LuxO, which serves as a coincidence detector for environmental signals, but the three pathways do not have equal consequences for production of LuxR. In the absence of HAI-1, the cells continue to control light production but at 10,000 times lower light production per cell. Therefore, they appear to pay much more attention to

the species specific HAI-1 signals than to the inter-species common signal AI-2.

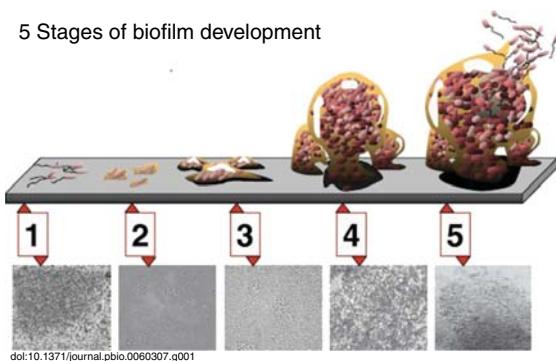

*V. cholerae* is responsible for endemic diarrhea disease. This species has a no HAI-1 system, but does possess CAI-1 and AI-2 systems similar to that of *V. harveyi* (Miller et al., 2002), but, instead of controlling luciferase operons, this system promotes virulence factor production and biofilm formation at low concentration and represses them at high concentration. Virulence factor production regulated by quorum sensing is not unique to *V. cholerae* but in these other pathogenic bacteria, virulence factors are typically induced at high population densities (Waters and Bassler, 2005). Waters and Bassler (Waters and Bassler, 2005) point out that the low density induction of virulence factors and biofilm formation in *V. cholerae* fits its life style in that the diarrhea from the *V. cholerae* infection flushes the bacteria out into the environment and suppression of biofilm formation at high cell density would promote dissemination.

Quorum sensing is not restricted to microbe to microbe signaling. Inter-kingdom signaling between microbe and host is illustrated by the histidine sensory kinase QseC that binds both the bacterial signal autoinducer AI-3 and epinephrine or norepinephrine from the host (Clarke et al., 2006). Epinephrine activates the same set of genes through QseC as does AI-3 (Jayaraman and Wood, 2008).

Enterohemorrhagic *E. coli* 0157:H7 that colonize the colon use this signaling to activate its virulence genes; loss of QseC sensory kinase receptor reduces this expression and pathogenicity (Clarke et al., 2006; Jayaraman and Wood, 2008). Even more levels of interaction are among the indigenous microbiota of the gut with the host in resisting *C. difficile* colonization (Britton and Young, 2012). See (Jayaraman and Wood, 2008) for more inter-kingdom communications and (Waters and Bassler, 2005) for examples of quenching of the microbial quorum sensing by the host that can be algae, legumes, or humans.

## 21.4 BIOFILMS

Biofilms are fascinating in their variety and complexity. They are communities of microbes encased in a matrix of polysaccharide. They form on many kinds of surfaces and have extreme health consequences when they form on indwelling catheters or the lung epithelia of cystic fibrosis patients (Lynch and Robertson, 2008; Waters and Bassler, 2005). Microbes by living in a biofilm increase their resistance to antibiotics, extremes of pH, dessication, uv damage, and predation. There are several stages of biofilm formation: initial attachment, irreversible attachment, maturation stages 1 and 2, dispersion (Figure 21.7 (Monroe, 2007; Sauer et al., 2007)). The microbes begin as planktonic free swimming forms and disperse back into this life style at the end of the biofilm cycle. See also the NSF funded biofilm teaching tool <http://www.hypertextbookshop.com/biofilmbook/v004/r003/>. There are many bacteria that can form biofilms, in monocultures or in mixtures that can also include fungi (Lynch and Robertson, 2008).

**Figure 21.7** Biofilm maturation is a complex developmental process involving five stages. Stage 1, initial attachment; stage 2, irreversible attachment; stage 3, maturation I; stage 4, maturation II; stage 5, dispersion. Each stage of development in the diagram is paired with a photomicrograph of a developing *P. aeruginosa* biofilm. All photomicrographs are shown to same scale.

The sensor systems (quorum sensing and cyclic di-GMP) that we have already examined have roles to play in biofilm formation. Quorum sensing allows intra- and inter-species communication in communities of biofilm microbes. Cyclic di-GMP at high levels promotes biofilm formation, in both *Pseudomonas aeruginosa* and *P. fluorescens*, but the mechanism varies with species. In *P. aeruginosa*, cyclic di-GMP controls extracellular polysaccharide deposition and flagellar function while in *P. fluorescens* it controls secretion and surface localization of LapA that controls the commitment to a biofilm existence (Monds and O'Toole, 2009). See also Figure 21.3 above for cyclic-di-GMP in *V. cholerae*.

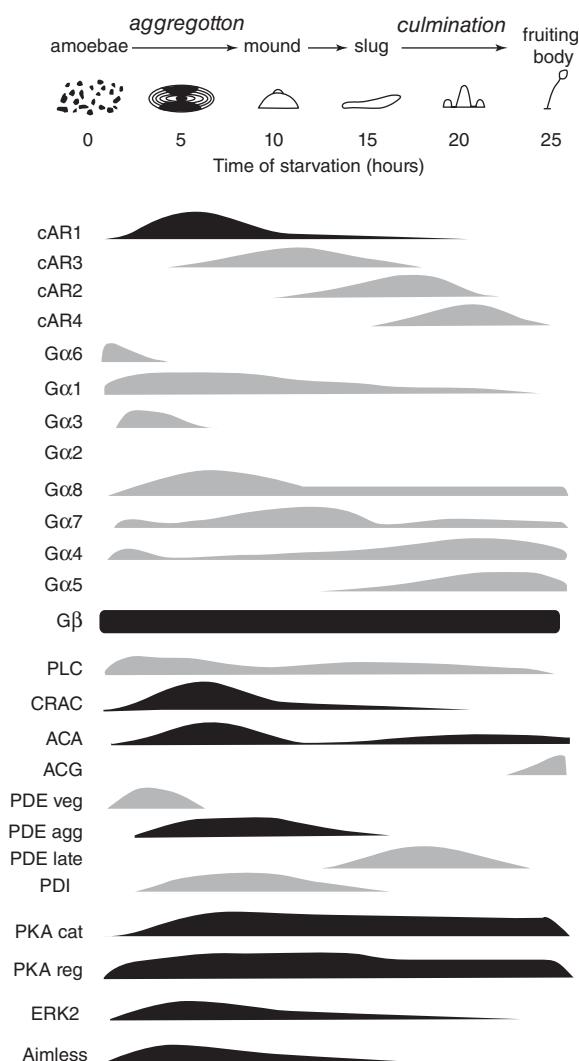

An illustration of the intersection of quorum sensing and cyclic di-GMP signaling is in *Pseudomonas fluorescens* biofilm formation. The adhesion protein LapA must be transported to the outer membrane for the formation of microcolonies in the evolution of the biofilm. Two regulators of LapA are cyclic di-GMP and inorganic phosphate ( $P_i$ ).  $P_i$  is sensed through a two component system of PhoBR (Monds and O'Toole, 2009) that activates target genes including rapA, a phosphodiesterase that reduces cyclic di-GMP. Under conditions of low cyclic di-GMP, the secretion and transport of LapA to the outer membrane is inhibited as is biofilm formation.

## 21.5 EUKARYOTIC MICROBES

As we see from the varied communication and chemical sensing strategies that prokaryotic microbes live social lives (West et al., 2007). Extremely rapid and sensitive chemotaxis allows bacteria to exploit marine niches (Stocker et al., 2008). Quorum sensing has fitness benefits for microbe populations (Darch et al., 2012) and also allows bacteria to behave as though a multicellular organism. There are interesting parallels in an eukaryotic microbe *Dictyostelium discoideum* that uses cell to cell communication and quorum sensing to bring together individual amoebae cells into a multicellular structure with multiple cellular phenotypes (Parent and Devreotes, 1996).

*Dictyostelium* amoebae are social. They communicate among vegetative, free moving cells with secreted molecules that signify density of the population and serve quorum sensing functions (see (Golé et al., 2011) for analysis of quorum sensing kinetics). The *Dictyostelium* amoebae feed on the bacteria in soil and decaying detritus of the forest floor. As they grow they secrete multiple factors that have been harvested from growth media and shown to affect transcription, motility, and adhesion, for example (Kolbinger et al., 2005).

When bacteria become scarce, the *Dictyostelium* cells begin to starve and aggregate to form a multicellular slug that differentiates into a base and stalk topped with a

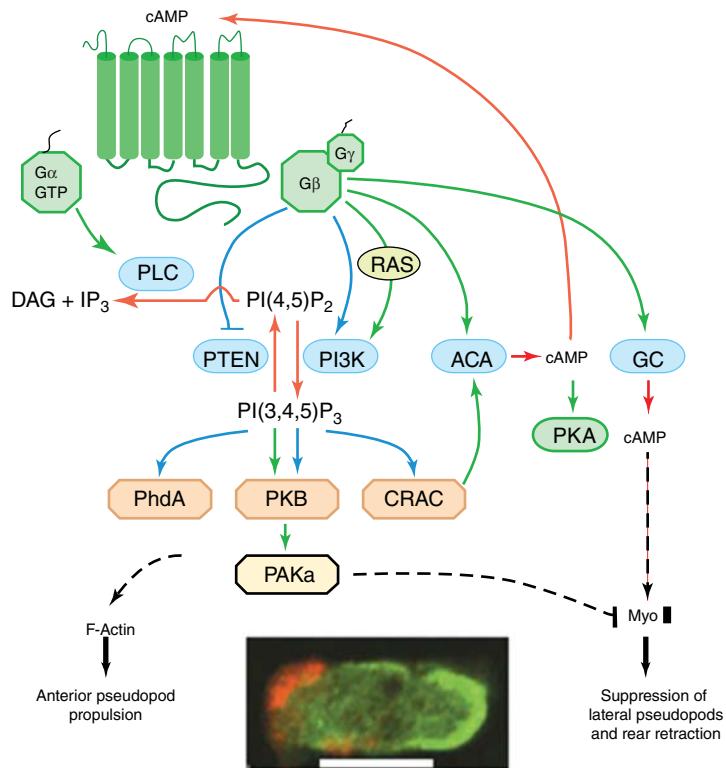

**Figure 21.8** Time course of expression of major RNA transcripts. Top panel illustrates the developmental stages appearing after the onset of starvation. Receptors, G proteins, regulators, and several effectors are shown below. Components essential for early development are heavily shaded.

fruiting body with spores (Figure 21.8). The spores will disperse and form new amoebae when conditions improve. The way in which the starving amoebae find each other is to move by chemotaxis up gradients of cyclic AMP (cAMP) that is initially secreted by a founder cell, followed by secretion of cAMP by more distant cells in a relay [see for review (Parent and Devreotes, 1996)]. The cells polarize and move in a spiral pattern up the cAMP gradient, eventually aggregating in sufficient numbers to form a slug. The ligand cAMP binds to the cAR1 receptor that signals through G proteins to activate adenylyl and guanylyl cyclases, PI3Kinase, PLC and inhibit PTEN (Figure 21.9). There also are signals independent of G

proteins to increase calcium uptake, for example[see for reviews (Parent and Devreotes, 1996); (Aubry and Firtel, 1999); (Kimmel and Parent, 2003; Manahan et al., 2004)].

In addition to the stages of slug and fruiting body formation, Figure 21.8 shows a time course of expression of many genes involved in signaling initiated by cAMP and development of differentiated cell types. Figures 21.9 and 21.10 (Kimmel and Parent, 2003; Manahan et al., 2004) illustrate the complex signaling that occurs upon binding of cAMP to the cAR1 receptors. These figures also show the spatial organization of the signaling pathways that lead to polarization of the cell and chemotaxis. The cells experience a gradient of cAMP with the highest concentration denoting the direction in which the amoeba should move to join other cells in aggregation. The area of the cell exposed to the highest amounts of cAMP forms pseudopods and becomes the leading edge of the cell that moves up the gradient. The back end of the cell suppresses pseudopod formation and undergoes myosin-based retraction. The steps in this process of polarization and motility are conserved in chemotaxis of neutrophils as they move up gradients of bacterially derived peptides like fMLP that signify infection (Figure 21.11) (Parent, 2004).

The aggregation of the *Dictyostelium* amoebae is not simply dependent upon the single signal, cAMP. Prior to starvation, the cells secrete a “prestarvation” factor that accumulates in proportion to the cell density, but is inhibited by the presence of bacteria (Rathi et al., 1991). When the prestarvation factor is high and bacteria are scarce, the stage is set for the aggregation of starving cells. As the cells begin to starve, prior to secreting cAMP, they secrete a glycoprotein conditioned medium factor (CMF) that integrates quorum sensing with the chemotaxis pathway (Gomer et al., 1991). When the concentration of CMF reaches a threshold indicating a minimum density of starving cells, the receptor for CMF is activated, the cAMP receptor cAR1 is expressed, and phosphodiesterase B is inhibited, preparing the cells for migration and aggregation. Neither CMF nor cAMP by themselves is sufficient for chemotaxis and aggregation, but both bound to their respective receptors are necessary for these processes (Van Haastert et al., 1996). These receptors integrate through a G-protein ensuring that cAMP cannot activate cAR1 without CMF and manipulation of cAR1 levels leads to concomitant changes in the CMF receptors. Dependence of chemotaxis upon CMF prevents an asynchronous cAMP-mediated aggregation of a small number of cells, insufficient to form a slug. In late aggregation the group size is further controlled by a secreted repellent and still more counting factors that regulate the cytoskeleton, motility, and cell adhesion so that the group size of about  $10^5$  cells form aggregate together to form a slug [(Gomer et al., 2011); (Tang et al., 2001)].

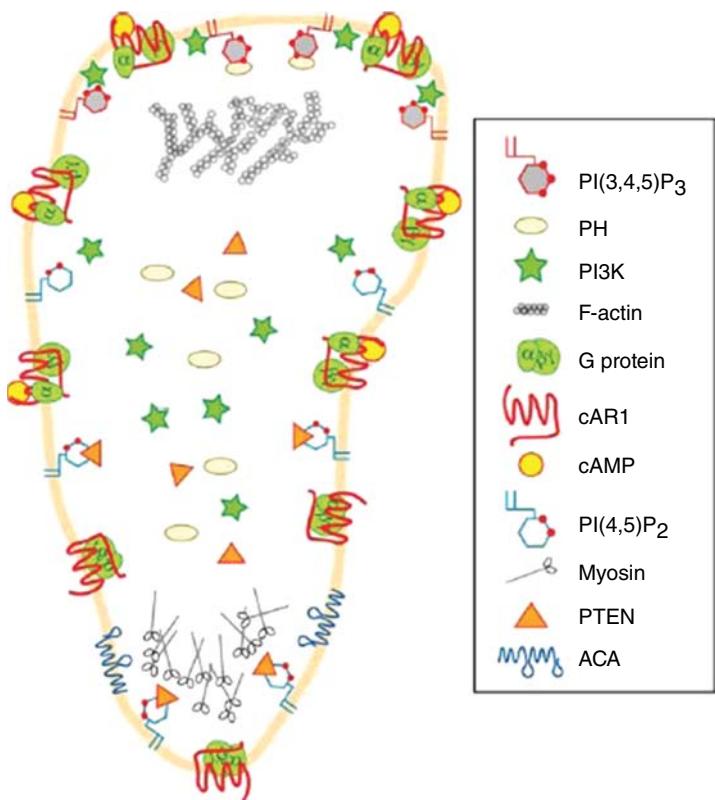

**Figure 21.9** Signal transduction events leading to the spatial and temporal regulation of chemotaxis. A simplified model depicting the major effectors (in blue) activated by cAMP receptors. Receptor stimulation ultimately gives rise to actin polymerization at the front for propulsion, myosin II assembly at the sides to suppress lateral pseudopod formation, and myosin II assembly also at the rear for retraction. The molecular details leading to the regulation of PTEN, PI3K, GC, and AC by G $\beta$  are still being elucidated. Ras appears to be directly required for the activation of PI3K, although its role in PI3K localization is not known. Green arrows, enzyme activation; blue arrows, membrane localization; red arrows, product relation; dashed arrow, complex regulations that have yet to be fully established. (Image) Myosin heavy chain (MHC) and actin filament distribution in polarized cells. Cells expressing MHC fused with green fluorescent protein (GFP) were fully differentiated, fixed, and stained with tetramethyl rhodamine isothiocyanate (TRITC)-phalloidin. The MHC-GFP posterior signal appears in green, and the actin filaments are in red. Bar, 10  $\mu$ m. (See plate section for color version.)

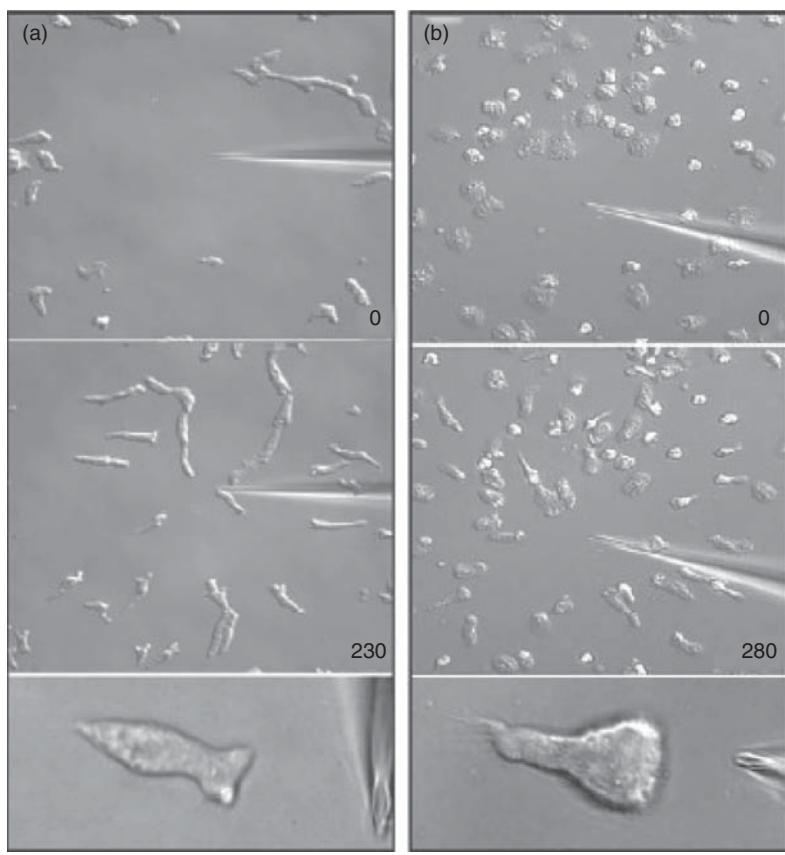

Following aggregation and slug-formation of *Dictyostelium* amoebae, the cells differentiate to form a sessile fruiting structure made of a basal disk, supporting a stalk with spherical spore mass on top (Figure 21.8). The recent identification of a morphogen for the differentiation of stalk cells brings us full circle back to di-c-GMP, the bacterial signaling molecule that plays roles in motility, quorum sensing, and biofilm formation (Chen and Schaap, 2012). Analysis of the genomes of all Dictyostelia groups has shown that they have orthologs of the enzyme required for d-c-GMP formation. However, the signature GGDEF motif of the prokaryotic di-guanylate cyclases is not found in the genomes of ciliated protozoa like *Paramecium* that, nonetheless, have chemo-sensing components in common with *Dictyostelium*, such as receptors for attractants cAMP and folic acid. *Paramecium* also have in common with bacteria a biased random walk mechanism for attraction and repulsion (Sasner and Van Houten, 1989); (Preston and Van Houten, 1987; Van Houten et al., 2010b; Van Houten et al., 2000).

## 21.6 CILIATED PROTOZOA

Free living ciliates use extracellular cues for location of mates, food, and optimal environments. *Paramecium tetraurelia*, for example, swim by beating its thousands of cilia (Figure 21.12) and change this beating as they respond to attractants that signify that their food source (bacteria) is in the area and to repellents that signify toxic conditions such as extremes of pH or salt (Valentine et al., 2008; Van Houten, 1998; Van Houten and Preston, 1988). Unlike *Dictyostelium* that accumulate by chemotaxis, *P. tetraurelia* accumulate or disperse by a biased random walk similar to behavior of bacteria. As in bacterial chemoresponse, chemical stimuli elicit changes in ciliates' swimming behavior with attractants causing long runs of smooth swimming and few random turns and repellents causing short runs and frequent turns (Figure 21.13). In contrast to bacteria, *P. tetraurelia* also modulate speed of swimming

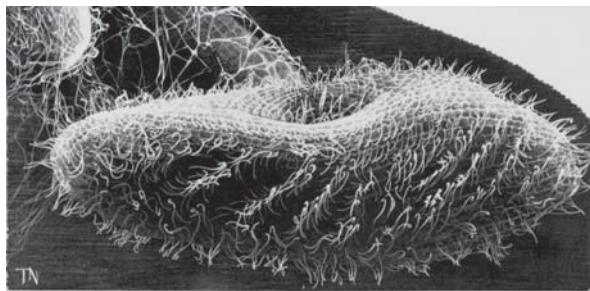

**Figure 21.10** Spatial localization of key components of the signaling pathway in *Dictyostelium*. The cAMP receptor cARI is uniformly distributed and G protein dissociation is believed to mirror receptor occupancy in the presence of an external cAMP gradient. In contrast, several components are found preferentially on the front [phosphatidylinositol 3-kinase (PI3K), PI(3,4,5)P<sub>3</sub>, PH domain-containing proteins, F-actin] or back [PI3-phosphatase (PTEN), adenylyl cyclase (ACA), myosin II] of migrating cells. The cell is migrating toward the top of the page.

Current opinion in cell biology

**Figure 21.11** *D. discoideum* and neutrophils migrating in response to chemoattractant gradients. (a) Differentiated wild-type *D. discoideum* cells were plated on a chambered cover glass, and subjected to a cAMP gradient (supplied by a micropipette containing 1  $\mu$ M cAMP). The bottom panel shows a high-magnification image of a polarized cell. (b) Peripheral blood neutrophils were plated on a chambered cover glass and subjected to an fMLP gradient (supplied by a micropipette containing 1  $\mu$ M fMLP). The bottom panel shows a high magnification image of a polarized cell. For both (a) and (b), the numbers on the lower right corner indicate elapsed time in seconds. The images on the upper panels were taken using 20X objectives and the high magnification bottom panel images were captured using 63X objectives.

**Figure 21.12** Paramecium tetraurelia showing the waves of cilia beating toward the posterior of the cell. From Grass Calendar, 1985.

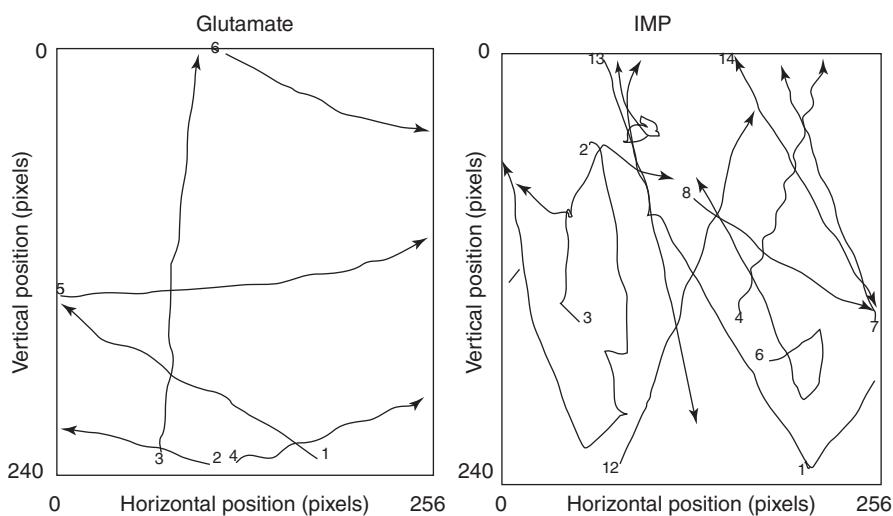

that reinforces the biased random walk by making the runs longer in attractants and shorter in repellents.

An important feature of ciliates like *P. tetraurelia* is that their ciliary beat frequency and form are under electrical control earning them the nickname of swimming neurons (Kung and Saimi, 1982; Machemer, 1989). Therefore, the swimming behaviors that underlie attraction and repulsion are determined by the membrane electrical changes that the stimuli induce (Valentine et al., 2008; Van Houten, 1979; Van Houten and Preston, 1988). The cilia beat toward the posterior of the cell, driving the cell forward, but at random times the cilia will change in unison and transiently reverse the power stroke of the beat toward the anterior. This change in power stroke sends the cell backward for a short time. The beat quickly returns to normal with the power stroke toward the posterior and the cell swims forward again in a new direction. There is a connection of this swimming behavior with membrane potential: forward swimming occurs as the membrane potential  $V_m$  is at rest; hyperpolarization increases beat frequency and the cell swims faster forward; depolarization decreases beat frequency and slows the cell (Machemer, 1974; Machemer, 1989); stronger depolarization above a

threshold triggers a regenerative calcium action potential that causes the cell to turn in its swimming path. The voltage gated calcium channels that are exclusively in the cilia carry the action potential current while K channels repolarize the cell to return the cell's  $V_m$  to rest and behavior to forward swimming state (Eckert, 1972; Eckert and Naito, 1972). It is the calcium entering the cilia through these channels that reverses the power stroke causing the cells to swim backward until ciliary calcium is sequestered or removed. Thus, the  $V_m$  controls the swimming behavior of the cells by controlling ciliary beat frequency for speed and frequency of action potentials for turns.

As the cells move through their environment of pond or stream in a random walk of smooth runs and random turns, chemical stimuli bias that walk. Attractants hyperpolarize the cells causing smoother swimming and fewer turns; repellents depolarize causing action potentials, slower swimming and more turns (Preston and Van Houten, 1987; Van Houten, 1978; Van Houten, 1979). These seemingly subtle changes in behavior are very effective in accumulating groups of cells, paramecia or bacteria, in areas of attractants or dispersing them away from repellents. (See (Valentine et al., 2008) and (Bell and Van Houten, 2008) for a historical perspective and foundational research that cannot be covered here).

A special feature of *P. tetraurelia* is the numerous behavioral mutants that have proven to be very helpful in dissecting the swimming components essential for chemoresponse. Pawn mutants that cannot swim backward for lack of the ciliary voltage-gated calcium conductance (Kung and Saimi, 1982; Saimi and Kung, 1987) cannot accumulate or disperse from attractants and repellents, except in rare situations where there are extremes of hyper- or de-polarization that cause attraction or repulsion by modulating speed alone (Van Houten, 1978). Other behavioral mutants made it possible to dissect the behavior

**Figure 21.13** Tracks of swimming cells in 5 mM K-L-glutamate in buffer and 1 mM K2IMP in buffer. Tracks were generated by analysis of videotapes of the swimming cells that swim fast and smoothly in glutamate and more slowly with frequent turns in IMP (Van Houten, 1998).

and membrane conductances involved in accumulation in the attractants biotin and acetate (Bell et al., 2007). The mutants helped to determine that the immediate onset of smooth fast swimming when cells are first exposed to acetate (on-response) is critical for successful attraction. In contrast, the off-response, when biotin is first removed and turning starts, is very pronounced and critical for accumulation of cells in this attractant. Because these mutants have been characterized by electrophysiology as well as swimming behavior (Preston et al., 1991; Preston and Kung, 1994), it was possible to use them to attribute ion conductances to the on- and off-responses in these stimuli (Bell et al., 2007).

Chemical stimuli for *P. tetraurelia* come in a variety of structures. Attractants include acetate, biotin, D- and L-glutamate, lactate, extracellular cyclic AMP, ammonium, and peptides like glutathione that are secreted or derived from bacteria. Since *P. tetraurelia* feed on bacteria, these attractants likely signify that food is present. Repellents include extremes of pH, high ionic strength, organic compounds like quinine and quinidine, inosine monophosphate (IMP), GTP, and ATP, and some compounds that serve as odorants and tastants in vertebrates (Clark et al., 1993; Rodgers et al., 2008; Van Houten et al., 2010a; Van Houten, 2000). Other than signifying sub-optimal conditions for growth, there is less of a simple rationale for repellents than for attractants.

There are at least three pathways for attractant chemoresponse in *P. tetraurelia* (Figure 21.14, reviewed in (Valentine et al., 2008; Van Houten, 2000)). In common to all of the pathways is the activation of a K conductance that hyperpolarizes the cell and causes smooth fast swimming characteristic of attractants. The stimuli folate, acetate, cyclic AMP, and biotin initiate the first pathway that includes Ca/calmodulin as the second messenger and also activation of the plasma membrane calcium pumps by Ca/calmodulin to sustain the hyperpolarization.

The second pathway has one known stimulus, L-glutamate. Glutamate rapidly activates a K conductance (Preston and Usherwood, 1988) and an adenylyl cyclase resulting in elevation of intracellular cAMP levels within 30 msec (Yang et al., 1997). This increase in intracellular cAMP is not seen in cells stimulated by acetate or ammonium, for example. The second messenger cAMP activates protein kinase A (PKA), whose participation in glutamate chemoresponse was shown through kinase inhibitor and RNA interference studies (Valentine et al., 2008; Van Houten et al., 2000). In turn, the increased cAMP and activation of PKA should be sufficient to cause the changes in ciliary beat that underlie the fast smooth swimming in glutamate because it has been established long ago that ciliary beat frequency increases with cAMP and activation of PKA (Bonini et al., 1986; Hamasaki

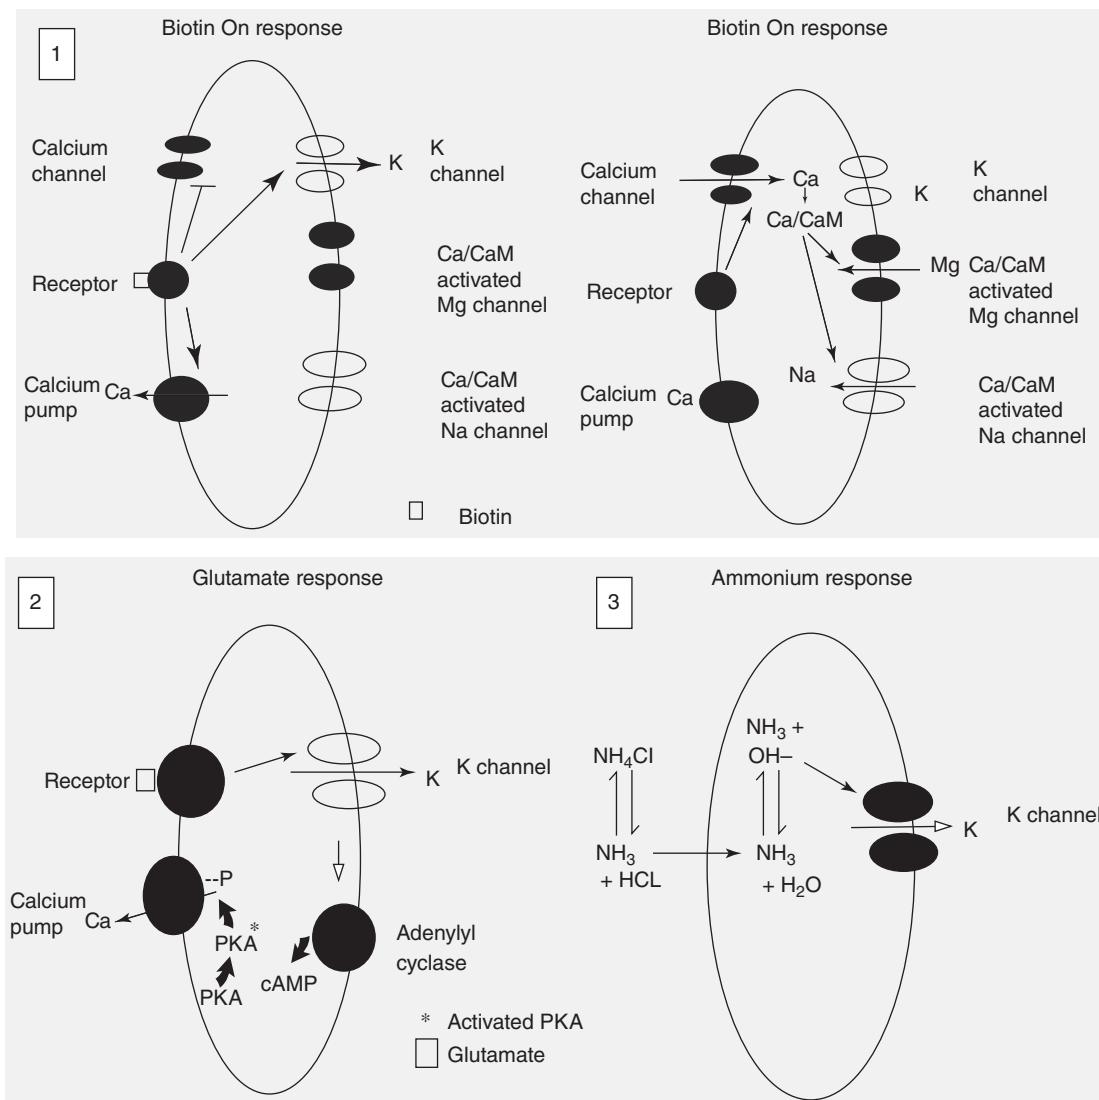

et al., 1991; Nakaoka and Machemer, 1990; Noguchi et al., 2003; Pech, 1995; Schultz et al., 1992).

Mammals can taste amino acids, including L-glutamate, which is a stimulus for umami taste. L-glutamate is detected by mammals through at least two types of 7-trans-membrane receptors: heterodimers of taste type 1 receptors (T1R1 and T1R3) as well as metabotropic glutamate receptors 1 and 4 (Chaudhari et al., 2009). A hallmark of umami taste is the synergy of glutamate with 5'ribonucleotides, which can be explained in part by the structure of the T1R receptors (Zhang et al., 2008). While the mechanism is not yet known, *P. tetraurelia* chemoresponse, likewise, shows synergy of glutamate and GMP stimulation on attraction behavior. However, in a departure from the mammalian pattern, IMP does not synergize with glutamate and even serves as a strong repellent (Van Houten et al., 2000). If we look for parallels between protozoan and mammalian systems, perhaps the *P. tetraurelia* response to glutamate, IMP and GMP are more similar to those of taste cells in the gut (Egan and Margolskee, 2008) that respond to glutamate and IMP with different temporal and signaling patterns (Tsurugizawa et al., 2011).

The third pathway *P. tetraurelia* chemoresponse is for the stimulus ammonium and has no apparent receptor (Figure 21.14) (Davis et al., 1998). Ammonium diffuses into the cell and very rapidly increases the intracellular pH. The cells swim fast and smoothly in ammonium suggesting once again that the attractant stimulus elicits a K conductance to hyperpolarize the cells. Trimeric G proteins, although present in *P. tetraurelia*, are only indirectly implicated by pertussis toxin effects on chemoresponse to acetate and ammonium (de Ondarza et al., 2003).

The varied attractant chemical stimuli for *P. tetraurelia* have a variety of cognate chemo-receptors. Receptors associated with Pathway 1 include a folate receptor that is a GPI anchored peripheral protein and redundant cAMP receptors that are expressed from two related proteins both of which appear to code for 7-transmembrane proteins (Paquette et al., 2001; Yano et al., 2003) Czapla thesis (Weeraratne, 2007). The Pathway 2 that signals the presence of glutamate is mediated by an NMDA Receptor Associated Protein (Jacobs, 2007; Romanovitch, 2012; Valentine et al., 2008). Cells of a different species, *P. primaurelia*, respond to agonists of  $\gamma$ -aminobutyric acid receptors ( $GABA_B$ ) with reduction in duration of backward swimming, implying a shortened duration of voltage gated calcium channels conductances (Ramoino et al., 2003). The source of the natural ligand may be the GABA that is released from these cells.

There is no evidence for bacteria-style quorum sensing in *Paramecium*, which was recently reinforced by experiments with *P. caudatum* that implicated physical

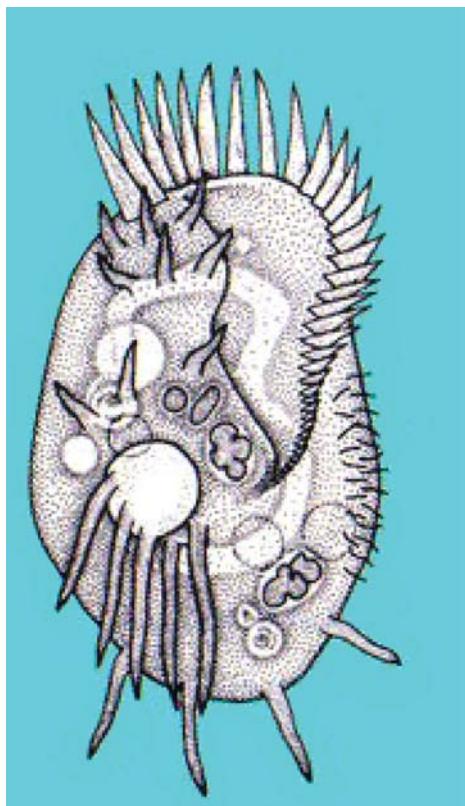

**Figure 21.14** Three pathways for *Paramecium tetraurelia* attractant chemoresponse. Pathway 1) shows signaling for stimuli biotin, acetate, cyclic AMP; Pathway 2) shows signaling for stimulus L-glutamate; and Pathway 3) shows signaling for ammonium as a stimulus. (Modified from Van Houten, 2000).

interactions rather than soluble cues secreted into the medium in the dispersal of paramecia when they find themselves in dense populations (Fellous et al., 2012). An interesting contrast is the process by which swimming zoospores of the marine seaweed, *Enteromorpha*, select suitable substrates for settlement and development. The zoospores attach to bacteria of marine biofilms as choice substrates, and identify biofilms by exploiting the bacteria's own sensory system. The zoospores sense the bacterial quorum sensing acyl-homoserine lactone that plays a role in biofilm formation in the zoospores' quest for optimal substrates (Joint et al., 2002).

*Tetrahymena*, like *Paramecium*, move by beating the cilia that cover their surface and show attraction and

dispersal from chemical stimuli. Cells of these two genuses share repellent responses to lysozyme and nucleotide triphosphates, possibly through a polycation receptor (Keedy et al., 2003). While it has been known for a long time that *Paramecium* are repelled by compounds like quinine and quinidine that are bitter to mammals (see for *P. caudatum* (Oami, 1996; Oami, 1998)) and for review of *P. tetraurelia* behavior and electrophysiological response to quinidine (Valentine et al., 2008), more recently bitter and irritating stimuli were shown to elicit repellent swimming responses from *Tetrahymena* (Rodgers et al., 2008). *Tetrahymena* also share with mammals the ability to respond to bacterial peptides and even platelet derived growth factor, β-endorphin, and insulin (Christensen et al.,

**Figure 21.15** *Euplotes* (Encyclopedia of Life, <http://eol.org/pages/62158/overview>, D. Patterson).

2003; Kohidai et al., 2002; Koppelhus et al., 1994; Leick and Lindemose, 2007; Schneider et al., 2005).

*Euplotes* do not swim through their watery home as *Paramecium* cells do, but rather these ciliates creep around on the substratum using cilia fused into cirri for propulsion (Figure 21.15). While creeping in their marine or fresh water environment, the cells secrete their pheromones, which signify their mating type. Because these cells are diploid, they can secrete up to two different pheromones that are coded for in the repertoire of mating type genes in their genomes. When cells of different mating types come into the cloud of each other's pheromones, they become mating reactive and pairs form between cells of different or the same mating type. The chances that the roving *Euplotes* will come upon a cell of a different mating type are good because for *E. raikovi*, a marine ciliate, there are 12 possible alleles of the mating type locus and for *E. octocarinatus* there are 10 mating types determined by combinations expressed from four co-dominant alleles.

The structures of the pheromones and their receptors for *E. raikovi* provided an unexpected twist on pheromone function. The peptide pheromones of *E. raikovi* are 38–50 amino acids long and are secreted into the

surrounding medium where they bind to surface receptors that are derived from alternative splicing of the same transcript that codes for the pheromone. A pre-pro-pheromone is processed into the secreted pheromone and a pre-pro-pheromone sequence, which is longer than the pheromone by a novel N-terminal sequence, is processed into the membrane receptor. When the cells' receptors are bound to their pheromone that they secrete, the cells are stimulated to grow vegetatively and divide by mitosis. (DiGiuseppe et al., 2002; Ortenzi et al., 2000; Vallesi et al., 1995; Zahn et al., 2001). When the peptide pheromone is from a different mating type, this pheromone binds to the heterotypic receptor and shuts down the mitogenic signaling, allowing the cell to enter into mating and nuclear divisions for meiosis. Thus the pheromone serves an autocrine function, and, much like a mammalian peptide growth factor, binds to a single pass membrane receptor. However, in mammals, the peptide hormone sequence is unrelated to the receptor sequence. Additionally in mammals, the peptide hormone does not promote mating or sexual behavior, as in the case of *E. raikovi* (Luporini et al., 1995).

*E. vannus* and *E. crassus* takes a different behavioral strategy for attraction to bacteria, their food. The cells move forward slowly and jerk backward called side stepping (Ricci et al., 1987), a tactic that keeps them in the area of signals from their food. As for *Paramecium*, the behavior has electrophysiological correlates. *E. vannus* cells performing this “side stepping” motion to remain near food experience long depolarizations (Schwab et al., 2008; Stock et al., 1997).

## 21.7 CONCLUSION

To bring this review to a conclusion, it seems appropriate to reiterate that prokaryotic microbes have complex interactomes of proteins that detect stimuli and signal to the cell about the environment's collection of other organisms, food, hosts, and conditions. The output of the signaling often is a change in motility, but the cells also use chemical signaling to temporarily become multi-cellular and make longer term adjustments to the environment through changes in gene expression. Bacteria that interact with human epithelia have very complex effects upon the host and vice versa through secreted signals. We are beginning to appreciate this complexity and the implications that chemical signals from bacteria have for human health and disease: we influence our biota and they influence us.

The eukaryotic microbes are varied in their chemore-sponse systems, and, as for bacteria, the output of chemical signal detection often is modification of motility. Perhaps the most striking differences between prokaryotic and eukaryotic microbe chemical signaling are the structures of the receptors, adaptation through methylation used by

bacteria only, and kinase mechanisms. Bacteria extensively utilize two-component histidine kinase signaling in which the same phosphate is transferred from one protein to another in the signaling pathway. Eukaryotic microbes chemoreponses primarily utilize kinases that derive phosphate from ATP. While histidine kinases are known in plants and animals, they do not primarily play roles in chemical signaling. However, there continue to be new commonalities uncovered, such as the use of di-cGMP as a secreted morphogen by *Dictyostelium*.

## Olfaction in Insects

PAUL SZYSZKA and C. GIOVANNI GALIZIA

### 22.1 INTRODUCTION

Insects are the most species-rich group of animals on the planet. They have colonized almost every terrestrial habitat, each of which is characterized by its own unique odor profile. Although the olfactory systems of different insect species must deal with these diverse olfactory environments, their olfactory systems share remarkable similarities across species and even with mammals (Ache and Young, 2005). In this chapter we describe the challenges faced by the olfactory system of terrestrial insects and how insects cope with such challenges.

Most of what we know about insect olfaction derives from studying a few species, each with its own set of motivational influences. Honeybees are the most important pollinators and use odors to find flowers, moths are among the most devastating crop pests which cause enormous losses to the economy each year, mosquitoes are disease vectors that cause millions of deaths every year, locusts form large swarms that wipe out crops, and fruit flies have become the most important insect model species to study molecular mechanisms of olfaction. Since all of these insects use olfaction as a primary sensory modality, it is important to know how their olfactory systems work in order to control them. In this chapter we describe the basic circuitry of odor coding in the insect brain, and present example where odors are used in an insect's life.

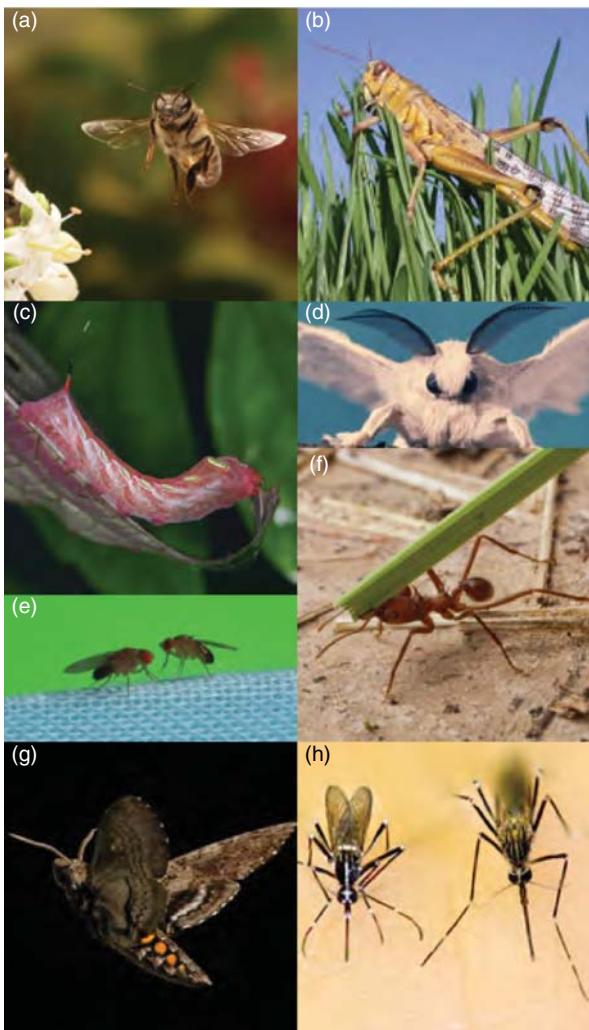

### 22.2 HOW INSECTS RESPOND TO ODORS

For many insects, olfaction is *the* main sensory system – they live in an olfactory world. In this section a few

examples of how odors are used by different insects are provided, taking into account the large variety of behaviors across species. Most commonly, insects use odorants for habitat localization, foraging, sexual reproduction, social communication and orientation.

Like mammals, including humans, insects need to identify odors that have innate meanings, learn new odors and their relevance, extract high-speed temporal information, and either distinguish or generalize across odors and their different concentrations. The main difference may consist in the temporal structure: mammals synchronize odor-driven activity to their breathing cycle, which is coupled to the inhalation of odorants (Macrides and Chorover, 1972). It has been proposed that insects fan their wings to induce a similar temporal structure (Loudon and Koehl, 2000), but that remains to be shown. Most importantly, the neural networks that process odor-information in the insect's brain follow the same logic as those of mammals. Thus, knowledge obtained from insects helps us in understanding our own olfactory system. However, understanding insect olfaction is also important in its own right: mosquitoes use odors to find us, with all the consequences for many mosquito transmitted diseases such as malaria and Dengue fever. Crop pests (e.g., different moth and beetle species) destroy an important portion of our food staples, both on the fields and in the warehouses, and they too use odors both to find their substrate, and to proliferate. And many pollinators – including honeybees – are essential for our harvest: they all find the flowers by smell. Thus, insect olfaction is important for agriculture, food supply, and public health. Understanding how it works will put us in a position to better protect, influence, and control our environment.

A generalist insect, such as the honeybee *Apis mellifera* (Figure 22.1a), exploits a variety of plant species.

**Figure 22.1** Insect model species for studying olfaction. Insects differ greatly in their behavior and environment. Note the different shapes of their antennae, which are their olfactory organs. (a) *Apis mellifera*, (b) *Schistocerca gregaria*, (c) *Manduca sexta* larva, (d) *Bombyx mori*, (e) *Drosophila melanogaster*, (f) *Atta vollenweideri*, (g) *Manduca sexta*, (h) *Aedes albopictus* & *A. japonicus*. Images were taken by John C. Abbott (a), David Gustav (b), Krushnamegh Kunte (c), R. Alexander Steinbrecht (d), C. Giovanni Galizia (e), Christoph J. Kleineidam (f), Armin Hinterwirth (g) and Ary Farajollahi (h). (See plate section for color version.)

During foraging a honeybee learns the odor of a flower that provides nectar and pollen. The relationship between odors and food can change within a short period of time. Old food sources run dry and new ones appear. Thus, the meaning of odors is ephemeral and generalist insects must code for many different and unpredictable odors. A specialist insect, in contrast, interacts with just a single or few plants, and thus has to code for a few, evolutionary determined odors. Pest insects like the desert locust *Schistocerca gregaria* (Figure 22.1b) or the hawk moth *Manduca sexta*

(a larva shown in Figure 22.1c, adult in 1g) are innately attracted by odors associated with their favorite foods and host plants. Intraspecific communication often makes use of pheromones, specialized odors that are directly related to behavior.<sup>1</sup> A sexually active male silk moth *Bombyx mori* (Figure 22.1d) detects and is attracted by single molecules of bombykol, the major sex pheromone component emitted by females (Butenandt, Groschel et al., 1959). Male fruit flies, *Drosophila melanogaster*, (Figure 22.1e) initiate courtship behavior by releasing the pheromone cis-vaccenyl acetate (Bartelt, 1985). Leafcutter ants of the genus *Atta* (Figure 22.1f) use pheromones to mark trails between their nest and food sources. These pheromones contain two major components which are sufficient to elicit trail-following. The ratio of both defines the species-specificity and allows different *Atta* species to distinguish between con- and heterospecific trails (Kleineidam et al., 2007). Flying insects, for example, moths (Figure 22.1g), possess a remarkable ability to identify and track a single odor in a highly turbulent, multi-odor background. This ability relies on analyzing the temporal structure of odor plumes, which contains information about the distance and location of the odor source (Vickers, 2000; Carde and Willis, 2008). The intermittent pulses of the sex pheromone released by a female moth provide the searching male with orientation cues (Justus et al., 2002). Mosquitoes are the most important vectors for arboviruses (arthropod-borne viruses). Mosquitoes such as *Aedes* (Figure 22.1h) find their blood meal following specific odors including ammonia and lactic acid, and fluctuating concentrations of CO<sub>2</sub> (Geier et al., 1999). Tritrophic interactions are particularly intriguing: As a response to feeding caterpillars, mediated by the saliva of the caterpillars, plants can attract parasitoid wasps by releasing particular semiochemicals. The wasps lay their eggs into the caterpillar, eventually killing it. A famous example of such an interaction is that of the butterfly *Pieris* and Brussels sprouts *Brassica oleracea* (Vet and Dicke, 1992).

## 22.2.1 The Olfactory Pathway: from Antenna to Mushroom Body

One of the important differences between humans and insect olfaction is the contact surface: while we have our odor-receptor cells in the mucosa in the nose, insects have a rigid exoskeleton, a chitinous cuticle with no mucosae.

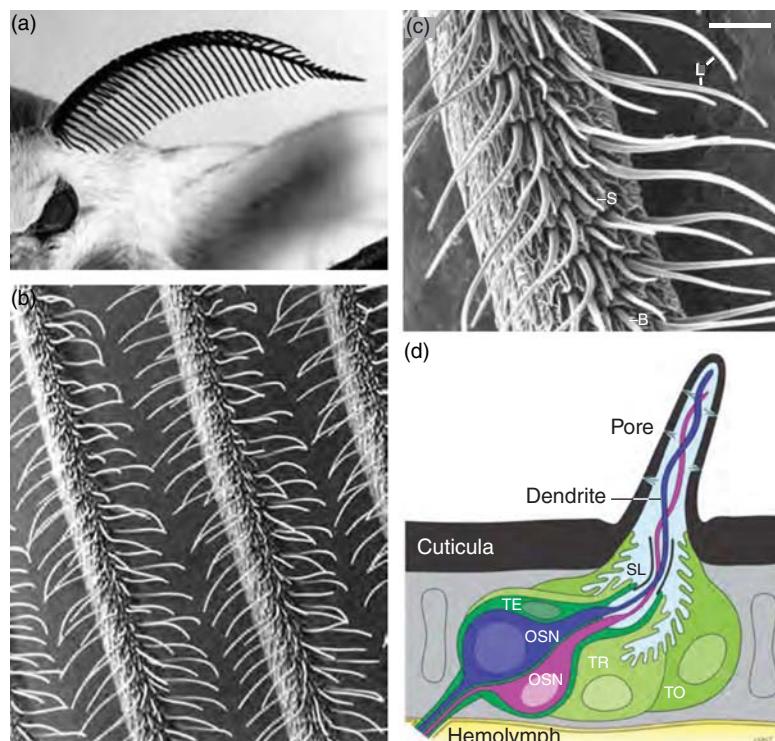

<sup>1</sup>The term pheromone was coined in 1959 to replace the term ectohormone (external hormone) in insects. Karlson and Lüscher (1959) defined pheromones as “substances which are secreted to the outside by an individual and received by a second individual of the same species, in which they release a specific reaction, for example, a definite behavioral or a development process.” See Doty (2010) for a critical discussion of the pheromone concept, especially when applied to mammals.

Their olfactory neurons are housed in so-called sensilla, which are often hair-like structures with pores (de Bruyne and Baker, 2008) (Figure 22.2). Odors enter the pores and reach the inner lumen of the sensillum, which is filled with sensillar lymph. The dendrites of olfactory sensory neurons (OSN) protrude into the sensillar lymph, so that odor molecules can reach them and elicit a neural response. Thus, in a way similar to mammals, odors have to pass a liquid phase (the sensillar lymph in insects, the mucous in mammals), before reaching the sensory neurons. Not all sensilla are hair-shaped. Indeed, there are many different sensilla shapes, short and long, flat and invaginated. Also, the number of sensory cells in each sensillum can vary from two to several dozens. The sensory neuron types are not randomly distributed across sensilla. For example, in male moths, which are highly sensitive to the female pheromone, the pheromone receptors are housed in very long sensilla trichodea (hair-like sensilla) which form a sieve-like structure that is capable of capturing every single odor molecule in the air (Figure 22.2a-c). Usually, each sensillum trichodeum has two OSNs, one for each of the two main pheromone components, thus allowing the animal to efficiently identify the species-specific pheromone blend. Olfactory sensilla are generally located on the insects' antennae, though in some species other body parts also have olfactory neurons, for example, the maxillary palps in flies.

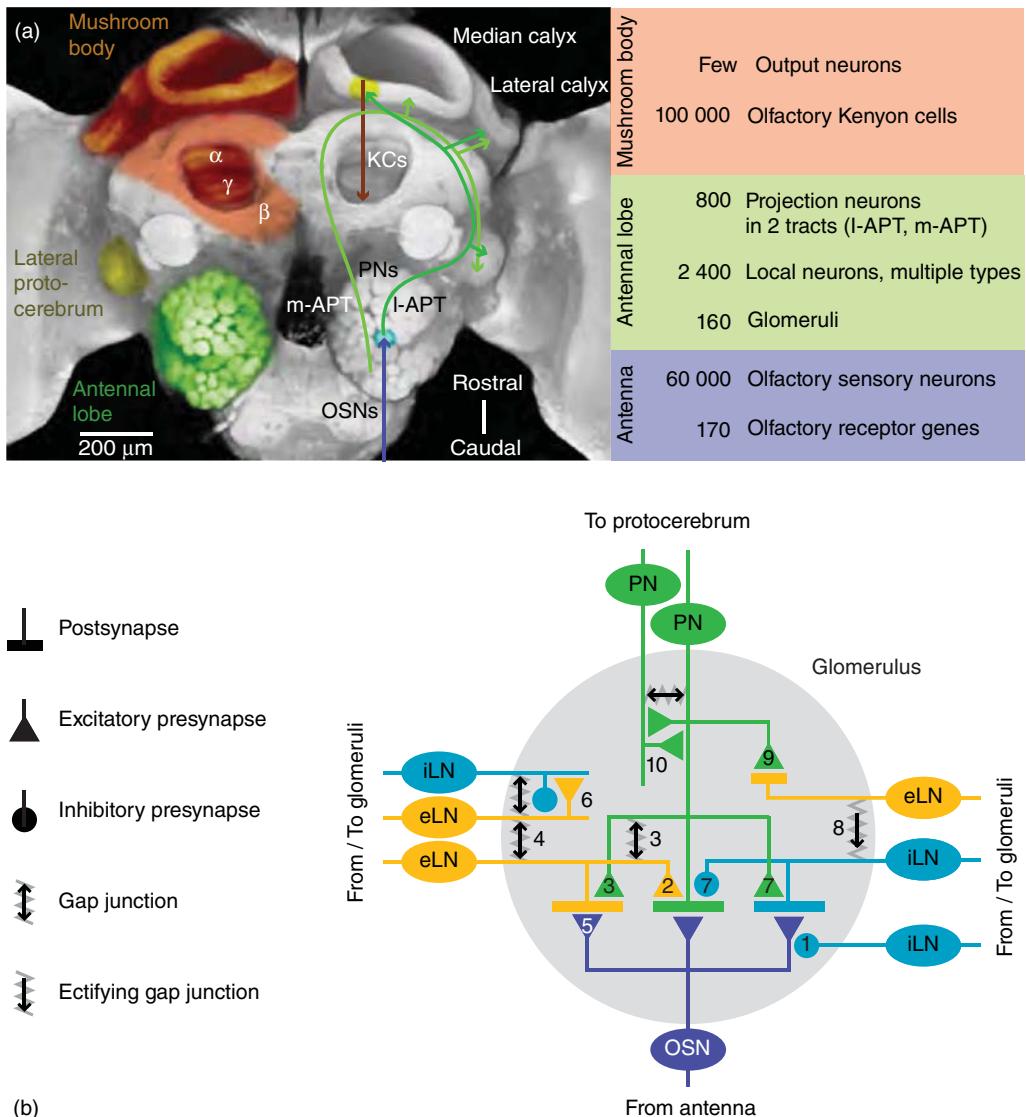

Olfactory processing begins in OSNs. In the fruitfly *Drosophila*, each OSN expresses one or a few olfactory

receptor proteins which differ in their affinity to odors (Larsson et al., 2004; Couto et al., 2005; Fishilevich and Vosshall, 2005). Insect olfactory receptors are 7-transmembrane proteins with their N-terminus facing to the cytosol (Benton et al., 2006). This is an inverted topology as compared to G-protein coupled 7-transmembrane proteins, which is the family of molecules of mammalian olfactory receptors, implying that insect olfactory receptors and mammalian olfactory receptors have evolved independently. In fact, insect olfactory receptors belong to a family of gustatory receptors that is very ancient in evolution but which has been lost in vertebrates. In order to function, each olfactory receptor protein needs to form a heterodimer with another 7-transmembrane protein called Orco (Sato et al., 2008; Wicher et al., 2008; Vosshall and Hansson, 2011). In contrast to mammalian receptors which are metabotropic, insect olfactory receptors act as ligand gated channels, with metabotropic auto-regulation (Nakagawa and Vosshall, 2009; Silbering and Benton, 2010). Some OSNs do not express olfactory receptors, but sense odors with ligand-gated ion channels (IR) which share some homology with ionotropic glutamate receptors (Benton et al., 2009; Grosjean et al., 2011; Silbering et al., 2011).

OSNs send their axons into the primary olfactory brain area, the antennal lobe (Figure 22.3a). In structure and wiring logic the antennal lobe is very similar to the mammalian olfactory bulb. The antennal lobe is subdivided into glomeruli. OSNs with the same receptor proteins

**Figure 22.2** Olfactory sensory neurons are housed in sensilla. (a) Antenna of a male silk moth *Bombyx mori*. (b) Scanning electron micrograph of the sieve-like antenna. (c) Single antennal branch with different sensillum types: long sensilla trichodea (L), short sensilla trichodea (S) and sensilla basiconica (B). (d) Basic structure of a sensillum. Pores in the cuticle allow odors to enter the sensillar lymph (SL). Odor receptors are located in the dendrites of olfactory sensory neurons (OSN). Non-neuronal accessory cells, the thecogen (TE), tormogen (TO) and the trichogen (TR), produce the sensillar lymph and shield it from OSNs' somata and inner part of their dendrites and from the hemolymph (insects' circulatory fluid). (Images were kindly provided by R. Alexander Steinbrecht and modified)

**Figure 22.3** The insect olfactory pathway. (a) View of the honeybee central olfactory system (Kindly provided by Randolph Menzel and modified). Olfactory sensory neurons (ORN, blue arrow) terminate in the antennal lobe glomeruli. Uniglomerular projection neurons (PN, green) transmit odor information from the antennal lobe to the mushroom body and to the lateral protocerebrum. PN axons project along the lateral or median antenno-protocerebral tract (I-APT, m-APT) to the lateral and medial calyces. The mushroom body intrinsic Kenyon cells (KC, red) send their axons into the mushroom body lobes, where they contact mushroom body extrinsic neurons. The yellow area in the calyx represents the Kenyon cells' dendritic field. (b) Collection of synaptic connections within a glomerulus in antennal lobe of *Drosophila*. Left: types of synaptic connections. Right: known synaptic connections between olfactory sensory neurons (OSN), excitatory local neurons (eLN), inhibitory neurons (iLN) and projection neurons (PN). Numbers refer to studies which described the respective synaptic connections: 1. lateral, interglomerular presynaptic inhibition by GABAergic iLN-to-OSN synapses (Olsen and Wilson, 2008; Root, Masuyama et al., 2008); 2. lateral, interglomerular excitation by cholinergic eLN-to-PN synapses (Olsen, Bhandawat et al., 2007; Shang, Claridge-Chang et al., 2007); 3. reciprocal excitatory krasavietz eLN-PN connections through gap junctions and cholinergic synapses (Huang, Zhang et al., 2010; Yaksi and Wilson, 2010); 4. reciprocal excitatory krasavietz eLN-eLN connections through gap junctions and cholinergic synapses (Huang, Zhang et al., 2010); 5. excitatory OSN-to-krasavietz eLN synapses (Huang, Zhang et al., 2010); 6. reciprocal krasavietz eLN-iLN connections through gap junctions and cholinergic synapses (Yaksi and Wilson, 2010); 7. reciprocal PNs-iLN connections through cholinergic and GABAergic synapses (Sudhakaran, Holohan et al., 2012); 8. rectifying electrical eLN-iLN synapses (Sudhakaran, Holohan et al., 2012) 9. excitatory PN-to-eLN synapses (Sudhakaran, Holohan et al., 2012) 10. reciprocal, intraglomerular PN-PN connections through gap junctions and cholinergic synapses (Yaksi and Wilson, 2010) (See plate section for color version.)

converge onto the same glomerulus, and thus provide every glomerulus with a distinct response profile (Vosshall et al., 2000). The output of a glomerulus is carried via projection neurons (PN) to higher order brain centers. Within the antennal lobe a network of intra- and inter-glomerular inhibitory local neurons (iLN) and excitatory local neurons (eLN) is involved in odor processing (Sachse and Galizia, 2002; Olsen et al., 2007; Shang et al., 2007; Silbering and Galizia, 2007; Silbering et al., 2008) (Figure 22.3b). Odor representations in PNs are therefore a result of the interaction of many neurons in the antennal lobe. PNs relay odor information to various areas in the brain. The most prominent ones are the mushroom bodies, named this way because their shape is reminiscent of the stipes and caps of mushrooms, and the lateral protocerebrum (“protocerebrum” is the name for the most anterior part of the insect brain). The mushroom bodies play an important role in odor learning and memory formation (Menzel, 2001; Heisenberg, 2003; Davis, 2011), the lateral protocerebrum is thought to be the structure with the first premotoneurons – thus controlling the insect’s behavior. In many species the mushroom bodies are multimodal and not only receive information from the olfactory system, but also from visual, tactile, and other modalities (Mobbs, 1982; Strausfeld, 2002; Strausfeld et al., 2003).

Mushroom bodies consist of densely packed neurons, the Kenyon cells. While Kenyon cells’ somata surround the calyces, their dendrites branch into them, and their axons travel along the lobes – that is, the “stipe” of the mushroom. The population of Kenyon cells is generally very large, ranging from about 2500 in the fruitfly *Drosophila melanogaster* to about 170,000 in honeybees (with a total of 340,000 Kenyon cells, they represent every third neuron in the bee’s 1,000,000 neuron large brain). The main input sides are the calyces, while the lobes are the main output sides (Figure 22.3a). The connectivity between PNs and Kenyon cells is characterized by divergence and convergence. Each PN branches over extensive portions of the calyces, and synapses onto many Kenyon cells. In the honeybee, for example, about 800 PNs diverge onto roughly 100,000 olfactory Kenyon cells. Each Kenyon cell in turn receives input from multiple PNs. In locusts, each Kenyon cell gets input from about 50% of about 800 PNs (Jortner, Farivar et al., 2007).

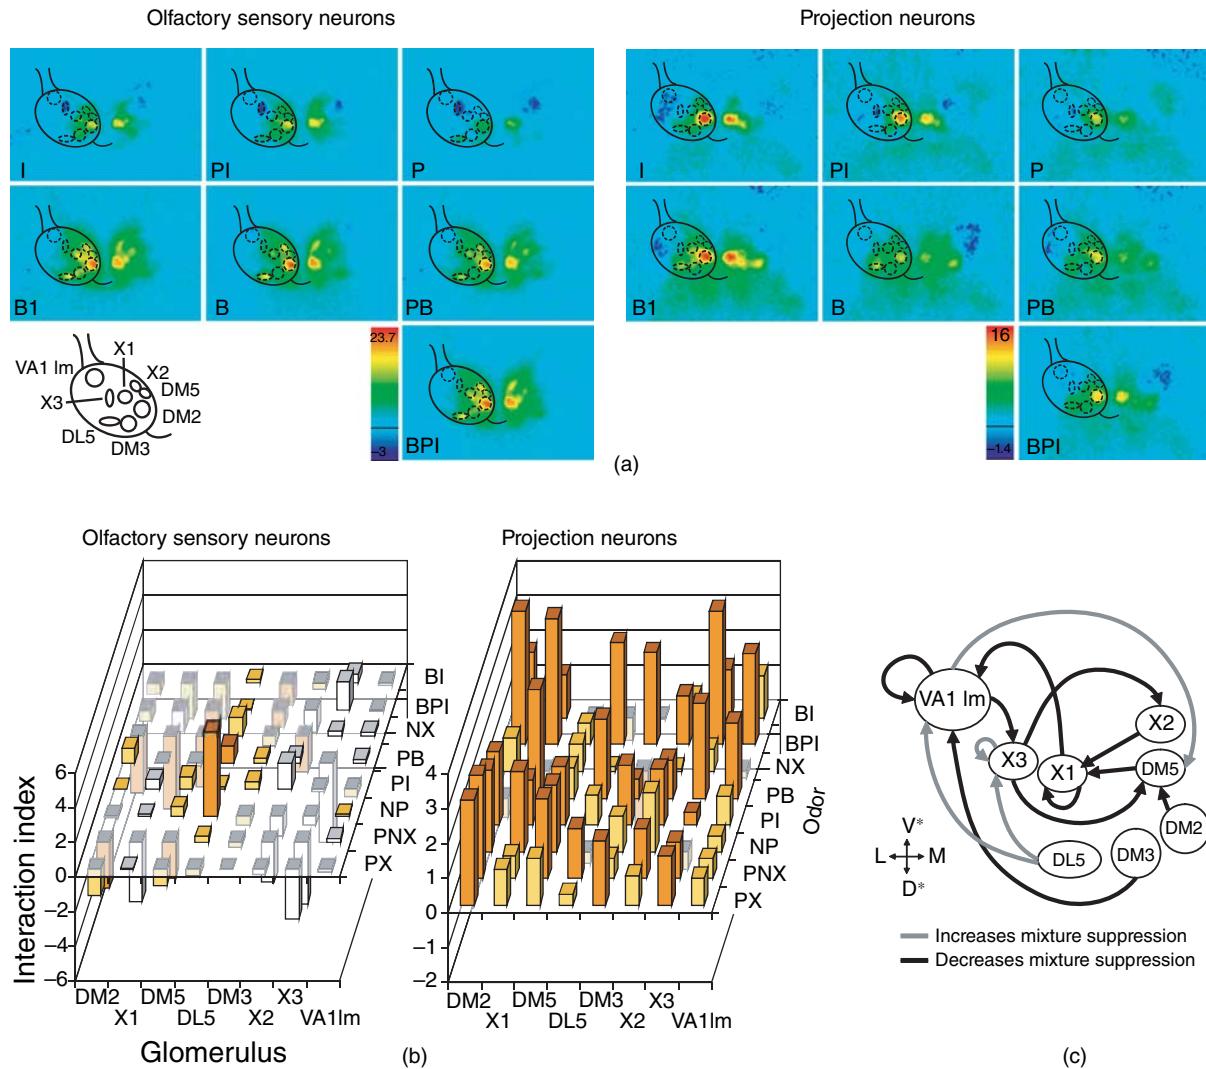

The glomerular map of the antennal lobe is transformed into a different map in the mushroom body. While inputs from different OSNs are spatially segregated in different glomeruli in the antennal lobe, they appear to partially overlap in the mushroom body, where information from distinct glomeruli is distributed onto many Kenyon cells across the calyces. Nevertheless, each odor stimulus creates a characteristic, combinatorial activity pattern in

the antennal lobe, and also across Kenyon cells in the mushroom bodies (Perez-Orive et al., 2002; Szyszka et al., 2005; Turner et al., 2008). Just as in the antennal lobe, there are complex internal networks within mushroom bodies. There are local networks within the calyx which involve reciprocal microcircuits between the bouton-like PN terminals, G Neurons employing gamma-aminobutyric acid (GABAergic neurons) and Kenyon cells (Ganeshina and Menzel, 2001; Christiansen, Zube et al., 2011), and there are more widespread circuits with feedback from the lobes back to the calyx (Grunewald, 1999; Grunewald, 1999; Strausfeld, 2002; Papadopoulou et al., 2011).

Odor representations in the lateral protocerebrum follow a different logic. It is often assumed that the lateral protocerebrum encodes innately meaningful odors and translates them into behavioral response. However, a recent study in locusts did not find support for this view and rather suggests that it plays a role in extracting general stimulus features and integrating bilateral and multimodal sensory information (Gupta and Stopfer, 2012). In the *Drosophila* lateral protocerebrum projection neurons (PNS) target different areas dependent of whether they are activated by fruit odors or pheromones (Jefferis et al., 2007). In fact, one area of the lateral protocerebrum appears to be dedicated to appetitive behavior, one to aversive behavior, and one to sexual behavior. The detailed circuitry, however, remains to be elucidated.

### 22.2.2 The Coding of General Odors: Combinatorial Odor Coding

How are general, non-pheromonal odors encoded in insect brains, along the antenna-antennal lobe-higher brain centers pathway? To start with: how do odor responses look like in the antennal lobe? First, the morphology and size of antennal lobes differs widely among insects: *Drosophila melanogaster* has about 50 glomeruli (Laissue et al., 1999), moths such as *Heliothis virescens* and *Manduca sexta* about 70 (Rospars and Hildebrand, 1992; Berg et al., 2002), honeybees about 160 (Flanagan and Mercer, 1989a; Galizia et al., 1999a), and several ant species over 300 (Kelber et al., 2009). Most glomeruli are stereotypic across individuals within a species and can therefore be identified, often already on the basis of their shape, relative position and response profile (Figure 22.4a) (Galizia et al., 1999b). This stereotypical arrangement reflects the one-to-one mapping of receptor populations onto glomeruli, dictated by the number of genes in the genome for odorant-sensor proteins. But despite this variability, it appears that the basic coding mechanisms are the same, and indeed very similar to that of mammals, including humans. The simple one-to-one connectivity between OSNs and glomeruli is

**Figure 22.4** Analytic and synthetic odor representations in the antennal lobe of *Drosophila*. (a) Optically recorded glomerular calcium responses in OSNs (left) and in PNs (right) in *Drosophila*. The numbers on the color scale indicate the maximum and minimum  $\Delta F/F$  (%). Odors were isopentyl acetate (I), propionic acid (P), 1-butanol (B) and all binary mixtures (BI, PI, PB), and the ternary mixture (BPI). The mask over the left AL shows the position of eight identified glomeruli. Note that the best odor for a given mixture in a given glomerulus was not always the same for OSNs and PNs, indicating that the antennal lobe network shapes the antennal lobe output. (b) Mixture interaction index ([response to the best component for the corresponding mixture] – [response to the mixture]) for OSNs and PNs. Positive values show inhibitory mixture interactions. OSNs represent mixtures in an *analytic* way as their responses could mostly be predicted from the components' responses, thus preserving component information. PNs show strong inhibitory mixture interactions, showing that the antennal lobe network processes mixtures in a *synthetic* way, which leads to a loss of component information. (c) Glomerulus-specific interactions shape antennal lobe output. Circles indicate identified glomeruli (X1, X2, VA1Im, etc.) and arrows indicate functional connectivity between the glomeruli. The black arrows reflect decreased mixture suppression and the gray arrows increased mixture suppression. For example, the black arrow from glomerulus X1 to glomerulus VA1Im indicates that OSN activity in glomerulus X1 positively affects the PN activity in glomerulus VA1Im, thereby decreasing mixture suppression in VA1Im. Similarly, for example, the gray arrow from glomerulus VA1Im to glomerulus DM5 indicates that OSN activity in VA1Im negatively affects the PN activity in glomerulus DM5, thereby increasing mixture suppression in DM5. (modified from Silbering and Galizia, 2007). (See plate section for color version.)

contrasted by a complex intra- and interglomerular network within the antennal lobe (Figure 22.3b), suggesting that the antennal lobe, like its mammalian counterpart, the olfactory bulb, is far more than a mere relay station for odor information. We will look at a few exemplary tasks of this circuit: signal-to-noise improvement, contrast enhancement, concentration coding, odor-mixture processing, and odor discrimination.

### 22.2.3 Signal to Noise Improvement

Among the most important properties in any sensory system is sensitivity. Our own photoreceptors are so sensitive that a single photon can elicit a neural response. Similarly, a single molecule of a pheromone can elicit a signal in the sensory neuron of a moth. However, these single events are not sufficient to recognize an odor source: as noted above, pheromones come in mixtures at a given concentration ratio, and thus many single molecule events have to occur. The glomerular structure in the antennal lobe is ideally suited to create the appropriate readout: all OSNs with equal response properties converge onto a single glomerulus. Assuming that the temporal distribution of action potentials would be a random (Poisson) event, then the inherent noise is related to the total number of action potentials as the square root, that is, with 100 action potentials, the standard deviation would be 10, and the signals-to-noise (s/n) would be 100:10, that is, 10% noise. With 10,000 action potentials, the noise would be 100 (square root), and s/n be 10,000:100, that is, 1% noise. Whether these action potentials come from a single neuron or from many does not matter, if they are all collected in the same glomerulus, and therefore, the more sensory neurons a system has, the higher the potential to increase s/n. It is no surprise, then, that sexual-pheromone sensitive glomeruli are particularly large: they collect the largest number of OSN axons, and achieve the highest s/n in the system!

### 22.2.4 Contrast Enhancement

Most OSNs have broad response profiles, that is, they do not respond to a single substance only, but rather to many (de Bruyne et al., 2001; Hallem et al., 2004; Galizia et al., 2010). This is an important property of olfactory systems: assume a fruit fly with 60 OSN types would only have highly selective OSNs. The olfactory environment of this animal would consist only of odors consisting of these substances, that is, 60 distinct odorants and their mixtures (still, a vast landscape of potential stimuli), and any odor-source that would not emit at least one of

these 60 substances would be odorless to the animal. This problem is solved by using generalist OSNs, which respond to many substances. Here, the requirements to the network, however, increase, because extracting odor identity becomes more difficult. For example, take a two receptor case: substance A would activate receptor 1 strongly, and receptor 2 weakly, substance B would elicit the opposite pattern. Thus, both substances elicit activity in both receptors, creating a somewhat ambiguous situation. (In fact, with such properties, it is impossible to solve ambiguity: in most cases different odor-mixtures exist that could elicit the same response pattern. The situation is similar to our color vision, where different color spectra can elicit identical color perception even under otherwise identical conditions). The antennal lobe increases the contrast in this situation, in two distinct ways. A network of interglomerular inhibitory neurons is activated by all odor-inputs, with the capacity of inhibiting all glomeruli (Figure 22.4) (Sachse and Galizia, 2002; Silbering and Galizia, 2007). Thus, weak glomeruli are reduced below threshold, while strong glomeruli remain active, creating a more distinctive activity pattern (Sachse and Galizia, 2003; Silbering et al., 2008) (this is related to “winner-take-all,” but different in that the winner is not a glomerulus, but a pattern). Furthermore, each local neuron has a distinctive innervation pattern: some innervate all glomeruli, others only a subpopulation (Flanagan and Mercer, 1989b; Sun et al., 1993; Chou et al., 2010). The latter group of neurons can compute odor-specific contrasts, and therefore optimize the representation of odor combinations that are innately important. Because these connections can change during the life time, also odors that are learned can be optimized by the experience of the animal (Fernandez et al., 2009; Rath et al., 2011).

### 22.2.5 Concentration Coding and Gain Control

The concentration of olfactory stimuli can span a wide range. A honeybee experiences a flower odor at high concentration when she learns the odor while sitting inside the flower and drinking the nectar. On a subsequent foraging flight, however, she has to detect and identify the same odor in the air at a concentration that is several magnitudes lower in concentration. Thus insects have to generalize across a wide range of concentrations. On the other hand, honeybees and *Drosophila* can be trained to discriminate between small concentration differences of the same odorants (Ditzen et al., 2003; Yarali et al., 2009). Individual OSNs typically have a dynamic range of two to three orders of magnitude (which is larger than most OSNs described in mammals). For example, a dOR22A receptor may begin

responding to ethyl hexanoate at a concentration of  $10^{-9}$  and may already saturate at a concentration of  $10^{-6}$ , with higher concentrations leading to the saturated response, or even to a decreased response (here, concentrations are given as dilutions of the odor in the olfactometer, not as molecules in stimulus air) (Pelz et al., 2006).

We have seen that s/n improvement (above) can lower the perceptual threshold. Adaptation of OSNs can increase the upper range: an animal in a smelly environment shifts its dose-response curve, so that odor-concentration differences can be perceived. Within the antennal lobe the network also improves concentration coding via a gain control mechanism: when no activity is present, excitatory activity “regulates” the projection neurons to be just active, creating a pattern of spontaneous activity (Sachse and Galizia, 2003; Root et al., 2007, 2008; Olsen and Wilson, 2008). Thus, even minute stimuli will already create a suprathreshold excitation: the signal is amplified. Conversely, at high concentration, the inhibitory lateral network pushes activity down (Das et al., 2011), enhancing interglomerular contrast (Silbering et al., 2008), and flattening the dose-response curves (Sachse and Galizia, 2002). This leads to a great enhancement of the dynamic range of odor concentrations that can be processed within the system. The interplay between excitatory local neurons and inhibitory local neurons is essential for gain control and concentration processing (Root et al., 2008; Silbering et al., 2008; Acebes et al., 2012). The olfactory system needs to extract both, information about the odor’s concentration, and a concentration-invariant information about odor quality. Interestingly, PNs with concentration independent odor-quality responses have been reported (Stopfer et al., 2003; Yamagata et al., 2009).

### 22.2.6 Odor-mixture Processing

Most naturally occurring odors are mixtures. Wine odor (so attractive to both humans and fruit flies) contains hundreds of different volatiles. It is this very high number of contributing substances that allows us to enjoy the large variety of wine odors, as well as many other odors. Just as occurs in humans, it is important to realize that an animal likely experiences the mixture as the perceptual unit (or Gestalt) of an odor. Thus, the brain does not extract the single odor components, but rather creates a synthetic representation of the odor mixture. We have seen examples where this concept is realized, and examples where it is not. In many species sexual pheromones are only behaviorally active when given at the right mixture (i.e., when the corresponding glomeruli have the right relative activity pattern). In contrast,  $\text{CO}_2$  is processed by highly selective receptors. However, whenever the corresponding glomerulus is active, the animal will react to  $\text{CO}_2$ , independently of co-occurring odors. At this

point it is important to note that even these “hard-wired” circuits are not strictly hard-wired. All olfactory processing is modulated by the internal state of the animal (sexual arousal, hunger, etc.), states that are generally mediated by large modulatory neurons that branch in many brain areas. Depending on their activity, a “stereotypic” olfactory stimulus may have a very strong behavioral effect, or even no effect at all.

Within the circuitry of the antennal lobes, inhibitory connections create mixture-unique patterns (Figure 22.4). Thus, both in behavior and in physiology, a mixture of two substances A and B does not elicit an overlay of A and B, but rather a new situation AB, with some similarity to A and to B, but also with distinct features (sometimes termed “unique cue”) characteristic of the mixture itself (Deisig et al., 2006, 2010; Carlsson et al., 2007; Silbering and Galizia, 2007; Riffell et al., 2009; Kuebler et al., 2011; Su et al., 2011). The amount of inhibition, and the similarity of the resulting pattern AB to its component patterns, differs widely depending on species and odor. In fact, this is in part driven by evolution, and hard wired (as with the mixture-specific cells that have been found in the sexual pheromone system of moths), and in part driven by experience. When a honeybee is trained to discriminate between two similar odor mixtures, the representation of these mixtures gradually changes in the brain to make them more dissimilar to each other, thus aiding their discrimination (Fernandez et al., 2009).

### 22.2.7 Processing of Concurrent Odors from Multiple Sources

The spatial and temporal structure of airborne odorants is determined by the physics of atmospheric dispersion (Murlis et al., 1992): close to the ground odors distribute mainly via diffusion and olfactory stimuli dynamics are comparably slow, due to the lack of turbulences. However, this changes completely above the laminar boundary layer: airborne odorants distribute in plumes that fluctuate at different timescales (Riffell et al., 2008). Individual odor-plumes can last and occur at intervals ranging from milliseconds to minutes. Since odor-plumes of different odor sources intermingle, the olfactory system needs to segregate concurrent odors from independent sources in order to recognize them as different odor-objects (Hopfield, 1991). Insects can exploit short temporal asynchronies between odor plume onsets to segregate odorants from different sources (Szyszka and Stierle, 2014). For honeybees, a 6-millisecond temporal difference in stimulus coherence is sufficient to segregate an odor-object from a background odor (Szyszka et al., 2012), and moths and beetles can distinguish plumes of attractive sex pheromone from plumes of a behavioral antagonistic odorant when they are separated by a few milliseconds (Baker et al., 1998; Andersson

et al., 2011). It is not clear how odor-background segregation based on millisecond stimulus onset-asynchrony is internally represented. In locusts and honeybees, neural representations of mixtures partly match those evoked by the individual components if their onsets differ by a 6 to 100 milliseconds (Broome et al., 2006, Stierle et al., 2013).

### 22.2.8 Discrimination and Generalization

Generalization and discrimination are the main challenges for an animal encountering mixtures. For example, the odors of flowers of the same plant species can differ due to flowering stages, pollination status and the time of the day (Phamdelegue et al., 1989; Schiestl et al., 1997). Discrimination is important to avoid landing on a flower that has no nectar. However, restricting odor recognition to a precise stimulus would not work either: in a natural situation, no two odors are alike. A flower growing on the sunny side of the meadow will smell slightly different from the same species on the shady side, or on a more alkaline soil. This creates a problem for insects such as the honeybee, which are flower constant during their foraging trips, that is, which harvest nectar from a single species as long as the food quality is good. For some very specialized insects the system is so strict that a dependent mutualism has evolved between the flower and the insect. Consequently, the insect has to generalize from one odor to different similar odors. Generalization is the counterpart to discrimination, and it is creating this borderline between “just similar enough to be judged as the same” and “so different that it must be something else” that creates one of the major coding tasks in the olfactory system. In *Drosophila*’s olfactory lobe, the network of local interneurons modifies the responses in PNs based on their valence for the fly: odors that belong to the same behavioral meaningful category become more similar to each other in the combinatorial activity pattern, while odors that belong to another category become more dissimilar, thus aiding the brain in creating the generalization-discrimination divide (Niewalda et al., 2011; Knaden et al., 2012). Another example for the necessity to discriminate well: the leaf-cutting ants *Atta vollenweideri* and *Atta sexdens* mark their trails with pheromones that only differ in the ratio of their components, but they have no difficulties in discriminating between conspecific and heterospecific trails (Kleineidam et al., 2007).

How relevant is the similarity of odor-evoked activity patterns for the animal? The perceived odor similarity correlates well with the physiological similarity between odorant-evoked combinatorial glomerular activity patterns in the honeybee (Guerrieri et al., 2005). In *Drosophila*,

processing within the antennal lobe increases the correspondence between perceived similarity and physiological similarity in PNs as compared to OSNs (Niewalda et al., 2011). Indeed, blocking inhibitory connections within the antennal lobe using pharmacological tools changes both temporal and spatial properties of odor-response patterns and reduces the capacity of animals to differentiate among similar odors (Stopfer et al., 1997; Sachse and Galizia, 2002). Thus, both innate circuitry and learned components modify the “olfactory landscape” of odor representations to create a landscape where odors that belong together are more closely associated with each other.

### 22.2.9 The Coding of Special Odors: Sexual Pheromones

Among the best studied cases in insect olfaction is the capacity of male moths to find a female by following the odor trail of a sexual pheromone over very long distances (up to several km). Several aspects are important to understand this system. Most pheromones are mixtures of more than one substance (Kaissling, 1996). The hypothesis is that a mixture allows for better coding of odor-quality over a large range of concentrations. Assume a pheromone would consist of only a single substance, and that an animal had a single, highly sensitive neuron for this substance. Even the most selective neuron might still have some cross-reaction to other substances, when given at high concentration. Consequently, a single neuron type does not give sufficient information to differentiate between a very low concentration of the best ligand (maybe a female on a tree far away), and a very high concentration of a weak ligand (maybe the female of a closely related species with a similar, but slightly different pheromone, sitting on the next branch). A combination of two neurons is much more distinctive. Furthermore, this robustness transports to the sending signal: some closely related species do not differ in their pheromone components, but only in the relative ratio, that is, whether substance A or substance B is the major component. Thus, again, a mixture gives a safer and more robust communication signal for pheromones. Moths have even evolved the capacity of detecting time-onset differences down to a millisecond (Baker et al., 1998): only the conspecific female will release all components at exactly the same time. Onset asynchrony therefore indicates that the odor plume must come from different sources, and not from a conspecific female – following this signal would be a waste of resources.

Generally, for each pheromone component, there is a dedicated OSN population. Each population innervates a glomerulus. Therefore, activity in a glomerulus is a clear signal that a particular chemical substance has been smelled (this is sometimes called a “labeled line,” though some scholars use “labeled line” in a more restrictive way,

that is, only for signals that have a dedicated processing stream all the way to eliciting a stereotype behavior). Since the components of the pheromone are detected by different OSNs, which innervate different glomeruli, the conspecific pheromone signal is uniquely identified by a pattern of active glomeruli: in the case of a pheromone composed of two substances, the signal consists of the two corresponding glomeruli lighting up. We do not yet know exactly how this combinatorial pattern is read out and then converted into behavior (i.e., an upwind flight towards the pheromone source), but we do know that already within the antennal lobe there are mixture-specific neurons (Riffell et al., 2009), and that synchrony of neural activity in the glomeruli involved is crucial for a reliable recognition of the pheromone (Heinbockel et al., 2004). Interestingly, the necessary combinatorial pattern is not limited to the presence of some glomeruli – the absence of others is also required. In the moth *Heliothis*, pheromone components of closely related species act as direct inhibitors (Vickers et al., 1998). The glomeruli involved in sexual pheromone processing in this species are four: two codes for the two main components of the conspecific pheromone, and two for components of other, closely related species. The relevant combinatorial pattern thus consists of the first ones being active, and the other two being silent – activity in one of the latter is sufficient to block upwind flight, that is, search for a female.

In moths, the sexual pheromone-sensitive glomeruli are in the antennal lobe close to the entrance of the antennal nerve. Since they are innervated by a very large number of OSNs (to increase sensitivity), these glomeruli are generally large, and the complex of all sexual pheromone-sensitive glomeruli is called the macrogglomerular complex. The number and shape of glomeruli in the macrogglomerular complex differs widely across species, in most species studied it is in the range of three to four.

### 22.2.10 The Coding of Special Odors: CO<sub>2</sub>

Carbon dioxide (CO<sub>2</sub>) is a special odor. Humans cannot smell it, even though we have internal sensors for CO<sub>2</sub>: the concentration of CO<sub>2</sub> is tightly controlled in our blood, and sensed as dissolved bicarbonate.<sup>2</sup> Controlling CO<sub>2</sub> in our blood is important for homeostasis, that is, keeping bodily conditions constant. In some insect species, CO<sub>2</sub> plays a similar role: ants and bees live in large colonies, some of which are located in burrows dug several meters

<sup>2</sup>In humans, CO<sub>2</sub> at high concentrations can be detected intranasally by the trigeminal (CN V), but not by the olfactory (CN I), nerve. The intranasal trigeminal system detects somatosensory sensations elicited by volatiles, such as cooling, burning, and stinging (see Chapter 50).

deep into the ground. Controlling oxygen and CO<sub>2</sub> in these conditions is vital, and when CO<sub>2</sub> levels rise above permissive values, the animals open ventilation paths to aerate the hive (Kleineidam and Tautz, 1996; Weidenmuller et al., 2002). The CO<sub>2</sub> receptors have properties that match this necessity to measure absolute concentrations: their responses are mostly tonic, that is, when in a certain CO<sub>2</sub> concentration, the neurons fire with a given frequency that is constant, so that the brain can directly translate firing frequency into CO<sub>2</sub> concentration (Lacher, 1964; Kleineidam et al., 2000). The sensilla are also adapted to slow rather than fast measurements: the receptor neurons are located within sensilla consisting of a long, invaginated tube, so that fast fluctuations of external CO<sub>2</sub> are filtered out. The gene of the CO<sub>2</sub> receptor is not yet known.

The situation is totally different in mosquitoes: they use CO<sub>2</sub> to find hosts. Humans and other mammals exhale CO<sub>2</sub> in a rhythmic pattern, and some mosquito species have evolved to sense such fluctuations in CO<sub>2</sub> (Geier et al., 1999). Their receptors are mostly phasic, that is, their action potentials increase when the CO<sub>2</sub> concentration changes but are reduced to a small tonic component when the concentration remains constant (Grant et al., 1995). The receptor is known: it is not directly related to other odorant receptors, but rather evolved from a gustatory receptor, suggesting that it is not sensing CO<sub>2</sub> but a reaction product, for example, bicarbonate. The same CO<sub>2</sub> receptor is expressed in the fruit fly *Drosophila*, a species for which many details of its brain circuitry are known (de Bruyne et al., 2001; Jones et al., 2007; Kwon et al., 2007). It appears that CO<sub>2</sub> is processed using a labeled-line strategy: all receptors innervate a single glomerulus (Suh et al., 2004). Deleting these receptors makes the fly anosmic to CO<sub>2</sub>. CO<sub>2</sub> is a repellent odor for flies, leading to a rapid escape response. Interestingly, highly aversive odors activate adjacent brain areas, and it appears that odors that are innately negative and/or repulsive have their distinct pre-motor area here (Jefferis et al., 2007), an observation that is paralleled in the antennal lobe, where odors of positive and negative valence have their preferred coding regions (Knaden et al., 2012).

### 22.2.11 Odor Representation is Transformed Between Antennal Lobe and Mushroom Bodies

The logic of odor coding is transformed between antennal lobes and mushroom bodies. The most apparent change is a sparsening of activity: odors usually activate a high percentage of PNs in the antennal lobe, but only activate a small percentage of Kenyon cells (Perez-Orive et al., 2002; Wang et al., 2003; Szyszka et al., 2005; Honegger et al., 2011). This population sparseness (i.e., few Kenyon cells

active for each stimulus) goes hand-in-hand with lifetime sparseness (i.e., each Kenyon cell responds only to a small number of odors). Thus, Kenyon cells are narrowly tuned, and some are even selective for particular stimulus concentrations (Stopfer et al., 2003). To analyze the transformation of odor representations in the mushroom body and to evaluate the contribution of pre- and postsynaptic processing in honeybees, we characterized three consecutive processing stages: first in PNs of the antennal lobe, second in PNs' synaptic terminals in the mushroom body calyces, and third in the postsynaptic Kenyon cells (Szyszka et al., 2005). The percentage of activated units that responded to one odor only (out of four tested odors) increased across the three processing stages from 55, to 70, to 92%, while the units that responded to two odors or more dropped from 45, to 30, to 8%. The sparsening of the Kenyon cell code is a progressive process and involves a series of transformations. These are accomplished by the divergent-convergent connectivity between PNs and Kenyon cells, by the weak synaptic connections between PNs and Kenyon cells, and by the odor-driven inhibition of Kenyon cells (Perez-Orive et al., 2002; Jortner et al., 2007; Gupta and Stopfer, 2011; Papadopoulou et al., 2011). Moreover, local microcircuits in the mushroom body calyx modify the PN output (Szyszka et al., 2005; Yamagata et al., 2009). However, even though the Kenyon cells' odor representations are sparse, the odor code still remains combinatorial. In fact, the dimensionality is even increased: 50% activity chance across 160 glomeruli means 80 active glomeruli, while 1% activity chance across 100,000 Kenyon cells means 1000 active Kenyon cells. It is this expansion of possible combinatorial patterns from the antennal lobe to the mushroom bodies that increases the coding capacity, and more importantly affords the possibility to create complex odor categories.

### 22.2.12 Odor Coding Dynamics

Kenyon cell responses also differ from PN responses in temporal aspects: PNs respond to odors with long lasting, often temporally complex responses, which are superimposed onto a high level of background activity (Abel et al., 2001; Perez-Orive et al., 2002; Sachse and Galizia, 2002; Galan et al., 2006; Szyszka et al., 2011; Nawrot, 2012). Kenyon cells, in contrast, show brief odor responses of only a few spikes, generally at odor onset and at odor offset only, and background activity is nearly absent (Perez-Orive et al., 2002; Stopfer et al., 2003; Szyszka et al., 2005; Ito, Ong et al., 2008; Turner et al., 2008). The combinatorial pattern across Kenyon cells is not equal at odor-onset and at odor-offset. A honeybee flying through an odor plume will get information both when it enters the plume and when it exits the plume. The reduced level of activity during the stimulus raises a conundrum: the temporal

complexity created in the odor response of PNs by the antennal lobe network appears to be ignored by the readout in the mushroom bodies. Indeed, behavioral responses suggest that animals do not need a long time to recognize an odor (Ditzen et al., 2003), suggesting that slow activity patterns across PNs cannot be relevant for odor recognition under normal circumstances. Associative learning experiments in honeybees and moths confirm that only the onset of odor-elicited activity carries behaviorally relevant odor information: In bees the first bout of PN activity is relevant, whereas ongoing post-odor activities are not (Szyszka et al., 2011), and in moths only a few Kenyon cell spikes at odor-stimulus onset are relevant (Ito et al., 2008). It appears as if ongoing PN activity would be wasted. However, this activity may be important for other brain areas, for example the lateral protocerebrum, or it may be used for establishing the contiguity between an odor and a meaningful stimulus during associative learning (Szyszka et al., 2008) – a hypothesis that remains to be investigated.

Spiking activity in individual neurons is always fast, and creates a situation for the brain where synchrony can be used for information coding. In the antennal lobe, synchrony of spikes across glomeruli is important for binding information across glomerular patterns (MacLeod and Laurent, 1996; Christensen et al., 2000; Tanaka et al., 2009). Odor-evoked oscillations have been found across the animal kingdom, and may be important to create time-windows to read-out spike synchrony across PNs. The sharp onset and the temporal precision of action potentials across Kenyon cells in the mushroom bodies may also be related to the necessity of reading out across-neuron activity patterns based on synchrony. A detailed review of these fast components in odor-evoked activity is beyond the scope of this review, and can be found elsewhere (Laurent, 2002).

## 22.3 CONCLUSION: FROM ODOR TO BEHAVIOR

In this review, we have followed odor representation along the olfactory system from olfactory sensory neurons, through the antennal lobe, into the mushroom bodies. This is not yet the behavioral readout, and more research is needed to close the circuit. We have investigated two coding systems: innate-meaning odor-coding ( $\text{CO}_2$  and sexual pheromones) and general odor coding. The latter are situations that involve many odor sources with different smells, while the more specialized systems use few, and innately predetermined processing circuits. While innate systems often use labeled line like odor-coding schemes (see discussion of  $\text{CO}_2$  coding, above), the combinatorial logic of general odor coding prevails: odor stimulus, pattern of activity across glomeruli in the antennal lobes, a

transformed and different pattern of activated cells in the mushroom bodies, and a resulting behavioral output Galizia CG 2014. It is the latter that now enters into the focus of olfactory research in insects: while in few specialized cases the lateral protocerebrum may already be the place where an olfactory input elicits the premotor command, the link from odor representation to behavior remains to be elucidated in insects. It will become apparent that this link is not simple: First, natural odors occur in a temporally fluctuating, multi-odor background, yet insects possess a remarkable ability to extract intelligible odors under such complex conditions. The neural basis of odor-background segregations remains currently unknown. Second, even a plain odor stimulus does not elicit a stereotype response. Rather, the state of the animal is important: circadian rhythms, sexual state, thirst or hunger, and previous experience all influence in a decisive manner how an odor is responded to by the insect. All of these modulatory systems are represented in the brain by dedicated neural circuits, and these circuits interact with the olfactory pathway along all its stages: at the antenna, in the antennal lobe, in the mushroom bodies and in the lateral protocerebrum. It is in this interaction that we see a strong need for further research. Understanding these circuits will help us understand our own olfactory system, but most importantly it will help us understand the olfactory world of insects: how do they find the right flower to visit, the right leaf to pierce, or the chosen victim to attack.

# Chapter 23

---

## Olfaction in Aquatic Vertebrates

KEITH B. TIERNEY

### 23.1 INTRODUCTION

Vertebrate olfaction evolved underwater and it has remained underwater ever since, regardless of whether it has come to be used in terrestrial environments. The reason for this is simple: wherever vertebrates are, their olfactory epithelium is bathed in mucous. This is not to say that aquatic and terrestrial vertebrates can detect the same bouquet of odorants – quite the opposite. Terrestrial vertebrates were given the “evolutionary option” to sense odorants that were volatile and not soluble in water. For terrestrial vertebrates, “smelling air” brought certain adaptations such as olfactory binding proteins (OBPs) to chaperone volatile and frequently hydrophobic odorants to a diversity of olfactory receptor proteins located on olfactory receptor cells (Firestein, 2004; Millery et al., 2005). For aquatic vertebrates, “smelling water” brought developments in its own right, not only in terms of odorant receptor proteins (Eisthen, 1997; Hansen and Zielinski, 2005), but also in terms of anatomical adaptations that deal with moving water (Cox, 2008).

For vertebrates that live either in or around water, a division can be made between those who have noses that interface with air and those who have noses that interface with water. A major consideration is the nature of the medium that conveys the odorants. The far greater relative density and viscosity of water vs. air has necessitated numerous adaptations in aquatic species to direct water flow over the olfactory epithelium, as described later in this chapter. Importantly, in light such factors, evolutionary specializations have defined the classes of odorants to which the noses of water- and air-living species can detect, with dissolved vs. volatile categories often being quite distinct. In fish, where volatility is not a major issue, odorants are commonly classified in relation to structure,

such as amine-containing odorants (Hara, 2005; Miklavc and Valentiničić, 2012; Rolen et al., 2003), nucleobase odorants (Brown et al., 2001; Parra et al., 2009; Rolen et al., 2003), prostaglandins (Belanger et al., 2010; Cole and Stacey, 1984), steroid (cholesterol)-based odorants (Cole and Stacey, 2006; Stacey et al., 2003), sugar-based odorants (Mathuru et al., 2012), and ions (Hubbard et al., 2002). Although many airborne odorants detected by air-living species are also named on the basis of structure (e.g., mercaptan containing), other classification schemes are nascent, such as ones based upon hedonics (Djordjevic et al., 2012). Alternative means of detecting chemicals have evolved in some terrestrial vertebrates, such as the vomeronasal organ (VNO), the Grueneberg ganglion, and other specialized systems (see Chapters 51 and 52).

Although an argument can be made that the behavioral and physiological responses of vertebrates that smell in water meaningfully differ from those that smell in air, it is noteworthy that olfaction enables a similar diversity of responses in both groups. In water and air, olfactory-based activities include searching, be it for food (Hirsch, 2010; Miklavc and Valentiničić, 2012), a home locale (Benvenuti et al., 1993; Yamamoto et al., 2010), or the right environmental conditions (Hubbard et al., 2002; Nevitt, 2011), providing information of importance to relatedness (Leinders-Zufall et al., 2004; Olsén et al., 2002), a predator’s presence (Amo et al., 2008; Idler et al., 1956), and the timing and preparation of reproduction (Stacey et al., 2003; Veyrac et al., 2011).

A primary way that air and water smellers differ is in the number and types of olfactory receptor proteins they possess. Bony fishes, which gave rise to terrestrial vertebrates, have ~150 distinct olfactory receptor proteins (Firestein, 2004). However, terrestrial vertebrates generally have many more such proteins. For example, there

appear to be ~1200 distinct receptor proteins in mice (Firestein, 2004; Zhang et al., 2004). Although this suggests that water-smelling vertebrates may be comparably disadvantaged over land-dwelling vertebrates, this is likely incorrect: fishes have increased variability in their receptor repertoire which confer the ability to detect a large array of odors (Hashiguchi and Nishida, 2005, 2006). This chapter begins with a historical account of landmark scientific studies of olfaction in fish. The chapter's primary goal is to succinctly describe the olfactory systems and abilities of all aquatic vertebrates, that is, vertebrates that are active underwater. This includes ones that (1) develop and live underwater, (2) develop underwater but leave the aquatic environment, and (3) develop on land yet spend appreciable time living in and around aquatic environments. In the first two groups, there are fishes and amphibians that spend either the majority or portions of their lives underwater yet may leave for periods from the brief to the extended (e.g., mudskippers, frogs, and salamanders). In the last group, numerous examples exist of animals that have returned to an aquatic existence, including birds, reptiles, and marine mammals. Across all vertebrates, while much of the cellular machinery has homology, there is a diversity of odorant detection abilities and incredible morphological-structural differences that warrant description.

## 23.2 HISTORY OF THE SCIENTIFIC STUDY OF OLFACTION IN FISH

In 1909, Burne authored “The anatomy of the olfactory organ of teleostean fishes” (Burne, 1909). This lengthy paper (~54 pages) is remarkable in that it was arguably the first to showcase the diversity of anatomical structures associated with fish olfaction. The paper contains several detailed illustrations with cutaways showing not only the olfactory structures but also those underneath. It also contains a brief review of other sources known at the time (all of ten references). It still gathers citations today, but owing to its age, it is sometimes not cited appropriately by databases, and so the actual number of citations is not known (current Google Scholar citations number 94).

The ability of migrating salmon to home to their natal streams is now widely accepted to be driven by olfaction. The first paper to experimentally test this theory was authored by E. Horne Craigie (Craigie, 1926). In his study, a sample of 513 returning Pacific sockeye salmon were captured, tagged, and released several kilometers before they entered the riverine portion of their migration. However, before being released, half had their olfactory nerve tracts surgically severed. The results of the study were not conclusive, but loss of olfaction clearly reduced the number of salmon who returned to their native stream. The suggestion to disable olfaction (and thus the likelihood that it was

the sense) was credited to George H. Parker, a zoologist at Harvard. It wasn't until 25 years later that the olfactory imprinting hypothesis was formalized by Arthur D. Hasler and Warren Wisby (Hasler and Wisby, 1951). This area of research remains active, with recent studies identifying the nature of the critical odorants (Ueda, 2012; Yamamoto et al., 2010). In 1956, a game-changing methods paper was published by Ottoson entitled “Analysis of the electrical activity of the olfactory epithelium” (Ottoson, 1956). While research had already been published of recordings of the electrical properties of the olfactory bulb, this was the first paper to describe the activity of the peripheral olfactory epithelium. Also noteworthy is the species tested, a facultative aquatic vertebrate – the common frog (*Rana temporaria*). This paper was invaluable to the study of olfaction as it gave rise to what became known as the electro-olfactogram (EOG). This paper also has citation issues (and can be incorrectly listed as 1955) and but still is widely cited (Google Scholar citations: 322). Years later, Evans and Hara (1985) authored a paper on how to use this technique in fish with gel-filled electrodes. This paper remains the standard operating procedure for assessing olfaction in fish.

The 1970s saw a revolution in terms of the significance of olfaction to physiological and behavioral responses. One of the first papers to demonstrate the role of odorants to mating processes tested the ability of male goldfish (*Carassius auratus*) to discern between ovulated and unovulated females based on compounds within ovarian fluid (Partridge et al., 1976). This work arguably established the foundation for a legacy of studies exploring sexual signaling molecules in fishes. It also pioneered the use of a Y-maze to determine odorant preferences of fish, a procedure which became widely adopted. Even recently, a large in-field Y-maze was used to demonstrate the ability of species-specific molecules to control the movement of an invasive fish species, the sea lamprey (*Petromyzon marinus*) (Johnson et al., 2009). With olfaction being indisputably invaluable to fishes, it is easy to make a case that its disruption has far reaching influences on fish populations. The first data to show that human-produced compounds could impair olfaction came from a technical report from the Fisheries Research Board of Canada (Sutterlin et al., 1971). This paper showed that surfactants, such as those found in soaps that are often released into the aquatic environment, could reduce the olfactory responses of fish. The paper was also unique in several other ways – it measured numerous compounds (150), it endeavored to link the toxic effects to chemical structure, and it explored whether the compounds could themselves evoke olfactory responses (e.g., can fish smell novel compounds that would not be encountered in their evolutionary history?). This

paper arguably was the first of many to look at “olfactory toxicity” in fish (reviewed in Tierney et al., 2010).

A theme in many present olfactory studies is the linking of odorants to their cellular machinery and to the neurological circuits of the brain. While this sort of information is intriguing on its own, much has been accomplished under the auspices of fish as models for human research. In this, no fish is more popular than the zebrafish. A recent study used gene trapping in mutant zebrafish lines to link a specific olfactory sensory neuron (OSN) class (microvillus) to locations in the olfactory bulb, and to the odorants and behaviors they evoke (Koide et al., 2009). With a high degree of homology between zebrafish and mammals, future studies may be useful in helping to elucidate the neurologic processes responsible for such neurodegenerative diseases as Alzheimer’s and Parkinson’s (see Chapter 18).

## 23.3 ANATOMY

Olfaction depends on the transport of odors to the receptors located in epithelia; this involves bulk flow of the medium (convection) and diffusion of the odors. Aquatic organisms face a challenge their terrestrial counterparts do not: water is far denser ( $800\times$ ) and more viscous ( $50\times$ ); hence, molecules diffuse more slowly than in air (e.g.,  $10,000\times$  for  $\text{CO}_2$ ). However, water has at least one advantage: it facilitates the dissolution of molecules that air cannot. As a result of the challenges water presents, fishes have developed several adaptations to deal with its motion. These include specialized nostrils, structures to guide water flow, and cilia and accessory sacs to pump it. With the diversity of fish species, the hydrodynamics of underwater olfaction are largely underexplored (Cox, 2008). Unfortunately, space limitations of this chapter allow for only a cursory examination of such processes.

### 23.3.1 Nares

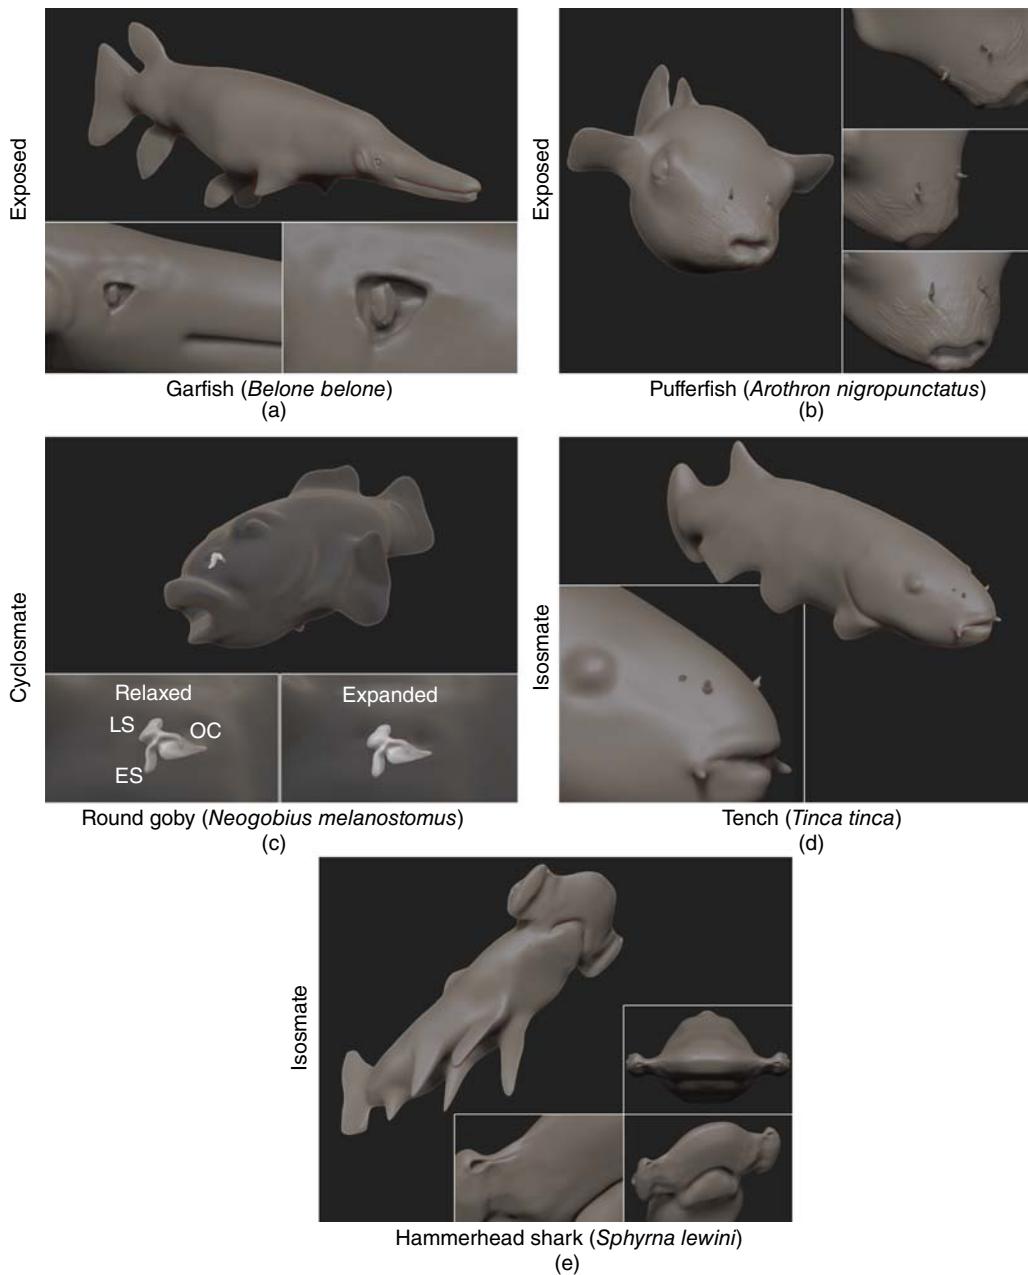

Aside from the monorhynic (one nostril) adaptation of ancient jawless fishes, most fishes have bilateral nostrils or “nares” located rostral (anterior) to the eyes, as occurs in air smelling vertebrates. However, unlike air smellers, the nares of most fish consist of two openings, an anterior incurrent opening and a posterior excurrent opening (Zielinski and Hara, 2007) (Figure 23.1d). These openings are often structured to direct flow into a chamber that contains the olfactory epithelium. Thus, the incurrent naris may not be just a hole, but a tube (sometimes referred to as a vestibule) (Døving et al., 1977), such as occurs in the tube nose goby (*Proterorhinus marmoratus*). The excurrent naris may be both a tube and a slit. An example of such a tube/slit combination can be found in the striped eel catfish (*Plotosus lineatus*) (Theisen et al., 1991). Some species

do not have a covering over their olfactory epithelium at all, such as garfish (*Belone belone*) (Theisen et al., 1980) (Figure 23.1a) and flying fishes of suborder Exocoetoidei (Burne, 1909). Other species may have adaptations associated with their nares, such as hammerhead sharks (family Sphyrnidae) that possess prenarial grooves that presumably act to direct flow (Kajiura et al., 2004) (Figure 23.1e).

By virtue of the location and number of their nares, water smellers can be uniquely adapted for tropotaxis or klinotaxis. Tropotaxis is evident in fairly linear movement up a concentration gradient and is used in organisms able to detect a gradient between two or more anatomically separated receptors. Klinotaxis is typified by relatively less linear movement up a concentration gradient and is used by organisms that must establish a gradient by moving one receptor through it. The hammerhead sharks mentioned above, for example, have nares spaced far apart which will facilitate the detection of an odor gradient over their cephalofoil head (Kajiura et al., 2004). Conceivably this “stereo-olfaction” provides a means for more direct movements towards an odor source (e.g., prey). Conversely, the jawless fishes that have a single naris serving one olfactory chamber (Zielinski and Hara, 2007) may need to physically move their sensory epithelia through the gradient. This type of movement will be evident in pronounced “side-to-side” searching.

### 23.3.2 Olfactory Chambers

As a general rule, fishes have blind olfactory chambers, that is, chambers that do not connect to any pharyngeal spaces. An exception again is in the jawless fishes, specifically the hagfishes, which have a chamber that is connected to the gill openings (Holmes et al., 2011). However, there are other oddities found in fishes. For example, in lamprey several small spherical cavities exist below, and are connected to, the main olfactory chamber via tubes. These “tubular diverticula” are referred to as the accessory olfactory organ (AOO) and are thought to be analogous to the VNO (Thornhill, 1972). These cavities contain ciliated cells and are believed to function in the communication of reproductive or migratory information (Ren et al., 2009). Additionally, while they do have a single chamber, there is a central tissue fold that may functionally separate this chamber (Theisen, 1973). A truly unique anatomy exists in the puffer (*Sphoeroides maculatus*): the chamber resides at the end of a 4 mm papilla (Copeland, 1912) (Figure 23.1b). This has the obvious advantage that the olfactory tissue is placed directly in the flow about the fish, but it also places the tissue in harm’s way. Perhaps for this slow swimming fish that has its own unique method of protection, placing the sensitive olfactory epithelium in a refuge is unnecessary.

**Figure 23.1** Fish have a diversity in olfactory structures and the routes by which water is moved past the olfactory epithelium. Some species have their olfactory epithelium exposed to the environment, either in pits (a) or on stalks (b). Other species, referred to as cyclostomes may have blind sacs connected to the olfactory chamber and associated with bones of the jaw, such that the action of opening and closing the mouth expands the sacs to pull water through the chamber (c). Many active swimming species referred to as isomates do not have sacs, but rather use the pressure associated with swimming to create nasal water flow. Some of these fish may use tubes (d) or prenarial grooves (e) to direct nasal flow. Olfactory chamber, OC; accessory nasal sacs: ethmoidal sac, ES; lachrymal sac, LS. The olfactory sac was modelled from Belanger et al. (2003). Illustration by Kofi Garbrah.

### 23.3.3 Nasal Flow

For many active fishes, swimming and the action of cilia serve as the primary ways to move water through the nose. For more sedentary fishes, water must be circulated through the chamber by the pumping action of

accessory sacs (Figure 23.1c). These strategies are typically associated with pelagic (water-column) and demersal (bottom-dwelling) species; however, this is not always the case. Pelagic species may have sacs and demersal species may not (Burne, 1909; Zielinski and Hara, 2007). Døving

et al. (1977) proposed a classification system for the two ventilatory strategies, categorizing fish as either isosmates or cyclosmates, respectively. In terms of efficiency with isosmates, swimming action may increase nasal ventilation fivefold (Døving et al., 1977). For isosmates, the energy associated with swimming can be utilized for “olfactory ventilation”, thereby eliminating the cost associated with building specialized olfactory structures. For cyclosmates that rely on pumping water over the olfactory epithelium, they are likewise coupling another energetic activity with another – in their case, respiratory ventilation. For these fishes, the expanding and collapsing of the olfactory sacs is coupled to the ventilatory cycle (Nevitt, 1991). In this way, their sense of smell has a rhythmic component, much like air smellers. Additionally, opening and closing of the mouth may effectively allow cyclosmates to “sneeze” (Døving et al., 1977; Kapoor and Ojha, 1972; Nevitt, 1991).

There is diversity in the sacs that cyclosmates have to generate flow. Some species possess two sacs: the ethmoidal and lachrymal sacs (Figure 23.1c), while others have only one sac (Zielinski and Hara, 2007). The lachrymal sac is so named from its association with the lachrymal bone of the jaw and may be more ventral; the ethmoidal sac is named from its association with the ethmoid bone that separates the nasal cavity from the brain and may be more dorsal (Burne, 1909). Both sacs typically flank the rear of the olfactory chamber and are proximal to the openings of the caudal nares (i.e., are distal from the openings of the rostral nares). In terms of size, the lachrymal sac is typically larger (Nevitt, 1991). It has been hypothesized that the two-sac system, perhaps in conjunction with a collapsible caudal nares flap that acts as a valve, allows for unidirectional flow in the olfactory chamber (Døving et al., 1977; Pfeiffer, 1964). Some fish achieve pumping using a one sac/valve system (Kux et al., 1988). In either case, what likely occurs is that with inhalation (jaw opening) water is pulled in through the openings of the anterior nares, past the olfactory epithelia, and into the rear sac(s). With exhalation (jaw relaxation), water is forced out of the sac(s) and through the caudal nares. What is unknown is whether the complete filling and emptying of the nasal chamber occurs with every ventilatory cycle (i.e., a “one cycle” system). With fishes with a lengthy olfactory chamber (Kux et al., 1988), perhaps multiple ventilatory cycles are needed, but this remains to be determined.

A curiosity is that some of the most ancestral fish have an olfactory ventilatory strategy that is most comparable to that of air smellers. Thus, hagfish have an array of olfactory receptors within an olfactory epithelium that is in line with their gills (Holmes et al., 2011). With this system these fishes have an oscillating, albeit unidirectional, water flow

in the olfactory chamber directly related to the respiratory cycle.

A question arises as to whether fish can sniff? In fact, they can increase the flow of water to their olfactory organs which, in some cases, occurs in a manner similar to sniffing in various land dwelling mammals. There are arguably two routes by which this process occurs. First as mentioned above, they can increase the pumping of the accessory olfactory sacs by modulating their jaw movement, as if they were coughing (Nevitt, 1991). Second, they can repeat sample an area of high odorant concentration by physically moving into and out of such an area. This has been observed in zebrafish (*Danio rerio*) when an odor is presented into a tank using a point source (Tierney et al., 2011). Such behavior may extend over periods of minutes. This form of sniffing is likely utilized to a large extent in actively swimming species who dwell within water columns.

### 23.3.4 Olfactory Epithelium

The olfactory epithelium of fishes can be described as ranging from simple to elaborate, from having no folds to having complex two-tiered lamellae arranged in rosettes. This variation may reflect the relative importance of olfaction (the larger the surface area, the more important olfaction), but it may also have to do with habitat niche and a trade-off with rigidity or perhaps even drag. At the extreme end of surface area are reef-associated fishes such as the barred snapper (*Hoplopagrus guentherii*), which has been reported to have more lamellae than any other fish, with up to 230 per naris (est. surface area of 2450 mm<sup>2</sup>) (Pfeiffer, 1964). These numbers outshine migratory salmon, species that indisputably depend on their noses to guide them over tremendous distances. In chum salmon (*Oncorhynchus keta*), for example, there may be 18 lamellae with as many as 14 million olfactory cells per naris (Kudo et al., 2009). These numbers appear to be dynamic and increase allometrically as fish mature. An example of a fish at the other extreme of surface area is the invasive round goby (*Neogobius melanostomus*), which have a single lamella (Belanger et al., 2003). This species provides an argument against the surface area-olfactory importance hypothesis, since the success of the round goby in colonizing new areas has been at least partially attributed to its use of semiochemicals (Katare et al., 2011). However, this species is a cyclosmate with two olfactory sacs. Cyclosmates may not need a large surface area since they can increase their water sampling rate (Zielinski and Hara, 2007).

The olfactory epithelia of some fishes are exposed to the water on rigid papillae or stalks. For example, in fishes of the suborder Exocoetoidei, which include flying fishes and garfishes, the olfactory epithelia are present on papilla

within recessed, but exposed, cavities (Theisen et al., 1980) (Figure 23.1a). Other fish, such as the puffer mentioned above, lack a cavity altogether and have their tissue on stalks in a manner similar to that seen in some arthropods (Copeland, 1912) (Figure 23.1b). For the Exocoetoidei, it is possible that the relatively simple and open structure may be an adaptation to reduce drag or facilitate olfactory perfusion. An argument for the perfusion theory can be made based on the ontogeny and life history of a species of garfish (*Belone belone*): non-sensory ciliated cells exist in the less active juveniles and not the active adults. In fishes with asymmetry, such as flatfishes, the olfactory epithelium may also be asymmetrical. For example, in the sole (*Solea senegalensis*), which has one naris in contact with the substrate (and likely interstitial fluid) and one in contact with the water column, olfactory detection of social cues appears to be greater on the water column side (Velez et al., 2007).

The cellular structure of the olfactory epithelium of fish is as complex as that seen in other vertebrates. In species with rosettes, the bases and tips of lamellae are typically dominated by non-sensory cells. The sensory cells on the “tongues” of the lamellae are typically evenly distributed across the epithelium (Hara and Zhang, 1996), but may also have patchy distribution, such as in the striped eel catfish (*Plotosus lineatus*) (Theisen et al., 1991). A way to group cells of the olfactory epithelium is whether or not they serve a sensory function. Non-sensory cells include at least four types: supporting cells (sustentacular or nonciliated supporting cells), stratified epithelial cells, ciliated cells, and goblet cells, all of which are morphologically distinguishable (Datta and Bandyopadhyay, 1997; Theisen et al., 1980). Sustentacular cells are apparent as columnar cells lacking projections, but may include microvillus supporting cells (Byrd and Brunjes, 1995). Ciliated, non-sensory cells may be present and likely generate flow (mucociliary clearance), but they have also been hypothesized to serve structural or hydrodynamic roles (Theisen et al., 1980). Goblet cells are the mucus secreting cells of fish. Unlike mammals, fish lack Bowman’s glands. Goblet cells and thus mucus production is distributed across the olfactory epithelium (Byrd and Brunjes, 1995).

With sensory cells, there are also three morphologically distinct types: ciliated, microvillus, and crypt cells (Hansen and Zielinski, 2005; Zielinski and Hara, 2007). Unlike the non-sensory cells, all of these are bipolar, first order neurons. Of the three types of OSNs, the ciliated cell is a major component of the olfactory epithelium and resembles ciliated cells of other vertebrates (Eisthen, 1997). This cell type has a perikaryon that is sunken into the olfactory epithelium and a dendrite that extends to the surface which terminates in several apical cilia. The other major cell type – the microvillus cell – differs principally in two ways: it has a more superficial body

and apically has a few microvilli (short protuberances). While microvillus cells were historically thought to be absent in mammals (Eisthen, 1997), data suggest otherwise (Moran et al., 1982; Elsaesser and Paysan, 2007). The third cell type – the crypt cell – occurs in lower numbers, differs markedly in appearance and appears to be unique to fishes (Bettini et al., 2012; Ferrando et al., 2006; Hansen and Zielinski, 2005; Yoshihara, 2009). Crypt cells are an ovoid cell that interfaces directly with the olfactory epithelium and that has an apical cavern with abbreviated cilia (Hansen and Zeiske, 1998). Not all three sensory cell types are present in all fishes: cartilaginous fishes do not have ciliated OSNs (Eisthen, 1997) and crypt cells are absent in lobe-finned (sarcopterygian) fishes (Hansen and Finger, 2000). Curiously, all three cell types or analogs are present in the lamprey (Laframboise et al., 2007; Theisen, 1973). A final category of cell present in the olfactory epithelium but not included in the above is the basal, stem cells which give rise to all.

### 23.3.5 Olfactory Tracts and Connections

The OSNs send their axons along three distinct bundles in the bilateral olfactory tracts to innervate the mitral cells of the bulb (Hamdani and Døving, 2007). Each bundle appears to be made up of axons of a distinct OSN type. The lateral olfactory tract (LOT) contains microvillus axons, the lateral-medial olfactory tract (LMOT) contains crypt axons, and the medial-medial olfactory tract (MMOT) contains ciliated axons (Hamdani and Døving, 2007). These bundles project to different areas of the olfactory bulb (OB). Ciliated OSNs project to the medial area of the OB (Sato et al., 2007), microvillus OSNs to the anterior dorsal OB (Morita and Finger, 1998), and crypt OSNs to two ventral or possibly dorsomedial areas of the OB (Gayoso et al., 2011, 2012; Hansen et al., 2003). For the lamprey and its unique ciliated cells of the accessory olfactory organ, the axons terminate in the medial region of the OB (Ren et al., 2009).

The OSN types, the tracts, and the OB regions they reach can be associated with specific behaviors. The LOT may correspond to feeding responses (Koide et al., 2009), the MMOT may correspond to alarm reactions (Hamdani et al., 2000), and the LMOT may correspond to reproductive behaviors (Doving and Selset, 1980; Weltzien et al., 2003).

### 23.3.6 Olfactory Bulb

In most vertebrate species, the OB is comprised of two bilaterally symmetrical structures positioned at the front or base of the brain. While fishes do not appear to differ in the number of bulbs, they may differ in OB placement and morphology (Zielinski and Hara, 2007). In fishes, the

OB may be “pedunculated”, that is, placed away from the brain proximal to the rosettes. This arrangement is believed to be apomorphic (derived) (Northcutt, 1986) and can be found in species such as the sea catfish (*Ariopsis felis*) (Morgan, 1975) and the coelacanth (*Latimeria chalumnae*) (Northcutt and Bemis, 1993). Alternately, the OB may be “sessile” and adjacent to the telencephalon (the plesiomorphic, ancestral condition). This arrangement can be found in fishes such as zebrafish (Byrd and Brunjes, 1995) and sea bass (*Dicentrarchus labrax*) (Cerdá-Reverter et al., 2001). The shape of the OB may vary as well – in the hammerhead shark mentioned above, the OB is coupled to and runs the length of the rosette tissue in the cephalofoil (Kajiura et al., 2004). The utility of a pedunculated OB remains to be determined, but perhaps it is related to cranial space considerations.

Fishes have four main concentric OB layers that are observed in other vertebrates: the olfactory nerve (axon), glomerular, mitral (external plexiform), and granule cell layers. However, there are some important differences in fish OB neurons and their organization. The morphology of the mitral cells need not have the typical mitre shape and the glomeruli (neuropil) can be less defined (Byrd and Brunjes, 1995). Additionally, fishes have a fourth cell type in their OB that mammals do not – the ruffed cell. This cell has an unmyelinated axon that contains numerous complex protrusions (Kosaka, 1980). Ruffed cells receive excitatory input from mitral cells (not OSNs) (Zippel et al., 1999) and are closely associated with them, conceivably serving a role similar to that of a glial cell (Byrd and Brunjes, 1995; Satou, 1990). Conversely, mammals have two classes of cells which fish may not: periglomerular cells (three types) (Kosaka and Kosaka, 2005) and tufted cells (Arévalo et al., 1991). However, recently cells found in the small-spotted catshark (*Scyliorhinus canicula*) were referred to as tufted-like and periglomerular-like (Ferrando et al., 2012).

## 23.4 GENETICS AND PHYSIOLOGY

Vertebrate olfaction appears to have evolved in fish, as the tunicate (sea squirt *Ciona intestinalis*), a chordate sister to fishes and other vertebrates, do not have genes orthologous to vertebrate olfactory receptors (Churcher and Taylor, 2009; Niimura, 2009). Present day fishes include examples that represent the base of vertebrate evolution and those that have continued their evolution in parallel with terrestrial radiation. However, not even the most ancient groups of the jawless fishes are lacking olfactory abilities. Lampreys, for example, guide remarkable migrations using olfaction, albeit using a direct coupling between olfaction and swimming activity (Derjean et al., 2010). In another ancient, arguably basal group – the cartilaginous “elasmobranchs”,

which include chimaeras, rays, and sharks – olfaction can be very well tuned, especially to amino acids that serve as food odorants (Tricas et al., 2009).

Vertebrate odorant receptors were first named by their location in terrestrial species, with those from the main olfactory epithelium (MOE), or what we consider the “nose”, being labelled “OR” (for odorant receptor) (Mombaerts, 1999) and those from the vomeronasal organ (VNO) being labelled “VR” (for vomeronasal receptor) (Dulac and Axel, 1995). By the nature of these locations, these receptors were believed to serve different roles: ORs were assumed to detect volatile odorants and VRs non-volatile odorants (Keverne, 1999). While generally true, this dogma is no longer supported; in fishes ORs and VRs are known to receive soluble odorants (Sato et al., 2005; Speca et al., 1999). Furthermore, OR and VR receptors are typically found dispersed across the olfactory epithelium in fishes which makes functional distinctions difficult. It is likely that VR and OR sequestration was an adaptation for terrestrial colonization, with the VNO receptors being placed in a location such that they may receive soluble odorants via the tongue (Halpern, 1987). Therefore, the receptor nomenclature is an artifact of classifying terrestrial species irrespective of their aquatic origins (Cao et al., 1998). A final group of odorant receptors present in both fish and other vertebrates is the trace amine-associated receptor (TAAR) family, which detects compounds similar to monoamine neurotransmitters (e.g., norepinephrine or dopamine) at very low concentrations (Borowsky et al., 2001; Hussain et al., 2009).

Discussions of receptor proteins and their associated cellular machinery often include the ligands that bind them (odorants in this case). However, with olfaction, receptor-odorant combinations are often not known or can only be speculated upon (Table 23.1). An additional complication is that odorants may bind to more than one receptor. Odorants can be grouped by class and include amine-containing (amino acids, polyamines, trace amines, urea, and ammonia; Dallas et al., 2010; Michel et al., 2003; Rolen et al., 2003; Tricas et al., 2009), nucleobase (nucleic acids, nucleosides, and nucleotides; (Rolen et al., 2003; Yacoob and Browman, 2007), prostaglandins and steroid-based (steroids and bile salts) (Belanger et al., 2010; Meredith et al., 2012; Stacey et al., 2003; Zhang and Hara, 1994), as well as sugar-based (e.g., chondroitin; Huertas et al., 2007), and ions ( $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ , possibly  $\text{K}^+$ ; Hubbard et al., 2002). The roles that many of these odorants play are still unknown (Table 23.2), and vary among fishes.

### 23.4.1 OR Receptors

The OR genes are classified as Type 1 or 2 and are found in all vertebrates (Niimura and Nei, 2005). The Type 1 OR

**Table 23.1** Olfactory receptors, their classes and the types of odorants they respond to.

Olfactory Receptor Type		Odorant Class	Organism	Reference
Odorant Receptors (ORs)				
	Type 1

\*T = terrestrial; A = aquatic

families appear to have evolved after jawless fishes and include six classes named alpha through to zeta ( $\alpha$ ,  $\beta$ ,  $\delta$ ,  $\gamma$ ,  $\epsilon$  and  $\zeta$ ) (Niimura, 2009). There are two additional Type 1 ORs in the lamprey (lamp-a and lamp-b), whereas the other six are absent (Niimura and Nei, 2005). The Type 2 OR families appear to have evolved before jawless fishes and include five classes ( $\eta$ ,  $\theta 1$ ,  $\theta 2$ ,  $\kappa$  and  $\lambda$ ) (Niimura, 2009). If we consider the presence and absence of the classes in aquatic vertebrates (fish and amphibians) vs. terrestrial vertebrates (reptiles, birds, and mammals) as an indication of what type of odorants are detectable, it appears that  $\delta$ ,  $\epsilon$ ,  $\zeta$ , and  $\eta$  detect soluble odorants, while  $\alpha$  and  $\gamma$  detect volatile odorants. The presence of  $\beta$  across phyla argues for its role in detecting either odorant type. The  $\theta 1$ ,  $\theta 2$ , and  $\kappa$  ORs may not be OR genes (Niimura, 2009). Overall, fishes can vary appreciably in the ORs that they have, from two in the elephant shark (*Callorhinchus mili*) to 176 in zebrafish (Niimura, 2009).

### 23.4.2 VR Receptors

As mentioned previously, fishes lack a VNO. However, they do not lack VRs as they can be found in microvillus and crypt cells (Oka et al., 2011; Yoshihara, 2009). There are two classes of VRs – V1R and V2R – and they are structurally dissimilar and have been hypothesized to receive very different odorants (Shi and Zhang, 2007). In mice, the V1R family is known to be associated with volatile odorants (e.g., 2-heptanone) (Boschat et al., 2002), whereas in fishes, V1R ligands remain unknown. However, research suggests that this receptor family recognizes a small number of odorants that likely do not serve species-specific roles, since these receptors are highly conserved across species (Johansson and Banks, 2011). The presence of V1Rs in sea lamprey (Grus and Zhang, 2009) supports this and also indicates an early evolution of this receptor class. Their occurrence in fishes also suggests that either V1R receptors respond to soluble odorants, or that volatile

odorants are present underwater. Regardless, an expectation for volatile odorant receptors would be that their diversity is greater in tetrapods, and this appears to be the case. For example, the mouse has 187 V1Rs and zebrafish has just two (Shi and Zhang, 2007). V1Rs may present a curiosity in fishes: a recent study found that a single V1R gene may be expressed only in crypt OSNs, which for the first time suggests that a cell type can be specific to a receptor (Oka et al., 2011), akin to the rod/cone paradigm.

Unlike V1Rs, V2Rs appear specialized for soluble odorants, regardless of organism. In the mouse V2Rs detect water soluble peptides (Kimoto et al., 2005; Leinders-Zufall et al., 2004) and in fishes they detect amino acids (Specia et al., 1999). Since V2Rs receive soluble odorants, it might be reasonable to expect similar numbers in fishes and tetrapods. Indeed, the numbers are not dissimilar (e.g., 44 in zebrafish vs. 70 in mouse) (Shi and Zhang, 2007). However, in fishes, V2Rs represent a unique receptor group, the diversity of which expanded after tetrapods evolved (Hashiguchi and Nishida, 2006). This evolution appears to be the result of gene duplication within and across chromosomes (Hashiguchi and Nishida, 2005).

### 23.4.3 TAAR Receptors

This receptor class exists across all vertebrates, but fishes appear to be especially well endowed with >100 TAARs present in some species (Gloriam et al., 2005). In fishes, there are three classes of TAARs (I, II, and III) (Hussain et al., 2009). Classes I and II appear to have developed in jawed fishes and are not present in jawless fishes (Hussain et al., 2009).<sup>1</sup> Classes I and II carried forward to other vertebrates (amphibian, birds, mammals) (Hussain et al., 2009), while Class III appears to be a teleost-specific young class of olfactory receptors (Hussain et al., 2009). Considering fishes have an entire class of TAARs that terrestrial vertebrates do not, the olfactory abilities of fishes might be far better than implied by the relatively lower overall number of receptors.

The odorants that classes I and II TAAR receive include food cues, since trace amines are found in arthropods, bacteria, and plants (Axelrod and Saavedra, 1977; Branchek and Blackburn, 2003). Alternately, since trace amines may be excreted in urine (Reese et al., 2007), they may serve a role in social responses. What is interesting is that class III is missing an aminergic ligand binding motif found in the other two TAAR classes and so the ligands are unknown (Hussain et al., 2009). Overall, much remains to be discovered concerning the role of TAARs in fishes; however, their diversity suggests the importance of their ligands (Niimura, 2009).

<sup>1</sup>Sea lampreys do, in fact, have 21 functional TAAR genes. However, they are in their own class (Hashiguchi and Nishida, 2007).

### 23.4.4 Signal Transduction

All odorant receptor proteins are coupled to guanosine-nucleotide-binding proteins and so are G-protein coupled receptors (GPCRs). However, the  $G_{\alpha}$  subunits that activate (or inhibit) the second messenger systems and evoke generator potentials differ in the OSN classes. Specifically, ciliated OSNs have  $G_{\alphaolf}$ , microvillus have  $G_{\alphaq}$ , and crypt have two forms of  $G_{\alpha o}$  (Hansen et al., 2003; Oka and Korschning, 2011). The first two  $G_{\alpha}$  subunits are stimulatory, working to activate adenylate cyclase (AC) and phospholipase C (PLC), respectively, while the second messenger cascade of the last ( $G_{\alpha o}$ ) is not clear. The  $G_{\alpha o}$  subunit is known to have an inhibitory function, but it is uncertain if it acts through AC or PLC (Dellacorte et al., 1996; Hansen et al., 2003). Conceivably  $G_{\alpha o}$  may be in a sub-population of spontaneously active amino acid-sensitive neurons (Kang and Caprio, 1995). These OSNs showed increased, decreased or no change in firing in response to amino acids (Kang and Caprio, 1995). Regardless of  $G_{\alpha}$  subunit type, some amino acid detecting neurons are narrowly “tuned”, responding to a single compound, while others are more broadly “tuned”, responding to more than one compound (Kang and Caprio, 1995; Nikonov and Caprio, 2007). A major difference with fish OSNs is that some break the one neuron-one odorant receptor rule that was proposed for vertebrates (Serizawa et al., 2005; Yoshihara, 2009). Specifically, a study on zebrafish found some ciliated OSNs express two or three types of ORs: zOR103-1 and one or both of zOR103-2 and zOR103-5 (Sato et al., 2007).

### 23.4.5 Biotransformation

Odorants and other compounds are deactivated through phase I (PI) and II (PII) biotransformation enzymes. Several PI enzymes, that is, cytochrome P450 (CYP) isoforms (Matsuo et al., 2008), and at least three PII enzymes, for example, glutathione S-transferase (GST) isoforms, can exist in olfactory tissues ( $\pi$  – Starcevic and Zielinski, 1995; Yanagi et al., 2004;  $\mu$  – Pérez-Lopez et al., 2000;  $\theta$  – Pérez-Lopez et al., 2000). In fishes, CYP1A1 has been localized to lamellar tips (the non-sensory epithelium), and, with exposure to a CYP inducer ( $\beta$ -naphthoflavone; BNF), in the sensory epithelium as well (Monod et al., 1994; Saucier et al., 1999). In mice, PI and PII enzymes colocalize to non-neuronal cells (Weech et al., 2003). The ability of compounds to induce PI enzymes (or markers thereof) has also been used as a toxicological endpoint. For example, ethoxresorufin O-deethylase (EROD; a CYP 1A1 substrate) activity increased in the olfactory epithelium by >5-fold following exposure to 3,3', 4,4'-tetrachlorobiphenyl (TCB; a PCB) (Cravedi et al., 1998). In the olfactory bulb, BNF exposure was

used to characterize the CYP induction time course, as CYP1A mRNA was increased within 4 hr of exposure (Chung-Davidson et al., 2004). Studies characterizing olfactory PII responses are more rare. One study noted that inducing cell death (through severing the bulbar innervation) caused a rapid decrease in GST activity that returned after two months (Starcevic and Zielinski, 1997). Another study found that insecticide exposure increased GST activity (Tierney et al., 2008).

## 23.5 FUNCTIONAL ASSESSMENT

With such a complex tissue and such a diversity of structures and cells, it is unsurprising that a diversity of methods have been used to explore underwater olfaction. Studies have measured the ability of odorants to: (1) excite the olfactory epithelium (Evans and Hara, 1985), (2) excite specific OSNs (Lastein et al., 2008; Valentincic and Koce, 2000), (3) activate brain neurons and form topographical maps (Bandoh et al., 2011; Nikonov and Caprio, 2005; Nikonov et al., 2005; Zou et al., 2005), (4) evoke downstream motor neurons (Derjean et al., 2010), (5) evoke physiological responses (Olsén et al., 2006), and (6) evoke behavioral responses (Bhinder and Tierney, 2012; Stacey, 2003). In fishes, the method of choice has been a technique pioneered in frogs (Ottoson, 1956) – the electro-olfactogram (EOG) – which assesses changes in potential across the olfactory epithelium, that is, generator potentials (Baldwin and Scholz, 2005). The EOG has been used to quantify the detection threshold for a diversity of odorants in a vast array of fishes. Examples include  $\sim 10^{-5}$  M for L-alanine and L-glutamine in hagfish (*Myxine glutinosa*) (Døving and Holmberg, 1974),  $\sim 10^{-10}$  M (alanine and cysteine) in scalloped hammerhead shark (*Sphyrna lewini*) (Tricas et al., 2009), and  $10^{-14}$  M (3kPZS) lamprey (*Petromyzon marinus*) (Johnson et al., 2009).

A second area of functional assessment that has received considerable attention in aquatic olfaction is olfactory-evoked behaviors. Behavioral responses have been measured in numerous ways: Y-mazes have been used to characterize attraction to streams (Scholz et al., 2000), siblings (Olsén and Winberg, 1996), foods (Rehnberg et al., 1985), and mates (Yambe and Yamazaki, 2001); avoidance troughs have helped determine whether fishes avoid contaminants, such as metals (Giattina et al., 1982; Hansen et al., 1999) and pesticides (Saglio et al., 2001; Tierney et al., 2007b), or predators (Rehnberg et al., 1985); open arenas have been used to characterize alarm responses (Brown, 2003; Mirza et al., 2009; Pollock et al., 2003; Speedie and Gerlai, 2008). In recent years, tracking software has helped with measuring behaviors. For example, changes in larval zebrafish swimming can be measured in 96 well plates (Baraban et al., 2005) and fish movements

can be quantified in three dimensions (Cachat et al., 2011). A challenge with behaviors is that individual variation can be considerable: some fishes may be active and grow inactive when presented with an odorant while a sibling may do the exact opposite (Shamchuk and Tierney, 2012).

## 23.6 TERRESTRIAL OLFACTORY ADAPTATIONS

Amphibians are ideal organisms to showcase the transition from aquatic to terrestrial existence as they contain life phases adapted to both. Furthermore, some amphibians remain adapted to both environments into adulthood, possessing unique elements of olfactory anatomy and physiology. In the African clawed frog *Xenopus*, for example, the principle olfactory chamber is subdivided into the lateral and medial diverticula (a VNO is also present) (Altner, 1962; Hofmann and Meyer, 1991). These two chambers can be selectively opened to the environment using a flap of skin. While the head is underwater, the more ventral lateral diverticulum is open; while above water, the more dorsal medial diverticulum is open. A study indicated that the olfactory receptors of these subdivisions were specialized for their environments, with fish-like receptors expressed ventrally and mammalian-like receptors expressed dorsally (Freitag et al., 1995). This divide therefore potentially represents a structural means to selectively receive soluble vs. volatile odorants (Freitag et al., 1995). Larval *Xenopus* lack this structure and express both types of receptors (and cells later expressed in the VNO) in the principal chamber (Hansen et al., 1998), and so are ontogenetically akin to their origins. As the receptor locations are remodelled during development (Hansen et al., 1998), conceivably this is a limitation of developmental control.

An expectation for amphibians would be that they switch from detecting soluble compounds to volatile compounds between juvenile aquatic and adult terrestrial phases. However, this does not appear to be the case (Shibuya and Takagi, 1963). A secondary expectation might be that the activity of the more aquatic receptors would be down regulated between these phases. This also does not appear to be the case (Inoue and Nakatani, 2010). In fact, the opposite may be true: the detection of an amino acid mixture (alanine, arginine, proline, and glutamic acid) increased up to 115 hr after land transfer in the Japanese newt (*Cynops pyrrhogaster*) (Inoue and Nakatani, 2010). The authors noted that olfactory cilia grow in length over this time period (Shibuya and Takagi, 1963) and so postulated that there had been an increase in receptor number. However, the method of olfactory assessment they used (EOG) is dependent on many factors, and the duration of the experiment may have been insufficient to observe

longer-term changes. If amino acid reception remains throughout terrestrial life, what would be its purpose?

Several other terrestrial adaptations first emerge with amphibians. For example, ORs used for detection of volatile odorants are first seen and they can have several (*Xenopus* has 1638; Niimura, 2009), olfactory binding proteins can be found, but only as tadpoles transition to land (Millery et al., 2005), similarly a Bowman's gland (Jungblut et al., 2011).

## 23.7 APPLICATIONS AND PERSPECTIVES

Olfaction has found relevance as an endpoint in many fish toxicology studies as it is of such importance and is exquisitely sensitive to waterborne contaminants (Tierney et al., 2010). This thinking was presciently arrived at, as one of the first functional measurements of fishes olfactory physiology explored the effects of surfactants (from detergents) on the olfactory responses of Atlantic salmon (Sutterlin et al., 1971). This study set the tone for decades of research demonstrating the effects of dissolved metals and natural and synthetic organic compounds on fish olfaction. A limitation with many of these studies is that they determine short term effects and not the ability of the tissue to cope (physiologically adapt) with the agent. Nevertheless, these studies can determine two types of OSN impairment: general impairment of all OSNs and impairment of specific subtypes (Tierney et al., 2007a). As to what these two inhibitory routes mean to olfaction, each can be framed as changes in vision: a general OSN impairment may be akin to myopia, that is, only being able to sense things “close up” (loss of ability to detect low odorant concentrations), while specific impairment is akin to colour blindness, that is, perceiving odorant information incorrectly. What these changes might mean to fishes such as migratory salmon remain unknown. A caveat is that it can be difficult to relate changes in olfaction to OSN damage. Many synthetic contaminants are structurally similar to natural compounds that act as odorants, for example, the herbicide glyphosate and the amino acid glycine (Tierney et al., 2006). Additionally, natural organic compounds can also interfere with olfaction, such as humic acid (Fabian et al., 2007).

## 23.8 SUMMARY OF KEY DIFFERENCES IN FISH VS. MAMMALIAN OLFACTION

Unlike mammals, in fish:

- There are typically two openings per nostril, one for incurrent flow and the other for excurrent flow.

- The olfactory chambers are generally blind sacs.
- Bowman's glands are absent but mucus producing goblet cells are distributed across the olfactory epithelium.
- Nasal flow is typically achieved in one of two ways:
  - By the pumping of two sacs whose filling is coupled to ventilation or “coughing”
  - By the action of cilia and/or the pressure associated with swimming
- Unique cell types exist in the olfactory epithelium and the olfactory bulb. Examples include crypt and ruffed cells, respectively.
- There is a diversity of vomeronasal and trace-amine associated receptors not present in tetrapods.
- The one-to-one, olfactory sensory neuron-to-odorant receptor protein rule does not hold for all fishes.
- A morphologically distinct cell type (crypt) may express just one receptor gene, and so is akin to photoreceptor cells.

## The Chemistry of Avian Odors: An Introduction to Best Practices

GABRIELLE A. NEVITT and PAOLA A. PRADA

### 24.1 INTRODUCTION

Over the last century, birds have been important models in sexual selection and evolutionary theory. Consequently, multiple aspects of the visual ornaments and songs of birds have been catalogued and studied for literally hundreds of species, while any mention of scent is routinely either ridiculed or denied in most textbooks. This was not the case, however, for ornithologists and natural historians living in the early 1800s. At this time, a controversy concerning the Turkey vulture's (*Cathartes aura*) sense of smell was raging mostly because John James Audubon defied the then commonly accepted observation that Turkey vultures scavenged using their sense of smell.

But why was Audubon so set on disproving something so obvious? Some might say he was biased, but we hold that it was his ignorance of chemistry that really got him into trouble. According to biographer William Souder (Souder, 2005), Audubon held to the theory that "nature is parsimonious—that creatures may, for example, rely on keen eyesight or a sensitive ability to smell, but not both." A 'definitive' experiment involved using a painting of a dead sheep as bait: "A coarse painting on canvass was made, representing a sheep skinned and cut-open." Upon discovering it, vultures "commenced tugging at the painting. They seemed much disappointed and surprised, and after having satisfied their curiosity, flew away." Among other problems with experimental design beyond the scope of this review, we now know that Turkey vultures (*Cathartes aura*) are sensitive to sulfides emitted by freshly decaying proteinaceous flesh, similar to those sulfides found in pigments of oil based paints (Luxan and Dorrego, 1999; White et al., 2006). These compounds are

so attractive to vultures that they have been purposefully used to scent natural gas, so that pipeline leaks in remote areas can be located by the kettles of vultures overhead (Stager, 1964; for review, see DeBose and Nevitt, 2008).

From the vantage point of 2012, Souder's descriptions seem almost comical, but the ideas put forth in Audubon's publications, and the popular attention that followed, set the stage for both academic and public denial that any bird could smell, with a lasting impact on the development of behavioral ecology as a discipline, and the potential influence of chemical senses in such behaviors, from foraging to personal odor recognition. If Audubon could 'prove' that even Turkey vultures lacked a sense of smell, then how could olfaction be important to the behaviors of other birds? This simple Type 1 error – rejection of the null hypothesis even though it is true – changed the course of the study of chemical senses. The result was that birds, a class of vertebrates that arguably presents some of the most tractable experimental models for the study of chemical senses, have been passed over in favor of rodents, salamanders, and flies. Just as importantly, with renewed interest in avian olfaction, researchers getting into this field should be cautious of Type II errors, or false positive error, particularly in an era where manuscripts are published rapidly, and analytical tools and technologies are just as rapidly developed beyond the expertise of even conscientious reviewers.

With avian chemical senses experiencing a hey-day, there have been several recent reviews of avian olfaction, and the interested reader is referred to these (Campagna et al., 2012; Hagelin and Jones, 2007; Hagelin, 2007; Nevitt and Bonadonna, 2005; Nevitt and Hagelin, 2009;

Nevitt, 2000, 2008; Rajchard, 2007, 2008; Roper, 1999; Wallraff, 2004; Wenzel, 2007). Our goal is not to repeat these reviews, but rather provide interested readers with background information about potential sources of avian odor, and to educate behavioral ecologists about the relative strengths and weaknesses of chemical approaches in a user-friendly manner. We are focusing on this problem because one of the most rapidly growing areas of avian chemical ecology is the study of personal odor and how it may or may not contribute to chemical signaling in birds. Much of this work is being carried out by laboratories that do not focus on the chemical senses, and by young researchers in behavioral ecology who need to be able to build bridges with analytical chemists to design effective and realistic experiments to test hypotheses. Many studies are being published even though they have not used calibrated methods. Just as Audubon's study did, they may make headlines, but they do not necessarily authentically progress scientific understanding.

In this review, we first introduce readers to potential sources of avian scent, and provide an overview of functional chemistry necessary to understand the literature. We then review analytical techniques focusing on understanding best practices, and finally highlight representative studies that we feel have used these methods appropriately. In non-prejudicial fashion to achieve quality, we have purposely avoided studies that have been highlighted in recent reviews, but have included them in table form for the interested reader (Table 24.1).

## 24.2 SOURCES OF AVIAN ODOR CHEMICALS

Several different physiological sources likely contribute to the scent of any given bird. These sources include: the skin and feathers, glandular and skin secretions, dietary products, and digestive oils and feces.

### 24.2.1 Skin and Feathers

Avian skin is distinguished from that of other terrestrial vertebrates by its lipophilic properties (reviewed by Menon, 1984) and that it is characteristically much thinner in order to conserve weight as an adaptation for flight. Although it tends to be only a few cell layers thick, it is composed of a dermis and an epidermis, and functions primarily to provide a permeable barrier to regulate water loss and to prevent dehydration (reviewed by Pass, 1995). In birds, invaginations of the skin also form feather follicles, but these follicles do not contain glands as hair follicles do in mammals (reviewed by Stettenheim, 2000). Instead, due to its lipogenic nature, the entire skin can be regarded as a fat-producing holocrine gland (Lucas, 1970, 1980).

Menon and Menon (2000) provide an excellent overview of the gross anatomy and typical pattern of epidermal lipogenesis, secretion and sequestration of lipid within the stratum corneum, and the following discussion should be regarded as only a cursory review of a truly fascinating and involved subject.

Given the diversity of birds, avian skin can be highly variable depending on the region of the body, the reproductive state of the animal and the species (Wrench et al., 1980; Menon et al., 1981), but there are common features. Among other functions, the dermal layer stores fat, contains larger blood vessels and nerves associated with the feather follicles, and otherwise supports the epidermal layers and integument. Following Menon and Menon (2000), the epidermis is composed of multiple (typically four to five) layers of cells called sebokeratinocytes due to their tendency to produce lipid (sebum). As cells move upward towards the epidermal surface, they change their form and function. Thus, cells progress from basal (germinative) and sub-basal layers, to layers such as the stratum transitivum, characterized by free lipid droplets and multigranular bodies analogous to epidermal lamellar bodies found in mammals. The outer-most layer is the stratum corneum or keratin layer which gives rise to specialized structures such as feathers, scales, claws, spurs, beaks, and horny sheaths.

Feathers are an obvious feature of avian skin. Among numerous functions, feathers provide insulation, aerodynamic flight power, water repellency, cleanliness, body support, and sex appeal (reviewed by Gill, 1994). The basic feather structure consists of a shaft with parallel branches on either side. This shaft has a short, tubular portion implanted in the follicle and a longer medullar portion above the skin.

Feathers are periodically replaced, but molt patterns are complex and vary by life history of the species in question (Stettenheim, 2000). Although this, to our knowledge, has not yet been convincingly shown, the constraint to molt suggests that developmental changes might be reflected in the chemical profile of the feather, skin, and preen gland secretions, or of products from bacterial, fungal, or other microbial interactions that adhere to the feather surface (reviewed by Rajchard, 2010). Specific feathers such as the powder down also have the potential to contribute to the generation of plumage odor by the production of a talcum-like substance that complements preen gland secretions in preening and waterproofing functions. This powder is composed of keratinized cells with lipid-type characteristics (Menon and Menon, 2000).

### 24.2.2 The Preen Gland

Unlike mammals, most species of birds do not have skin glands aside from the uropygial or preen gland, glands of the ear canal (Menon and Salinukul, 1989), and glands in

**Table 24.1** Summary of Avian Odor Chemicals Classified by Extraction Technique.

the vent region (Quay, 1967; King, 1981; Menon et al., 1987). However, due mostly to its size, accessibility, and morphological diversity (Jacob and Ziswiler, 1982; Johnston, 1988), the preen gland has been frequently investigated as a potential source of personal odor in birds. The preen gland is an integumentary, bi-lobate gland found in most species of birds (with some exceptions, including ostriches, emus, cassowaries, bustards, and some species of parrots). The preen gland produces a waxy oil that has been historically studied for its various roles in feather maintenance (Salibian and Montalti, 2009). Although the detailed anatomy varies between species, in general, preen oil is secreted from the gland and passes to the surface via ducts that lead to a papilla resembling a small nipple situated dorsally near the base of the tail (for a more detailed description, see Salibian and Montalti, 2009; Jacob

and Ziswiler, 1982). Oil from the preen gland collects on the skin and feathers; birds collect this oil by rubbing the back of the head against the opening of the gland, and then distribute it throughout the feathers and skin through the action of preening (Elder, 1954). In a variety of species, the preen gland is fringed by a feather tuft, and it has been suggested that the tuft functions as collection spot for oils (Jacob and Ziswiler, 1982).

Preen gland secretions tend to be a complex and highly variable mixture of natural esters, fatty acids, and long chain alcohols (Jacob, 1992). Extensive evidence from a wide range of species suggests that glandular secretions help to maintain plumage by conditioning the feathers and, in some cases, by controlling skin fungi, bacteria, and parasites through the actions of specific compounds (see discussion in Moyer et al., 2003; Shawkey et al., 2003).

Preen glands tend to be well developed in aquatic birds, so extensive research has also focused on the potential role that preen gland secretions play in waterproofing, thermoregulation, and in creating a protective barrier on the feather surface against various forms of environmental perturbation (Salibian and Montalti, 2009). Waxy secretions chemically repel water, but even more importantly they maintain the structural integrity of the feather, which, in turn, preserves loft and the associated airspaces to provide an insulating barrier (Kostina et al., 1996). While this has not, to our knowledge, been considered in the avian literature, preserving loft would also assist in presenting scented volatiles via the feather matrix from odor sources other than the preen gland itself.

### 24.2.3 Sources of Avian Scent that are Not Usually Considered

While the preen gland has received considerably more attention than avian skin as a source for personal scent, we suggest that, as a holocrine secretion unit (Lucas, 1970), the skin has great potential for odor production, storage, and rapid presentation through the secretion of lipids. This hypothesis predicts that lipid secretion might be highest in tissues associated with sexual displays or other aspects of reproductive behavior where scent might be adaptive for advertising quality. There is already correlative evidence for this idea in the literature, in that lipid secretion is higher in featherless, glabrous regions of skin. At least some of these skin regions tend to be sexually dimorphic, hormonally induced ornaments that are often used in courtship displays (for example, the combs and waddles of galliformes). Lipid production is also higher in brood patches, and, in some groups (storks and ibisis) where feathers are permanently lost during maturation. This suggests a possible avenue whereby lipid production, and any associated changes in scent, could conceivably be influenced by reproductive or metabolic hormones, and even transferred to the egg or chick (Sneddon et al., 1998; Burne and Rogers, 1999; O'Dwyer and Nevitt, 2009; Cunningham and Nevitt, 2011). Such possibilities need to be explored, but interestingly, outside the field of avian chemical senses, it has already been suggested that avian skin may be pre-adapted for sequestering lipophilic dietary compounds due to its high turnover rate. This concept has perhaps been most convincingly illustrated by detailed studies of the Pitohuis birds of New Guinea. Members of this passerine group sequester dietary-derived neurotoxic steroid alkaloids (primarily homobatrachotoxin) in their skin and feathers as an antipredator behavior (see Dumbacher et al., 1992; Dumbacher et al., 2009). According to these reports, these batrachotoxins interact with sodium channels of potential predators, and also function to chemically defend the bird from parasites. Pitohuis birds

advertise their toxicity through brightly colored plumage and by emitting a “sour” scent, detectable to humans. Although the origins of this scent have not been well worked out, the dietary origins of the neurotoxins alone suggest that consumed products can influence compounds presented in avian skin, and suggests to us a mechanism by which volatile compounds from diet or digestion might also be contributing to feather odor.

The ability of many seabirds, specifically the order Procellariiforms, to regurgitate stomach oil to their young or as a defense mechanism against predators, provides yet another basis for chemical odor generation (Clarke and Prince, 1976). It was thought at one point that these stomach oils could be another type of secretion; however, the high variation in chemical composition between individuals of the same species suggested instead that stomach oil is derived from dietary sources (Lewis, 1969). For example, pristane (2, 6, 10, 14-Tetramethylpentadecane), which is common in stomach oil, is a metabolic derivative of phytol found in different forms of plankton that these birds consume. Stomach oils reflect diet, and we routinely find these compounds on feathers of Leach's storm-petrels that haven't obviously regurgitated (Prada and Nevitt, unpublished observation), suggesting that at least some of these scented products are used to perfume feathers. Whether scents from stomach oil serve as communication signals about prey resources has not been demonstrated.

Despite being one of the most obvious attributes of birds to fieldworkers, feces are commonly (and somewhat ironically) overlooked as a source of personal odor in birds. It is recognized that feces of stressed chickens differ in both consistency and smell from that of unstressed birds (Jones and Roper, 1997). Jones and Roper (1997) suggested that this scent might function as a ‘non-vocal’ alarm call, though this has not, to our knowledge, been demonstrated. Avian fecal products have not been studied with respect to individual odor, but should be considered in light of studies in mammals (e.g., mouse urinary proteins or MUPS; reviewed by Beynon and Hurst, 2004).

In summary, although we provide only a brief introduction to the topic, identifying the origin of any individual scent is critical to understanding its biological function in behavioral contexts, yet this is one of the greatest challenges of this field. Equally important is that once odors are produced, they are generally trapped in some form of biological matrix that needs to be considered in context. That matrix can be a physical structure, like a feather, or a secretion, such as preen wax. In birds, both of these matrices are likely to contain endogenous or intrinsic compounds produced from the individual itself, or exogenous compounds that are environmentally absorbed or derived through a behavioral or developmental process. For example, although it is produced endogenously, preen wax will inherently interact with chemicals in the

environment, which together may contribute to the birds' personal scent. Microbial activity may further interact with one or both intrinsic and exogenous compounds and these interactions have yet to be worked out in any species of bird. Since identifying the chemical composition of the scent is usually an inherent goal, understanding the chemical properties that render compounds volatile should be a fundamental concern. The analytical presentation of the scent will also impact what compounds are accessible in high enough concentrations to be measured, and care must be taken to design experimental protocols and instrumental analyses that incorporate this understanding. We focus on these aspects in the next section.

### 24.3 WHAT MAKES SCENTS AND WHAT (USUALLY) DOES NOT?

The scent of a bird can be made up of hundreds of detectable compounds (Campagna et al., 2012), which can be confounding to analytical analysis because detection threshold by instrumental methods varies from compound to compound. The instrumental response is directly affected by the intensity (concentration) of the odor in the matrix being sampled. So, for example, a sample might yield different amounts and types of compounds when sampled from a secretion versus a feather simply because the physical matrix has different properties. Although scented compounds may be presented in a non-volatile matrix such as a secretion or on an organic substrate, whether or not a particular molecule contributes to an odor signature in air is likely to depend on the relative volatility of that compound. Volatile organic compounds (VOCs) that make up scent in air are characterized by their high vapor pressure at room temperature. These molecules have low boiling points, which is the physical property that allows the molecule to evaporate from its liquid/solid matrix and enter into the surrounding air. This measure should be reported in any serious investigation of odor chemistry in air.

A general classification of vapor pressures and volatility is presented in Table 24.2. Based on numerous studies in other terrestrial vertebrates, one might expect that, for a bird, molecules of interest should be the ones with the highest volatility because they may be the most accessible in air. Interestingly, a common feature of avian chemical odor analysis is that the detection and subsequent identification of compounds in many cases focuses on non-volatiles which may be useful in other contexts, such as working out metabolic pathways for production, but their relevance to scent is difficult to determine using standard analytical methods. In nearly every published analysis of bird odor, volatility is not reported, and rarely acknowledged (a notable exception is Reneerkens et al., 2007a, b).

Compounds of potential biological interest in birds include a range of functional groups, which impact odor. Appreciating the differences between the chemical functional groups becomes important for evaluating odor profiles, and this is a common obstacle for the non-chemist. With the exception of hydrocarbons, most of these functional groups (acids, alcohols, esters, amides, aldehydes, ketones) have a carbonyl structure that is defined by a double bond between carbon and oxygen (Table 24.3). Although the metabolic or behavioral role of many of these compounds is only beginning to be explored in most cases, we include here a brief tutorial on these common functional groups (Figure 24.1).

1. Carboxylic acids are defined by the carbonyl group and are attached to a hydroxyl group ( $-OH$ ). Carboxylic acids are common in both feather and preen gland secretions, and it has been suggested that at least two carboxylic acids (propanoic and 2-methylpropanoic acids) are modulated by sex steroids in grey catbirds (Whelan et al., 2010).
2. Alcohols are characterized by a hydroxyl group ( $-OH$ ) bound to a carbon atom. Alcohols tend to be derived from fatty acid reduction processes (Solomons and Fryhle, 2002), thus explaining their high occurrence in preen gland secretions and feathers.
3. When a carboxylic acid reacts with an alcohol, an ester is formed. Esters are made up of a mixture of fatty acids and alcohols. They are thought to be important to the

biosynthesis of the complex molecules of preen secretions (e.g. Dekker et al., 1999; Reneerkens et al., 2002).

4. Amides have a carbonyl group attached to a nitrogen atom. Amides are typically absent or occur in trace amounts in studies of secretions or feathers, but this may be due to limitations of the extraction methods typically used (Campagna et al., 2012).
5. Aldehydes are defined by a carbonyl group bonded to a hydrogen atom and an alkyl chain. They tend to be characterized by strong aromas, and have been shown to be a dominant component of feather odor in some species. For example, aldehyde content in feathers from Crested auklets (*Aethia psittacula*) constituted 73.7% of the identified molecules, with aldehydes such as n-octanal and n-hexanal contributing to their unique citrus scent (Douglas et al., 2001). Possible roles include chemical defense (Douglas et al., 2001) and social signaling (Hagelin et al., 2003, 2007).
6. Ketones are defined by a carbonyl group bound to two carbon atoms. For example, ketones have

been detected in preen gland secretion, some linear methyl ketones (tridecan-2-one, tetradecan-2-one and pentadecan-2-one) have been linked to seasonal changes in dark-eyed juncos (*Junco hyemalis*; e.g., Soini et al., 2007).

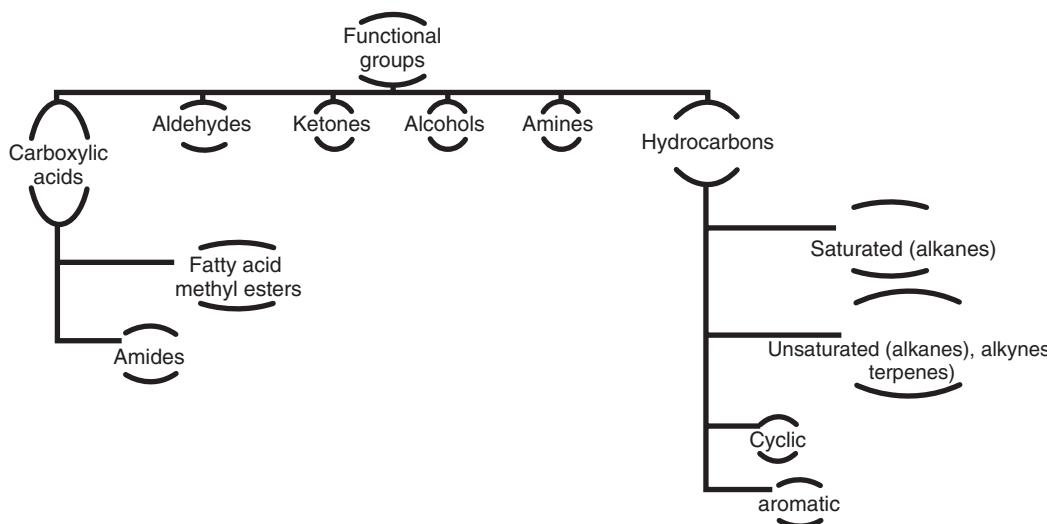

7. Hydrocarbons consist entirely of hydrogen and carbon and can be further characterized into subcategories such as aromatic, cyclic alkane, alkene, alkyne, and terpene hydrocarbons. Hydrocarbons are one of the most abundant functional groups in feathers and glandular secretion samples (Campagna et al., 2012), and may be derived from bacterial or other environmental sources (Yamashita et al., 2007; Jaspers et al., 2008).

### 24.3.1 Analytical Techniques for the Isolation of Avian VOCs

Many researchers come into this field with strong backgrounds in behavioral ecology but without the necessary background in analytical chemistry to evaluate and compare studies, and this has led to difficulties in interpreting and comparing results. Here we provide a basic framework of the methods used in the analytical laboratory that should help researchers to obtain the most accurate results, and hopefully to better understand the analytical techniques involved. Because the heart of a good analysis is sample preparation, the three major types of extractions currently being used for both volatile and non-volatile analysis of feather and preen gland are also described in detail in this section. However, these methods could be applied to other types of biological matrices, including skin and feces.

Regardless of the sampling method used, analytical analysis requires that certain conditions be met. First and foremost, to ensure optimal accuracy in any analysis, calculating the sensitivity of the instrument is critical. The sensitivity of an instrument is the measure of its ability to detect small differences in sample concentration. Without this step, compounds cannot be identified and concentrations cannot be measured. Despite its importance, several prominent papers have been published recently without this step.

To achieve this step, the response of the analytical instrument needs to be calibrated to a known sample analyte and concentration (Skoog et al., 1998). Two of the most common ways to do this are to: (1) produce a calibration curve using a variety of known compounds, or ‘standards’, or (2) to use internal standards as a means of calibrating the instrumental response. A calibration curve is derived from measuring several chemical standards (i.e., chemical compounds that have been putatively identified in the sample) at different known concentrations. Collection methods used must be identical to those used for the sample. A plot of response versus concentration can then

**Figure 24.1** Classification of Chemical Functional Groups.

be used to determine the concentrations of those same compounds, if they are present in the sample being studied.

The second method is generally applied in cases where it is difficult to match the standards with unknown compounds. In such cases, in addition, the relative concentration of compounds can be established using an internal standard. This approach involves adding a known concentration of a chemical compound to all samples, blanks, and calibration standards. This internal standard should not be present in the sample, but should have similar chemical properties to at least some of the unknown compounds. Accurate calibration is achieved by plotting the ratio of the sample signal to the internal standard signal as a function of the concentration of the standard. This method helps to compensate for both random and systematic errors, because the sample and the internal standards will respond proportionally to any variation, and serve as a robust control (Skoog et al., 1998). Precise external or internal calibration not only provides the analyst with the capability to accurately identify the analytes in an unknown sample, but also monitors whether the analytical instrument is functioning properly.

Finally, when performing volatile identification in any sample matrix, it is standard practice to report retention indices that can be compared to known retention values. This is commonly done using Kovat's retention indices, which allows the retention times to be converted into system-independent constants. The retention index of a chemical compound can be defined as its reported retention time normalized to the retention times of adjacently eluting n-alkanes. While retention times can vary with specific chromatographic parameters such as column type, diameter, thickness and/or length, the calculated retention indices are independent of these parameters and allow

compounds to be compared and their identity to be further confirmed.

In terms of optimal practices for handling and processing samples, when working in odor analysis, it is critical to wear nitrile gloves to collect or handle samples to prevent cross-contamination of any kind. This also requires extreme care in the sterilization and cleaning of all glassware, including the vials used to collect the samples, to make sure volatiles being detected originate from the sample source and not from background contamination. In the search for individual volatile odor markers from a specific population, species, gender, or individual, researchers in this field also tend to misunderstand the importance of sampling in replicate. It is well established from studies in humans, for example, that establishing a baseline for an individual is critical before individuals within a population can be compared (Gallagher et al., 2008; Curran et al., 2010; Prada et al., 2011). Thus, in the context of avian odor signatures, multiple samples from the same bird should be collected in replicate to capture the most accurate chemical odorprint from the individual being studied. Without replicate samples, it is difficult to determine if the detected compounds are characteristic of the individual, or due to contamination.

Although different extraction procedures have been used to study odor profiles of feather and preen gland secretions, detailed techniques are rarely reported. This suggests that future reviews comparing results among studies should be more explicit about techniques. Table 24.1 provides a list of recent studies that have used various extraction techniques to study avian VOCs from matrices such as feathers and glandular secretions. To familiarize non-chemists interested in avian olfaction with the advantages and disadvantages of methodologies, we present

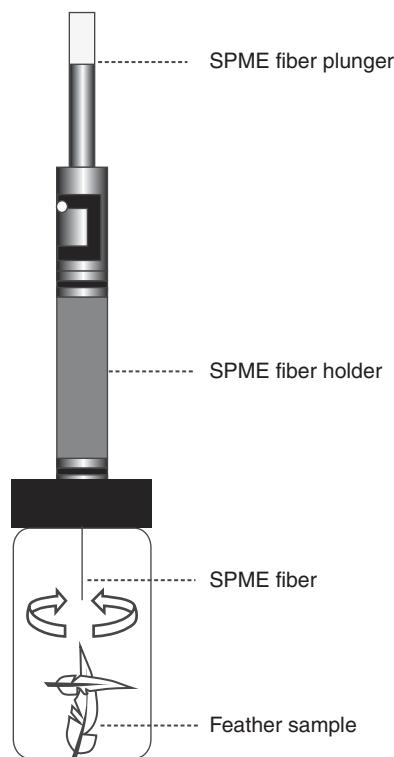

an overview of the three most commonly used extraction techniques.

### 24.3.2 Solvent Extraction

Solvent extraction uses organic solvents at room temperature, and is the most common and conventional separation method. This method is used to extract potentially scented compounds from biological matrices such as glandular secretions or feathers (Table 24.1). This method has been frequently used to study bird odors (Amo et al., 2012; Bonadonna et al., 2007; Dekker et al., 1999; Douglas et al., 2001; Karlsson et al., 2010; Kolattukudy and Sawaya, 1974; Leclaire et al., 2011, 2012; Mardon et al., 2010, 2011; Piersma et al., 1999; Reneerkens et al., 2002; Sandilands et al., 2004; Sweeney et al., 2004; Thomas et al., 2010; Zhang et al., 2008, 2010) and offers the advantage of being an efficient and robust method to extract complex, high molecular weight molecules. Samples can easily be preserved for analyses because the extraction does not need to be done immediately. The major variable to consider when performing this type of extraction is the polarity and type of solvent used, and this will depend on the types of compounds to be extracted and identified. However, this extraction method has several drawbacks for studying avian scent. Perhaps most importantly, if the goal of a study is to identify VOCs, it may not be the most appropriate method for the question because solvent extraction does not specifically target VOCs. Consequently some of the extracted compounds will not contribute to the odor. Instead, solvent extraction targets more complex, sometimes viscous, high molecular weight compounds that are not volatile at room temperature. The non-volatile constituents may also potentially interfere with the recovery of semi-volatile compounds, which, together with solvent impurities, can compromise the analysis of the sample. Finally, organic solvents can pose health hazards when used under field conditions, and transport and disposal can be costly.

### 24.3.3 Solid Phase Microextraction

Solid Phase Microextraction (SPME) is a useful technique for the rapid and accurate identification of volatile compounds in the air space (“headspace”) surrounding either a solid or liquid matrix. In headspace extraction, the headspace should be as small as possible as this increases the concentration of analyte and thus reduces extraction time. SPME has been used effectively to measure VOCs from mammals (Cablk et al., 2012), including human skin (Curran et al., 2010; Prada et al., 2011). In the context of birds, SPME has been used to extract odors from feathers (Douglas et al., 2001; Hagelin et al., 2003; Williams et al., 2003) and preen gland secretion (Burger et al., 2004;

**Figure 24.2** Solid phase microextraction schematic.

Shaw et al., 2011; Whelan et al., 2010). SPME is typically used for the collection and subsequent identification of VOCs by chromatographic techniques, and has several advantages in that it is easy to use, fast, portable, and inexpensive (Penalver et al., 1999). SPME employs a fiber, which is a short, thin, solid rod of fused silica. These fibers are typically 1 cm in length and have approximately 0.11 mm as an outer diameter. SPME fibers are coated with different types of sorbents that vary by polarity and thickness; however fiber selection should be optimized for the types of compounds of interest (Table 24.4). A general consideration is that “like dissolves like” when selecting a fiber for an application. Polydimethylsiloxane (PDMS) and polyacrylate (PA) were the first fiber coatings utilized for SPME fibers. PDMS is apolar and has a high affinity for non-polar compounds. The PA fiber coatings are more polar and thus extract polar compounds. Fiber coatings containing more porous and adsorbent materials include blends of divinylbenzene (DVB) or Carbowax (CW) with PDMS. Fibers used for SPME technique can also be categorized as either absorption or adsorption fibers. Absorption (film) fibers extract analytes whereas adsorbent (particle) fibers physically trap or chemically react with the analytes. The latter are made from a porous material and analytes compete for sites on the fiber coating. Adsorbent fibers have a limited capacity (Wercinski, 1999). Table 24.4 provides a concise description of the most recommended

**Table 24.4** Summary of Fiber Coatings available for SPME Fibers.

Fiber Coating	Fiber Type	Application
Polydimethylsiloxane (PDMS)	Absorption	Used for non-polar organic compounds; analyte group volatiles MW 60–275
Polyacrylate (PA)	Absorption	Used for polar organic compounds; MW 80–300
Polydimethylsiloxane/divinylbenzene (PDMS/DVB)	Adsorption	Used for aromatic hydrocarbons and small volatile analytes such as solvents; MW 50–300
Carboxen/Polydimethylsiloxane (CAR/PDMS)	Adsorption	Used for gases and low MW compounds MW 30–225
DVB/CAR/PDMS	Adsorption	Used for volatiles and semi volatiles C3–C20; MW 40–275

fiber type depending on the volatility and molecular weight of the target analyte.

The fiber is attached to a metal rod, which is protected by a metal sheath that allows the fiber to be covered when not in use. For sampling purposes, the SPME fiber is withdrawn from the syringe needle and, by pressing down on the plunger, the fiber is then exposed to the headspace above the sample of interest for a predetermined time to absorb analytes. After sampling has concluded, the fiber is retracted and directly injected into a gas chromatograph (GC) for instrumental analysis (King et al., 2003). A schematic diagram of the SPME fiber assembly is shown in Figure 24.2 depicting the extraction of a feather sample. To our knowledge, Douglas et al. (2001) were the first investigators to use the SPME technique to extract odor volatiles from a feather matrix; they used fibers coated with 65 µm polydimethylsiloxane/Divinylbenzene coatings to measure VOCs from Crested auklet (*Aethia psittacula*) feathers. SPME fibers with 75 µm Carboxen-PDMS coatings have more recently been used for the collection and analysis of VOCs from uropygial glandular secretions of both *in situ* and dissected glands of euthanized Gray catbirds (*Dumetella carolinensis*; Shaw et al., 2011; Whelan et al., 2010).

#### 24.3.4 Stir-bar Sorptive Extraction

A second, newer form of solvent-less extraction is the stir bar sorptive extraction (SBSE) technique, commercially known as Twister®. In SBSE, the extraction is performed using a magnetic stir bar coated with sorbent material. Currently, only polydimethylsiloxane and modified ethylene glycol phases are available. The design of the stir bar allows the device to contain more sorbent material on its surface, thus providing space (capacity) for analyte

extraction up to one hundred times greater than in SPME (Baltussen et al., 2002). SBSE can be used to extract VOCs from either solid or liquid matrices. After extraction procedures, the bar is removed from the sample vial and placed in a thermal desorption inlet of a GC for analyte desorption. The extracted analytes are cryofocused at the front of the column for GC analysis. One major disadvantage when using SBSE is that only the thermal desorption step is currently automated, thus rendering this technique cumbersome for large sample sizes (Kłoskowski et al., 2007). SBSE has been successfully used to analyze VOCs from uropygial gland and the surface of wing feathers (via direct wiping of the SBSE on the wing) of dark eyed juncos (*Junco hyemalis*; Soini et al., 2007; Whittaker et al., 2010).

### 24.4 EXAMPLES OF APPROPRIATE PRACTICES

Chemical ecology of birds is in its infancy as a discipline and researchers are grappling with the problem of how to select appropriate techniques. Reviewers and editors rarely have the expertise to critically evaluate the validity of the analytical chemistry used, and literature reviews commonly fail to recognize fundamental differences or limitations of the techniques used. Here we review examples of chemical studies chosen to highlight the techniques we have described. In our opinion, these particular studies exemplify best practices in action.

#### 24.4.1 A Study of Anti-predator Behavior in Red Knots

A study focusing on Red knot (*Calidris canutus*) anti-predator behavior by Remeijer and co-workers

exemplifies what we consider to be the optimal convergence of biology, chemistry, and a solid experimental design rooted in natural history and a simple observation by the authors. Sandpipers (family: Scolopacidae) are ground nesting birds, which make them vulnerable to mammalian predators, and yet hunting dogs were often observed to overlook vulnerable females on eggs. The authors wanted to know whether this was because the nesting Red knots' scent was somehow masked. This hypothesis predicted that the odor chemistry of a bird changed predictably during the breeding season.

Reneerkens and coworkers went on to test whether the composition of preen oil changed with breeding phenology. They first evaluated the preen oil composition of 19 different sandpiper species using a novel analytical approach for this application – gas chromatography and tandem mass spectrometry (GC- MS/MS; Dekker et al., 2000). Gas chromatography/mass spectrometry (GC/MS) is more commonly used to analyze VOCs, but GC/MS targets fatty acids and alcohols that are released after the sample is hydrolyzed. GC- MS/MS allowed the investigators to elucidate the chemical structure of the waxy esters in the preen gland matrix, and how it contributed to scent. They demonstrated a shift from monoesters (lower molecular weight/more volatility) to diesters (higher molecular weight/less volatility) in preen gland secretions during the breeding season, and suspected that one function of this switch might be olfactory camouflage for nesting birds. The gas chromatograms were characteristic for the wax type, and offered a robust demonstration of seasonal shift in the chemistry of preen gland secretion with a clear functional advantage to the bird. Reneerkens et al. (2007a, b) note, however, that the wax composition is not volatile and thus the monoesters themselves may not be present in the odor. This result does, however, highlight that simple modifications in the chemical structure of these compounds can contribute to avian scent in an evolutionarily adaptive context, and this was a remarkable result. As a further test of their hypothesis, they used a sniffer dog to confirm the low volatile character of the diester secretions (Reneerkens et al., 2007a, b). The canine had a greater difficulty detecting this heavy weight diester mixture thus providing experimental support for olfactory camouflage using an appropriate biological detector for the question at hand – the canine nose.

#### 24.4.2 Dark-eyed Juncos and Crested Auklets

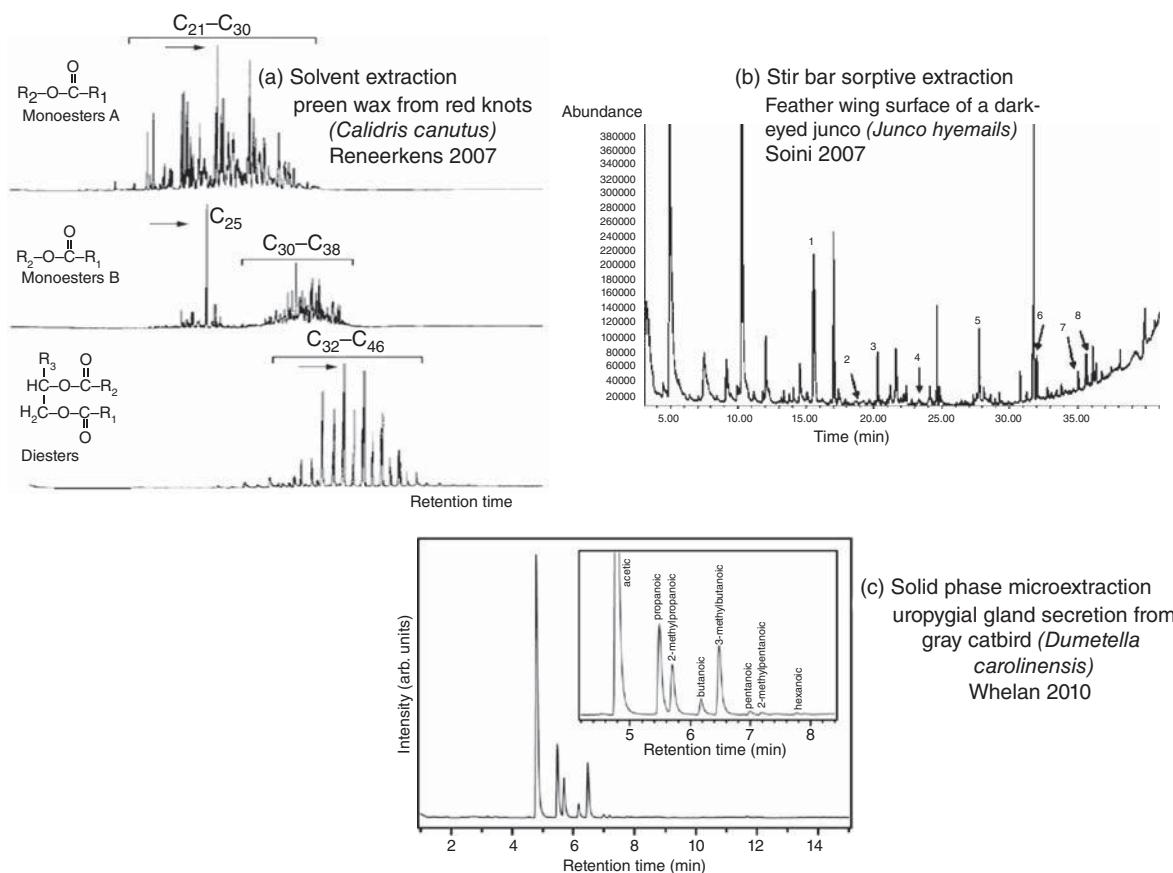

Reneerken's studies are currently state-of-the-art in terms of marrying a relevant hypothesis-driven question to solid chemical and field investigations. Investigations into other avian systems are much less developed, but offer great promise. As mentioned above, Douglas et al. (2001) were

the first to report the use of solvent-less SPME extraction technique for headspace analysis of feathers from Crested auklets (*Aethia cristatella*). In this study, the fiber was positioned near the specimen's neck and extracted for a period of 4.5 hours. Interestingly, they also performed a second extraction of feather samples using traditional solvent extraction (either methylene chloride or methanol) for comparative purposes. Although identification of specific compounds (e.g., hexanal) differed between methods, in both cases aldehydes such as n-octanal, n-decanal, and Z-4-decenal were detected, thereby confirming SPME as a novel chemical approach for studying feather odor.

More recently, Soini et al. (2006; 2007) were the first to apply the Twister (stir bar) method to study feather and preen gland odors. They used the stir bar technique to examine VOCs from biological samples, including human skin, fruits, fingerprints, and bird feathers (Soini et al., 2006). They used embedded internal standards to achieve highly reproducible and quantitative results for a wide variety of trace compounds. A year later, a more complete investigation focused on preen gland secretions from dark-eyed junco (*Junco hyemalis*) using a quantitative stir bar approach (Soini et al., 2007). The study provided insights into the effects of seasonal changes on chemical composition. Authentic standards were used for the verification of detected compounds, as well as an internal standard (7-tridecanone). Although studies were done on captive birds, replicate sampling was conducted for 20 individuals for both breeding and non-breeding study groups, thereby taking into consideration intra-individual variation over time. Multiple sampling yields a greater level of certainty in the analysis and identification of the detected VOCs. The GC-MS VOC profiles obtained from the secretions included linear alcohols, as well as a number of aldehydes, acids, and methyl ketones, thereby demonstrating the potential of the technique for volatile analysis on an important model species in field endocrinology. Figure 24.3 shows a brief comparison of chromatographic results obtained through the various extraction techniques.

## 24.5 CONCLUSIONS

The scent of a bird is generally a complex fragrance made up of a suite of volatile organic compounds (VOCs). Identifying these VOCs and their relative contributions to a species' or individual's scent is central to understanding their chemical nature, their potential biological source, and, eventually, whether or how they influence behavior. Not surprisingly, the instrumental analysis of VOCs is a rapidly expanding field in the race to find compounds of potential biological significance among birds, but robust methodological standards for odor collection and analysis are still being established. In this review we provided a

**Figure 24.3** Representative chromatographic results via different extraction techniques.

brief overview of the general sources of odors in birds, a description of the functional groups of interest for the ‘non-chemist,’ and a critique of the instrumental methods currently being used for this purpose.

The science of avian scent is growing in popularity, and this offers great promise for the future of this discipline. Still, much of the published chemical literature is preliminary due to inconsistencies or misapplication of analytical chemical techniques. We wrote this chapter to provide information to ornithologists who, like Audubon, are passionate about avian biology but may not have the foundation in the chemical classifications, techniques, and best practices necessary to most effectively examine hypotheses about avian scent. The wide array of avian species, chemical analytical tools, methods of extractions, and statistical methods present obstacles to biologists seeking to work in this field. This is a brief attempt to introduce foundational concepts that may be useful in getting around some of them.

To summarize, it is critical to select an appropriate species and extraction technique for the hypothesis being tested, and to analyze replicate samples. Despite the considerable extra time and effort required, chemical

calibrations are necessary to translate chromatograms into credible data. Finally, characterizing or differentiating one chemical profile from another does not, in itself, imply a function or a role for behavior. Differences in odor profiles, and any potential role in communication, needs to be demonstrated by an appropriate biological detector in an ecological context, in addition to using analytical detectors, before a scent can be called a cue. We hope this attempt to highlight best practices will help the field to progress to the point where avian scent can be examined in a comparative context, from production and regulation, to adaptation and function in the natural world.

## Olfactory Communication in Rodents in Natural and Semi-Natural Habitats

DANIEL W. WESSON

### 25.1 INTRODUCTION

Olfactory communication in rodents involves the passive or active release of a chemical signal into the environment for the purpose of influencing behavior. This signal must have the capacity to elicit neural responses in one of the several systems for olfaction in the brain, including most prominently the main and accessory olfactory systems (see Chapters 8, 10, 51, and 52). Both active and passive odor cue emission are governed by sex, hormonal status, age, behavioral state, past experience, and other factors (nutrient intake, illness) which together provide a highly dynamic source of signals not only in their release but also in the behaviors they elicit. Indeed, in “intraspecific” communication, the dynamics of these signals translate into numerous possible “messages” being conveyed onto conspecifics wherein they guide proper behavioral responses.

Traditionally, research into odor-guided behaviors in rodents has explored the occurrence of discrete stereotyped behaviors in artificially reduced laboratory environments. This most commonly occurs within the context of a small cage or an enclosed testing arena. This has been a highly successful framework for studies into odor-behavior relationships, resulting in elucidation of fundamental aspects of odor learning, odor detection, and odor discrimination. The laboratory environment results in an optimal context to collect behavioral and physiological data and provides control over environmental variations (temperature, light cycle, nutrients, other animals) which compounds the experimenter’s dependent variables. This is especially useful for studies of olfaction since not only can “real-world”

environmental factors affect the emission of odors and the motivation to gather odor information, but it can also have a direct impact on the odor itself. For instance, if one were to measure the impact of female ground squirrel scent marking on male ground squirrel behavior, a finding that the male was not attracted to the female scent mark could be interpreted as meaning it is not a socially-relevant cue. However, if it was a cold and windy day, now perhaps an alternative hypothesis could be approached: the scent mark dissipated in the wind and failed to evoke behavior in the male because he never received the signal. Compounding matters further, perhaps the male recently mated and thus is not in an appetitive motivational state. These and other issues have resulted in the commonplace occurrence of olfactory research in rodents to occur within the controllable confines of a laboratory.

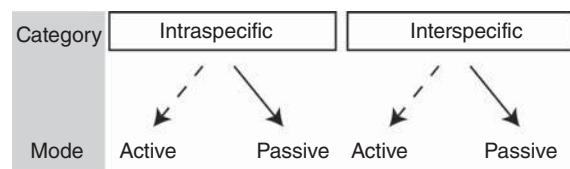

However, rodents did not evolve to perform complex behaviors in the context of limited cage environments. More particularly, rodents did not evolve remarkable mechanisms of olfactory communication for them to occur within the confines of a simple laboratory cage. Indeed, even basic aspects of social behaviors are altered dramatically, depending upon the physical context (Wills et al., 1983). Arguably, some forms of odor communication, such as the scent marking for signaling social status, are for most purposes useless in a laboratory cage where social status of a conspecific is worked out within a short period of group housing and, unless a new conspecific is introduced, not reassessed by cage-mates. Thus, it is difficult to imagine conclusions on odor-behavior relationships are as ethologically-relevant as possible when derived from experiments wherein animals are not only housed,

but also tested, in a highly artificial environment. In this context, not only are we as researchers likely missing highly significant information about how the environment impacts behavior, but also how animals have evolved to most optimally perform olfactory communication.

The purpose of this chapter, therefore, is to introduce main concepts of rodent olfactory neuroethology and draw upon some particularly elegant examples of studies in rodents within natural and semi-natural environments to explore principles of ethologically-relevant rodent olfactory communication. Examples from laboratory-based studies will also be used throughout to exemplify cases of olfactory communication not yet reported in natural contexts or those methodologically difficult to study in natural contexts. Together, these studies will be used to highlight means by which animals use odors to communicate with each other and other animals, as well as to validate (with some exceptions) laboratory-based studies. This chapter is not meant to be an exhaustive review of all studies on ethologically-relevant olfactory communication, and sincere apologies are made to those researchers whose studies I have not included, yet have also contributed to a greater understanding of the olfactory basis of rodent behavior. For those interested in further reading on complimentary aspects of odor-guided behavior in rodents and other mammals, see (Doty, 1986, 2010; Brennan et al., 1990; Leon, 1992; McClintock, 1998; Meredith, 1998; Slotnick, 2001; Wilson and Linster, 2008; Keller et al., 2009; Wachowiak, 2011).

## 25.2 INTRA- VS INTER-SPECIES OLFACTORY COMMUNICATION

As an initial framework for the understanding of rodent olfactory communication (Figure 25.1), it is useful to consider that rodents emit chemical signals which may be received by either members of their own species, or members of other species. Transfer of olfactory information between members of the same species can be referred to as intraspecific olfactory communication. Intraspecific olfactory communication is by far the most commonly studied form and entails commonly observed sociosexual behaviors including scent marking, face-to-face sniffing, anogenital investigation, and maternal behaviors of pup-retrieval and suckling. The role of olfactory signals in the orchestration of these behaviors will be discussed in detail later within this chapter (see Section 25.3). In intraspecific communication, rodents may utilize odors to influence behavior of a recipient conspecific, or may investigate received odors to explore the nature of a conspecific. In this context, the odor itself must have either an innate or a learned meaning to the recipient animal, which increases

**Figure 25.1** Framework for the understanding rodent olfactory communication. Rodents emit chemical signals which may be received by either members of their own species (intraspecific), or members of other species (interspecific). The emission of odors in both of these categories may be active (volitional) or passive. Rodents have evolved to display and also functionally utilize these different forms of olfactory communication adaptively.

the probability of a desired behavior to occur, whether to mate or to flee.

While the emission of olfactory signals may have initially evolved for intraspecific purposes, the release of these cues can have unwanted consequences. Indeed, olfactory cues enhance predation. In other cases, olfactory cues may signal to a predator unsuitability as a food source, and thereby prolong survival. Alternatively, in a more complex sequence of events, perception of a predator odor signal or perception of an odor from a stressed conspecific may result in an “alarm” signal in rodents to aid conspecifics in survival. These forms of olfactory communication, wherein chemical signals are emitted by a member of one species to be received by a member of another species, are referred to as interspecific and will be discussed in detail in Section 25.4 of this chapter.

## 25.3 ETHOLOGICALLY-RELEVANT INTRASPECIFIC OLFACTORY COMMUNICATION

### 25.3.1 Active Intraspecific Olfactory Communication

Active intraspecific olfactory communication behavior involves an animal engaging in an olfactory behavior with the intent to modulate conspecific behavioral and/or physiological responses. This is the equivalent of a human talking to another human or a dog barking at a dog. One conspecific will “say” a particular message with, in many cases, a desired response latent in their mind. In consequence to this, assuming the message is received, the receiver conspecific will engage in a divergent behavior from their existing behavioral state.

**25.3.1.1 Scent Marking.** Perhaps the most common form of olfactory communication in rodents within their natural environment is active intraspecific communication. Here I draw upon the wealth of studies regarding

scent marking behavior in rodents to exemplify common principles of active intraspecific odor communication. Indeed, this behavior is by far the clearest example of active olfactory communication in rodents and serves a variety of critical roles, mainly in terms of sociosexual behavior.

Scent marking is generally considered to be employed for the signaling of social status (reviewed in detail by (Hurst and Beynon, 2004; Roberts, 2007; Arakawa et al., 2008)). However, multiple views, perhaps not mutually exclusive, exist regarding the function of scent marks and why rodents so frequently lay down scent. Marking behavior in monogamous rodents (e.g., prairie voles, *Microtus ochrogaster*) and other monogamous animals has been interpreted to aid in maintaining the pair bond (Peters and Mech, 1975). More frequent dispersal of one's scent not only reinforces the bond but also might discourage unwanted intruder males from attempting to intervene. Scent marks may also aid animals in orienting and navigating within their territory. Thus, individual marks lay out a road map to navigate burrows and localize previous sources of food (Kleiman, 1966). Scent marking may also function by signaling fitness of the emitter to potential intruders (Gosling, 1982). Whether an invader would flee or stay upon detection of a scent mark may be determined by a mixture of possible costs of staying (possible bodily harm), the incentive to stay (how attractive the territory is), and the certainty of the animal that the detected signal was interpreted correctly (Gosling, 1982). For instance, detection of the scent mark of an identifiably fit male would deter intruders from invading territory whereas scent of a weak male (as described below) would be less of a deterrent. However, if the intruder was uncertain about the mark's meaning, and the territory was prime real estate, the likelihood that the intruder would stay and fight for the territory would increase. While the above examples are raised in terms of male competition, this similar theory extends into the function of scent marking in terms of mating and the female reception of scent.

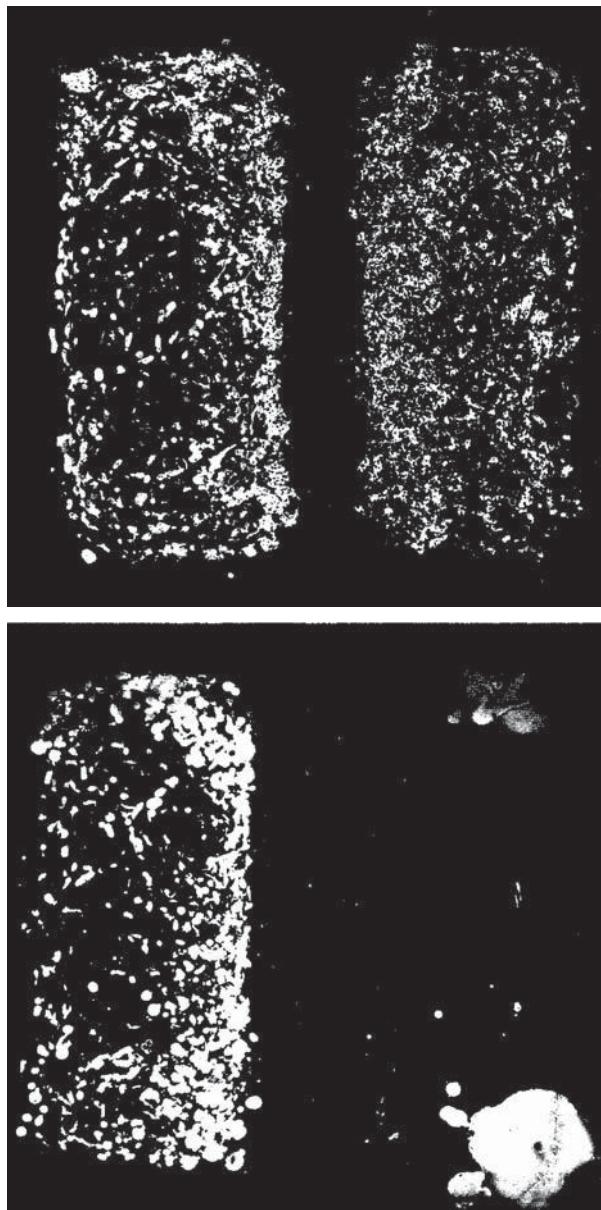

An extensive amount of research is available on the regulation of scent marking, making this a strong model system for ethologically-relevant olfactory communication. Scent marks are composed of odorants originating from a variety of species-specific sources, including urine and glandular secretions (McIntosh et al., 1979). Accordingly, male rodents may scent mark by rubbing their preputial area along the ground or along objects they climb over. This allows chemical signals to be deposited from the preputial glands around the genitals onto the environmental substrate. The remnant scent mark is thus made available for immediate reception (by a proximate conspecific) or for future reception by a distant conspecific. The acquisition of odor information from a scent mark may occur from the emitted volatile odorants, although in many cases the scent

mark's efficacy is greatest when the animal's nose actually contacts the mark. Indeed, male mice engage in more frequent scent mark displays themselves when allowed to come into direct contact with a conspecific's scent mark, versus when the scent mark is covered with a wire mesh (Nevison et al., 2003).

The nature and function of scent marking displayed by a male is closely linked to his social status. As shown in Figure 25.2, male mice that are defeated or subjugated in social interactions will inhibit future scent marking displays (Lumley et al., 1999).

Dominant males in a semi-natural open environment will mark more frequently and in a more dispersed pattern compared to subordinate males (McIntosh et al., 1979). Indeed, in some animals (e.g., the bank vole *Clethrionomys glareolus*) the size of the preputial gland is positively correlated with aggressive dominance (Gustafsson et al., 1980). Across strains of mice, the less aggressive the strain, the smaller the preputial gland (Yamashita et al., 1992), reflecting a drive to increase marking capacity in aggressive/dominant males. It is thus not surprising that male deer mice have larger midventral sebaceous glands than and that their size and secretions are influenced directly by male testosterone levels (Doty and Kart, 1972). Additionally, in semi-natural environments, scent marks by dominant males are most likely found in regions associated with intruder origin – areas with greatest need to deter threats (Gosling, 1982). The frequency and pattern of scent marking are both taken as evidence of the males' motivation to establish territory and also to attract potential mates. Indeed, the prevalence of scent marking among juvenile mice (*Mus musculus*) is a strong predictor of dominance in adulthood (Collins et al., 1997).

Laboratory studies in reduced environments have shown that both scent marking behavior and the behavior of investigating scent marks are gonadal hormone dependent. Investigation of an open area is inhibited by the presence of scent marks from gonadally intact males, however, castration of these marking males results in no difference in behavior of the investigator males (Jones and Nowell, 1973), likely, as discussed below, due to changes in the chemical composition of the marking male's urine or preputial secretions. Indeed, gonadectomy even results in decreased size of androgen dependent preputial tissue (Lumia et al., 1994; Djeridane, 2002). Males of many rodent species treated with testosterone and other testosterone analogs mark more frequently than castrated or physiologically intact (untreated) males (McIntosh et al., 1979; Lumia et al., 1994; Wesson and McGinnis, 2006). Further, treating male rats with androgen receptor inhibitors reduces scent marking behavior along with other sociosexual behaviors (Vagell and McGinnis, 1998). This androgen dependence of scent marking behavior is in

**Figure 25.2** *Upper photo:* Ultraviolet photographs of overnight urine marking patterns of socially naïve, male, wild house mice, one in each compartment of a 12 x 12 inch cage, separated from each other by a wire mesh partition. *Bottom photo:* Urine marking patterns following establishment of dominance in an agonistic encounter, with marking of dominant animal shown on left and subordinate shown on right. Note large urine deposit from the subordinate. From Bronson (1976); used with permission, Copyright Elsevier, 1976.

accordance with the escalation of scent marking behavior in pubertal males (Arakawa et al., 2008).

Relatedly, scent marks play a large role in regulating female choice of mates. Female deer mice (*Peromyscus maniculatus*) display differential preference for male urine odor depending upon the state of their estrus cycle (Doty, 1972). This finding is highly intuitive as one would expect

a sexually-motivated female to seek a dominant male who would pass on viable genes. Female meadow voles (*Microtus pennsylvanicus*) spend more time near the scent marks of a well-nourished male versus a malnourished one (Ferkin et al., 1997), in a manner evidently due to differential protein content of restricted diets. This is thought to be due to the females' motivation to select viable and successful mates with whom to reproduce (Roberts, 2007). Females of many rodent species, including mice, prefer to mate with males with whom they have had prior experience via their scent mark (Hurst, 2009). This familiarity effect is something of a paradox when considered in relation to the utility of odor cues to aid in dispersing genes and selecting mates with slightly differing body odor composition (Isles et al., 2001). However, the preference of females to mate with males whose scent mark is familiar might provide a mechanism for generalization in simply seeking more available mates.

While not addressed in detail herein, the chemical composition of scent marks which animals emit is becoming increasingly understood. To explore the chemical nature of the scent marks, researchers have utilized both liquid and head-space gas chromatography. In head-space chromatography, one can explore the types and amounts of volatiles emitted from a liquid odor source. Chromatographic evidence for differences in urinary compounds between dominant and subordinate mice exists (Harvey et al., 1989). In one study, Harvey and colleagues (1989) found 16 compounds which differ in concentration based upon social status of male mice, including dihydrofurans, acetates, and ketones which decrease in the urine of submissive mice and  $\alpha$ - and  $\beta$ -farnesene which increase in urine from dominant mice. Some of this research has focused on the presence of major urinary proteins (MUPs) which are heavy weight large molecules that possess considerable stability and resist volatility over small urinary molecules and additionally appear to regulate the factors involved in social signaling within the urine (Sharrow et al., 2002).

Complementing their overt behavioral actions, male scent marks have the capacity to exert physiological modulations to the female reproductive system, which enhances the probability of successful copulation. These include the ability for dominant adult male scents to accelerate puberty in juvenile females (i.e., Vandenberg effect) (Lombardi and Vandenberg, 1977) and to induce synchronous estrus (i.e., Whitten effect) (Whitten, 1956). Interestingly, in the Vandenberg effect, the physical presence of a dominant male can apparently suppress levels of a chemical or chemicals found in the urine of subordinate conspecifics. The authors found that it was this suppressed substance or substances which was responsible for accelerating puberty in females (Lombardi and Vandenberg, 1977) when upregulated in other males. Similar findings have been observed in other animals in addition to rodents

(Vandenbergh, 1989). Thus, physiological modulations of odor emission can occur by social factors which can in turn modulate endocrine functions in other conspecifics. Some of these have been found mostly or if not exclusively to be the result of a single urinary constituent. For instance, 6-hydroxy-6-methyl-3-heptanone has a strong capacity to accelerate puberty in female mice (Novotny et al., 1999). Thus, both male urine and scent marks can profoundly affect female behavior and physiology through the olfactory system. Notably, alternative hypotheses exist regarding some of these “pheromone-mediated” findings, including the Vandenbergh effect (for further details, see Doty, 2010).

Counter-marks can occur when a dominant male encounters a scent mark from a subordinate conspecific or when a potentially-dominant male enters an environment where scent markers from other males have been deposited (Rich and Hurst, 1999; Hurst and Beynon, 2004). In these cases, the dominant or new male will place a scent mark on top of the existing scent mark in a competitive behavior. While this “over-marking” would seem to create a complex chemical signal that may be confusing to future recipients, counter-marking is a successful way for the dominant male to actually *replace* a subordinate’s scent within his own (Hurst and Beynon, 2004). Indeed, female and even male mice show remarkable preferences for males whose scent mark was on top of the existing mark (Hurst, 2009). This is likely an important behavioral preference since it would aid females in finding the closest males. While counter-marking is commonly observed in mice and rats, it is not universal for all rodents, and voles in particular do not seem to actively counter-mark (Mech et al., 2003).

Given their critical role in behavior, it is perhaps not surprising that the function of scent marks varies with experience. Olfactory experience with scent marks has been studied extensively in voles, wherein voles of both sexes spend more time investigating novel scent marks (those from unfamiliar animals) versus those from familiar conspecifics (Ferkin et al., 2010). Novel scent mark investigation and investigation of flank gland odors are also subject to habituation (Beauchamp and Wellington, 1984). These basic principles of experience-dependent scent mark investigation behavior are also apparent in semi-natural contexts. In one very powerful example of this, ground squirrels (*Spermophilus beldingi*) clearly discriminate between familiar and novel conspecific odors even after hibernating for the winter (Mateo and Johnston, 2000).

While scent marking is most widely studied in males (likely due to the incorrect assumption that male rodents play the greatest role in initiating and controlling mating; Doty, 1974), female rodents also scent mark as a form of olfactory communication. However, the functions of female scent marks seem to differ greatly from that of males, and their occurrence is rarer, making studies into

the modulation and function of female scent marking behaviors difficult. Similar to that discussed above for male mice and rats, hormones influence the scent marking of females, with the most scent marking of females occurs during proestrus or early estrus (Hurst, 1990; Matochik et al., 1992). Even in laboratory conditions female scent marks are dictated by social status, with virgin females marking less frequently than their mothers (Heise and Rozenfeld 1999). In those species that have been evaluated, female scent marks appear to play a salient role in female to female interactions. Indeed, in female hamsters more scent marking behavior occurs upon reception of female scent than male scent (Johnston, 1977). In mice, female scent marking is more prevalent when in the proximity of a gonadally intact male than in the presence of a castrated one (Maruniak et al., 1975). Female urinary scent is highly attractive to sexually experienced males (Lydell and Doty 1972). Scent marking behavior appears, for both sexes, as a means for coordinating reproductive success.

Overall, the aforementioned studies on scent marking behavior highlight the fact that this form of olfactory communication is critical for rodent survival within nature. Scent marking patterns and strategies are highly plastic, being modulated by age, hormonal status, and social experience. Further, recognition of conspecifics based upon their scent marks is mediated by highly robust memories, which likely translate into better adaptive behavioral responses to both familiar and unfamiliar conspecifics.

### 25.3.2 Passive Intraspecific Olfactory Communication

While evidently emitted with no perceivable effort, passive odor cues robustly modulate a great number of conspecific behaviors, including conspecific sexual, aggressive, maternal, and food seeking/preference behaviors. While rodents spend considerable risk and energy depositing scent marks, in the following passive odor communication examples, information is exchanged without major energy loss.

#### 25.3.2.1 Sociosexual Behaviors.

Rodent body odors emitted from a variety of glandular sources modulate the occurrence of sociosexual behaviors. Each animal has an individualized odor-type, which is based upon numerous factors (Beauchamp, 1988; Yamazaki et al., 1999). Far more studies have been performed highlighting the role of body odors on mediating conspecific preference and sociosexual behaviors than can be nearly addressed within this chapter (but see Keller et al., 2009). Indeed, it has been known for many years that odors modulate sociosexual preferences of a wide variety of animals (e.g., Edwards and Burge, 1973; Beach, 1974). Further, appetitive and consummatory sociosexual behaviors are strongly

modulated by olfaction in a variety of rodents. Olfactory bulbectomy or nasal epithelium lesions, for instance, markedly influence copulatory behaviors of hamsters, rats and mice of both sexes (e.g., Doty et al., 1971; Edwards and Burge, 1973; Meisel et al., 1980; Wood and Newman, 1995; Keller et al., 2006).

In one study, Drickamer (1989) tested the role of male or female urinary odor, soiled bedding odor, and whole body odor on female mouse preferences. Different groups of females were tested at different ages, thereby allowing a test of the influence of female reproductive status on conspecific passive odor preference. Before puberty, females avoided the odors of males and showed a preference for grouped female odors. This shifted at the time of puberty, resulting in a strong attraction for male odors and an avoidance of odor cues from grouped females.

This same group of researchers later went on to use a semi-natural enclosure paradigm to explore a similar question of impact of reproductive state on odor preferences (Drickamer and Brown, 1998). In this study, relatively large populations of male and female mice were housed in a large wire mesh arena ( $25 \times 40$  meters) with numerous “mouse cities” that provided shelter and burrowing opportunities for the mice. These mouse colonies were allowed to flourish under no experimental intervention for 30 weeks. Throughout the study, live traps containing cotton nesting materials were placed within each enclosure, making it possible to capture random mice from the entire population during the course of the study. Cleverly, the authors utilized live traps that allowed for measuring odor preferences. They found that mice are attracted to traps previously holding another mouse. Using this approach, they inferred, for example, that a mouse that was caught in trap that previously held a female mouse preferred the smell of that female mouse. It was found that, as females mature, they change their odor preferences. Young female and male mice both avoided traps previously housing adult males. However, upon entering adulthood, female mice shifted their preference for traps that previously held adult males. Similarly, adult male mice preferred traps previously holding adult females. Thus in this semi-natural design, Drickamer and Brown (1998) were able to demonstrate that several basic principles of odor-guided social preference in mice seen in the laboratory were also present in a more natural setting.

Just as an attractive odor may result in social preference, an “unattractive” body odor may result in avoidance. For instance, a female may avoid mating with a male based upon his body odor composition and instead prefer to mate with a male with a different odor. This has been modeled in several ways, including treatment of rodents with *E. coli* lipopolysaccharide (LPS) (Arakawa et al., 2009) to induce a sickness odor phenotype. In one study, Arakawa and colleagues (2009) treated male rats with

LPS. LPS-treated male rat odor was avoided by both male and female conspecifics. Interestingly, the authors found that this avoidance was dependent upon the status of the stimulus animal, with the odor of prepubertal males treated with LPS failing to elicit avoidance behavior (Arakawa et al., 2009). Thus, perhaps conspecific avoidance of “sick” conspecifics only occurs when the conspecific is of age to be a threat or mate. Alternatively, this finding may be an experimental artifact of an influence of endogenous hormones on the immune-mediated expression of the sickness odor (Arakawa et al., 2009). This finding reflects that sickness odors transmitted through passive bodily means are potent modulators of sociosexual behaviors and highlight the utility of such odors in sociosexual behaviors.

**25.3.2.2 Aggression.** Aggressive behavior in rodents is tightly linked to body odor composition. Again, this behavior is largely dependent upon olfaction in a variety of rodents and has been documented from studies that differentially perturbed olfactory sensory input (Hull et al., 1974; Lumia et al., 1975; Edwards et al., 1993; Kounie and Stern, 1995; Stowers et al., 2002). The odor-dependence of aggressive behavior, taking into account differential body odors of animals (Beauchamp, 1988), provides an efficient mechanism for defending territory. In an early and elegant example of this phenomenon, the urine of a novel male was rubbed on a familiar male who was part of a dyad (Mackintosh and Grant, 1966). The conspecific in the dyad failed to recognize the familiar male whose odor had been masked with that of the unfamiliar male, resulting in escalated agonistic behaviors direct towards the previously familiar male. This is a powerful example of how body odors dictate social encounters, since the resident male is seemingly attending exclusively to bodily odors. The submissive males, however, are emitting little to no other communicative cues, such as ultrasonic vocalizations (Thomas et al., 1983). In another study, resident males displayed less aggression to novel males rubbed with odors of previously familiar males (Gosling and McKay, 1990). These studies suggest that rodents match the scents of animals (Gosling and McKay, 1990). This appears to be adaptive, since it allows rodents to generalize between animals efficiently as long as their body odor matches those of previously familiar animals. Such a mechanism would be highly useful and relevant within rodent burrow systems, where light is lacking and non-visual communication is required for communicating threat signals.

**25.3.2.3 Maternal Behavior.** In many species of newborn rodents, the young are born without functional sensory systems beyond that of olfaction. Thus, the recognition and care of newborns by dams is dependent upon emission of olfactory cues by pups (Sullivan, 2003).

Similarly, pups identify dams and localize nipples for nourishment based also upon olfactory cues (Teicher and Blass, 1976; Blass and Teicher, 1980; Logan et al., 2012). While the majority of research on this subject requires a laboratory environment for experimental manipulation and close observations, these olfactory dependent behaviors position odor cues as highly critical for survival in natural contexts and thus are discussed in more detail here (also see (Leon, 1992)).

Perhaps one of the most powerful models is the finding that the pup sucking response in rodents is largely odor-dependent (Stewart et al., 1983). Pups have trouble localizing and attaching to maternal nipples when the nipples have their natural maternal odors removed (Teicher and Blass, 1976). But do pups learn that maternal odors are ethologically relevant? Or instead are pups born seeking maternal odors? In one early investigation, Pederson and Blass explored this question by addressing when an odor must be experienced to determine the pup's first suckling response in albino rats (Pedersen and Blass, 1982). In their first experiment, the authors exposed pups prenatally and immediately postnatal to the odorant citral. These pups readily suckled nipples of an anesthetized dam which were cleaned of natural odors, and instead scented with citral. In a different experiment, Pedersen and Blass (1982) exposed pups to the smell of citral in utero, immediately following birth, or both in utero and immediately following birth. Only pups exposed to the citral odor in utero and immediately upon birth suckled. These results are highly informative of the mechanisms of early olfactory learning in an ultimately ethologically-relevant task. Interestingly, while not relevant to the current chapter, these results also lent evidence for prenatal events in olfaction (Pedersen et al., 1983), wherein memories for odors may even occur in utero. These experiments have been supported more recently in mice (Logan et al., 2012) and together demonstrate that the maternal odor cues serve as experience-dependent learnt odors (Leon et al., 1987) to promote pup survival.

Maternal behaviors (nursing, licking, and grooming) are required for thermoregulation and returning the pup to the nest for nursing (Fleming et al., 2002). Thus it is adaptive that pup body odor facilitates maternal behavior by aiding in pup localization/identification and retrieval. In one study, Mayer and Rosenblatt (1993) sought to test the critical nature of pup odors on maternal behavior. The authors abolished olfactory sensory input to the olfactory bulbs of lactating females with a zinc sulfate lesion of the nasal epithelium and later explored their preference for pup odors (Mayer and Rosenblatt, 1993). Bedding from cages containing the lactating female's pups was placed in two out of four holes of a hole board apparatus, and the remaining two holes were filled with clean bedding. Females with sham epithelial lesions (intact sense of smell) displayed

a strong preference for the holes containing bedding with pup odor, however, anosmic females did not. Thus, attraction of females to their pups is largely mediated by pup bodily odor (Benuck and Rowe, 1975), in a manner similar to that seen in other mammals (Lévy and Keller, 2009).

#### **25.3.2.4 Food Foraging and Preference.**

Semi-natural experimental designs lend themselves quite well to understanding the modulation of food foraging by odors. In one such study, Verplancke and colleagues used an artificially enclosed arena which was situated within a wooded area free of predators and human intervention (Verplancke et al., 2010). Within the enclosure, the authors placed feeders which allowed for both video recordings of the number of visits by bank voles and also the amount of food how much food was consumed. Relevant to this discussion, the authors scented the food with conspecific odors (male or female) to determine how conspecific odor modulates food intake. It was found that conspecific odor increases the number of visits to the feeders and the amount of foraging in this semi-natural context (Verplancke et al., 2010). Although, interestingly, in this paradigm the authors noted a several fold difference in non-scented food consumption compared to earlier laboratory studies. While only in one rodent species, the finding in the above study that animals enhance food consumption and proximity/activity around sites which smell like conspecifics is highly intuitive and it is reasonable to assume that rodents, just like humans, do this as a behavior of familiarity and comfort.

Within conspecific feeding conditions, odor of consumed foods originating from the facial region or breath of one conspecific are well known to modulate future food preferences and consumption behaviors in other conspecifics. While the majority of studies into this social transmission of food preference have occurred in reduced laboratory environments (Galef, 1985), this paradigm is highly relevant for the ethology of rodents and thus discussed here. In the classic design, a hungry rat (the "demonstrator") is allowed to eat food laced with an odor, for instance, cinnamon, for several days. Immediately after one of the food consumption days, a hungry conspecific is placed with the demonstrator and they are allowed to interact for a period of time. It is thought that during this time, the conspecific samples the odors emanating from the facial region and breath of the demonstrator and forms a learned association with that odor. Then the hungry conspecific is placed into a context where it has the choice to consume food laced (for example) with cinnamon odor versus cocoa. Significantly more consumption of cinnamon laced food indicates the social transmission of food preference. This paradigm is conserved across a considerable number of rodents (Galef, 1985; Bunsey and Eichenbaum, 1995;

Faulkes, 1999) and can be used to study odor preferences and aversions alike. However, some animals, like Norway rats, do not learn odor-based aversions within the natural social context, but instead readily form preferences for the breath of a sick/poisoned conspecific (Noble et al., 2001).

Intraspecific passive odor cues can also modulate the localization of food. This has been elegantly studied in eusocial naked mole rats (*Heterocephalus glaber*) allowed to live among their colony in a semi-natural burrow system constructed of clear plastic tubes (Faulkes, 1999). This labyrinth of clear plastic tubes when kept in a dark environment mimics the subterranean system of tunnels and burrows the naked mole rats naturally develop to live in. In this paradigm, colony mates prefer to spend time at a site within the tunnel system whereabouts a conspecific previously found and consumed food. They would even bypass other sites with the same food, to go to the site where the conspecific previously found their food. Conspecifics favored tunnels which were traveled in by the initial foraging mole, versus tunnels other colony members traversed while carrying the same food, thus suggesting a major role for passive olfactory cues in this foraging behavior. This finding reflects that the voles are not honing in on the smell of the food itself, nor even a generalized conspecific, but the initial conspecific who had consumed food. Indeed, this preference for the initial consumed tunnel site was abolished if that tunnel was replaced with a clean tunnel (Faulkes, 1999). This finding suggests that naked mole rats follow individualized odor trails (viz., those from 1 preferential conspecific) to localize food.

**25.3.2.5 Warning Signals.** Olfactory warning signals are sometimes referred to as “alarm pheromones,” and are thought to be emitted by rodents as a physiological response to stress, fear, or generalized anxiety. The method for odor emission in this context would likely be vastly different than active communication signals, like scent marking and thus, for the purpose of this chapter, I classify olfactory warning signals or alarm pheromones as a form of passive intraspecific olfactory communication. Very little is understood about this variation of olfactory communication, although evidence exists for the physiological transduction of these warning signals via the Gruenberg ganglion (Brechbühl et al., 2008) (see Chapter 52). This method of olfactory communication notably does not lend itself well to the natural environment and instead, many rodents have developed more visible or audible warning signals, most of which are actively communicated, to signal to conspecifics the presence of a predator or other threat. While these signals are risky in drawing the attention of predators, they would allow an animal to escape better than a scent trail which may be advantageous for predation.

This said, several examples in the literature have been interpreted to support the existence of alarm pheromones.

In one particular example, mice were subjected to different stressful paradigms and later the behavior of conspecifics was measured when they were placed within the chamber which previously housed the “stressed” mouse (Zalaquett and Thiessen, 1991). The authors of this study reported that mice avoided the side of an experimental tube which previously a stressed mouse had entered through and similarly that being in the environment of the previously stressed mouse resulted in generalized arousal and vigilance. Ultimately, perception of warning odors by design should aid in promoting survival of conspecifics by warning of predation or other threats.

## 25.4 ETHOLOGICALLY-RELEVANT INTERSPECIFIC OLFACTORY COMMUNICATION

While rodents have evolved to emit odor cues to influence conspecific behavior, a downside of this occurs when predators learn (or have developed instinct) to utilize the same cues for predation. Indeed, basically all of the examples above can be utilized in predation scenarios to the benefit of other animals. This highlights how while there are benefits involved in olfactory communication, there is also considerable risk involved. Animals therefore must adjust their patterns of olfactory communication to adapt in the presence of conspecifics versus when predation is likely. Therefore, within this section, I discuss a few particularly powerful examples of these forms of interspecific olfactory communication.

### 25.4.1 Active Interspecific Olfactory Communication

The idea that an animal might actively release an odor to communicate with a member of a different species seems counterintuitive. This is especially true in the case of rodents who may find predation among a large variety of animals in their ethological niche. Scent marks for instance, as discussed in detail above in terms of their ability to modulate an array of conspecific behaviors, are also readily used by predators to localize or “eavesdrop” on prey (Roberts, 2007; Hughes and Banks, 2010). Indeed, there is a strong connection between scent marking and an increased risk of predation. Unlike many other signaling systems in animals, olfactory signaling such as scent marking can be “turned off” at will. For example, in the field, experimentally increasing the amount of vole scent marking leads to increased predation of voles (Klemola et al., 2000; Kiovula and Korpimaki, 2001) due to the ultraviolet reflection given off by proteins within the scent marks and detected by some birds of prey. So, how could a

rodent volitionally modulate scent marking in a manner to increase survival?

While rare, there are examples of cases wherein a rodent emits an odor, or changes the deposition of an odor, with apparent insight into modulating the behavior of a potential predator. As a basic example, mice within laboratory environments decrease scent marking intensity when in the suspected presence of predators, although these findings do not uphold as strongly in semi-natural tests (for review see Roberts, 2007). For example, when the smell of cat (*Felis catus*) was placed in a large arena, neither scent marking rates nor the patterns of scent marking were impacted in mice (Hughes and Banks, 2010).

### 25.4.2 Passive Interspecific Olfactory Communication

In what manners might passively emitted rodent odors perform interspecific communication? This is a far less studied realm of olfactory communication. While a considerably vast amount of work has been performed demonstrating the influence of other animal odors on rodent behavior and physiological responses (e.g., Dielenberg et al., 2001; Wallace and Rosen, 2001; Campeau et al., 2008 and see below), beyond simply being used to locate rodents as prey, much less is known about the details of passive rodent odors in terms of interspecific communication.

**25.4.2.1 Food Foraging and Preference.** In the study of Verplancke and colleagues discussed above (Verplancke et al., 2010), in addition to using conspecific odors, the authors sprayed predator odors and “neutral” odors on food to explore the influence of these odors on bank vole food intake. Again, in this study the authors used an artificially enclosed arena which was situated within a wooded area free of predators and human intervention (Verplancke et al., 2010). Within the enclosure, the authors placed feeders which allowed video recordings of the number of visits by bank voles and also the amount of food consumed. The authors found that predator odor decreases the number of visits to the feeders and the amount of foraging in this semi-natural context (Verplancke et al., 2010). This study nicely illustrates how odor from another animal may modulate rodent behavior.

**25.4.2.2 Other Examples: Nesting and Interspecific Preference/Avoidance.** The nest site is a likely major source of olfactory signals which may enhance predation risks among rodents. Some animals have developed strategies for reducing this unwanted consequence. For instance, female deer mice (*Peromyscus maniculatus*) carry newborn pups from the birthing nest to novel nest sites to reduce unwanted nest odors (Sharpe and

Millar, 1980). Defecation (which has no apparent active or volitional component) can also enhance predation risk. Seemingly to reduce this risk, lemmings (*Dicrostonyx groenlandicus*) defecate in underground sites in the summer, but not during the winter when the snow offers coverage of odor signals (Boonstra et al., 1996).

Many rodent species are sympatric and while some do not have evident predator-prey relationships, they must deal with each other's presence in their ecological niche. Examining the olfactory modulation of this, Doty (1973) explored the role of odors in interspecific preference/aversion behavior in white footed mice (*P. leucopus noveboracensis*) and deer mice (*P. maniculatus bairdi*). In this study, virgin female deer mice were found to prefer conspecific male odor more than heterospecific male odor, as reflected by an increased time spent near the odor of the conspecific mouse. In contrast, white-footed female mice failed to show a preference or aversion for either stimulus (Doty, 1973). Thus, while with differences between types of rodents, rodents can readily discriminate interspecific from intraspecific odors, and use these distinctions to guide behaviors.

## 25.5 SUMMARY

Throughout this chapter, examples of how rodents utilize olfactory communication methods have been outlined. This by drawing upon work which stems from research performed in semi-natural or natural rodent “field” habitats and in some cases laboratory-based experiments which compliment or extend more ethologically-relevant paradigms. Both active and passive odor cue emission are governed by sex, hormonal status, age, behavioral state, and other factors (nutrient intake, illness) which together provide a highly dynamic source of signals not only in their release but also in the behaviors they elicit.

Future work addressing and extending major questions of olfaction within more ethologically-relevant and ideally natural habitats will be critical in bringing about a greater understanding of how rodents and other animals utilize smells (by releasing them or acquiring them) to adaptively survive in their environments. Little has been elucidated regarding how natural rearing, and the use of odors in nature, might entail considerably different neural responses to odors in a manner adaptive to survival in the wild. Further, major questions exist in terms of how rodents acquire (through sniffing for instance) odors in their natural habitat or even in ethologically-relevant social contexts. Answers to these and other questions will bring about greater understanding and appreciation for the complex olfactory world rodents naturally negotiate.

## Olfaction in the Order Carnivora: Family Canidae

PETER HEPPER and DEBORAH WELLS

### 26.1 INTRODUCTION

This chapter reviews olfactory behavior in the Carnivora, concentrating on the family Canidae. Although there have been “pockets” of study on various aspects of olfactory behavior in other Carnivora (e.g., Mellon, 1993; Rozhnov and Rozhnov, 1998; Sliwa and Richardson, 1998; Soini et al., 2012), most research has focused on canids and it is these studies that form the focus of this review. Canids are also of interest because of their unique status in ‘serving’ humans using their sense of smell. Indeed, the olfactory abilities of wolves were recognized by early humans and used to aid hunting and this contributed to the development of cooperation between man and wolves and the process of the domestication of this species (Ruusila and Pesonen, 2004).

The chapter is divided into three main sections. First, aspects of the olfactory system that may contribute to the canids’ acute sense of smell are considered. Second, the olfactory behavior of canids is discussed, and, finally, the applications of dogs’ olfactory abilities are reviewed. We will use selective examples to illustrate olfactory behavior in canids and highlight issues which require further study in order to fully understand the role of odors for these species. With regard to terminology, we use the term “canid(s)” to refer to the family Canidae and “dog” when referring to the domestic dog, *Canis familiaris*, whether this be a pet, kennelled, or experimental animal. When referring to domestic dogs that are wild or feral, we use the term “free-ranging dog.”

### 26.2 CONSIDERATIONS OF OLFACTION IN THE CARNIVORA

We commence with two observations regarding olfaction in the Carnivora as a whole. First, olfactory behavior generally has been subjected to little study in this Order. As a result, caution must be exercised in making assumptions about the role, or lack of role, of odors in Carnivoran behavior. For example, studies of olfactory structures in Pinnipeds (walrus, seals, and sea-lions) indicate they are under-developed in comparison to other, land-based, Carnivora. This has led to a view that they have poor olfactory abilities and that odor plays little role in guiding their behavior. Recent research has challenged this notion. Psychophysical studies have demonstrated that South African fur seals and harbour seals have good olfactory discrimination abilities and sensitivity to various odors (Kowalewsky et al., 2006; Laska et al., 2008). Further studies have demonstrated the use of olfaction in the natural behavior of pinnipeds. Female Australian sea-lions distinguish their own pups from others by their odor (Pitcher et al., 2011) and the South American sea-lion locates its pups by smell (Trimble and Insley, 2010).

Second, the absence of study has led to some “facts” regarding the abilities of certain Carnivora becoming widely accepted. Perhaps the best example of this is the widely held view that bears have excellent olfactory abilities, for example, polar bears can smell a seal from over 1 km (Seaworld, 2012) or 30 km (Wiki, 2012) away. Whilst published papers report observations of bears in the wild using odors to detect prey (e.g., Blanco et al., 2011),

there are no reports demonstrating that the sense of smell in bears is more or less acute than that of other species. Whether the bear's olfactory abilities are exceptional, or better than other Carnivora, therefore requires experimental study.

Available evidence, albeit sparse, suggests that all members of the Order Carnivora have a rich olfactory-guided repertoire of behavior. However, much further scientific study is needed to evaluate the olfactory abilities of, and role played by odor in, various Carnivora species.

### 26.2.1 Olfactory Sensitivity

Early interactions between humans and wolves are speculated to have resulted from encounters when hunting the same prey. Observations of the hunting behavior of canids may have alerted man to the animals' use of odors and contributed to an association that lasts today. Interest in the olfactory abilities of the canids has arisen because of their reputed excellent sensitivity to smells, far superior to that of man. Evidence for this has been derived from observations of the dog being able to detect the presence of odors, such as explosives and drugs (see Section 26.4), at extremely low levels. Other studies have attempted to quantify the sensitivity of the dog's olfactory system through more conventional psychophysical tests. As a general conclusion, such experiments have found that dogs detect odors at a much lower concentration than do humans (e.g., Neuhaus, 1953; Marshall et al., 1981; Marshall and Moulton, 1981; Krestel et al., 1984; Walker et al., 2006).

A major issue in evaluating the threshold levels of olfactory detection reported by different studies is that varied methodologies have been used and give rise to different threshold estimates for the same odor. For example, when assessing thresholds for *n*-amyl acetate using a naturalistic "find the target task," Walker et al. (2006) reported threshold detection levels of 1–2 parts per trillion, over 30–20,000 times lower than those reported by Krestel et al. (1984) of 52–326,000 parts per trillion using a conditioned suppression paradigm. The performance of dogs may vary according to the paradigm used and also the training provided. A further significant factor is that different studies have used different breeds, e.g., standard schnauzer and Rottweilers (Walker et al., 2006), beagles (Krestel et al., 1984), and German shepherds and fox terriers (Marshall et al., 1981). Not only may there be breed differences in olfactory abilities, there may also be differences between individuals of the same breed (Marshall and Moulton, 1981).

Despite these problems, studies are consistent in indicating that dogs respond to odors at much lower levels (1,000–1,000,000 times lower) than humans. Much further study is needed, controlling for among other variables, test

paradigm and dog breed, to document the sensitivity of the dog's olfactory system.

### 26.2.2 A Canid is not just a Canid

One note of caution must be added here. The family Canidae comprises some 38 different species. The amount of study examining olfactory behavior in each of these species varies considerably. For example, the experimental studies described above examining olfactory sensitivity have focused exclusively on the dog. It is assumed that similar levels of sensitivity are displayed by other canids. Whether this is true, however, is unknown. The extent that findings found for one species of canid generalize to other canid species is an area requiring further investigation for all aspects of olfaction.

## 26.3 CANID OLFACTORY SYSTEM(S)

The excellent olfactory abilities of canids have long been established, but the question of what the underlying structural and/or neural mediation of these abilities are remains unknown. Although neural structures of the dogs' olfactory system were being uncovered at the start of the 20th century, more recent developments in genetic research may contribute to our understanding of the factors mediating its olfactory abilities. Here, we briefly review the olfactory system of the canids, focusing on those elements that may account for their acute olfactory sense. Having an excellent ability to detect odors suggests that there are scents present in the animal's environment that impart important information for the individual and its behavior. This section thus also discusses the odors produced by canids.

### 26.3.1 Olfactory Sensory Structures

The olfactory system of the canids, and indeed the Carnivora, is basically similar to that found in all vertebrates (Stoddart, 1980). Canids possess both main and accessory olfactory bulbs and a vomeronasal organ. Olfactory bulb volume, when compared to total brain volume, is higher in dogs (1.95%), than in herbivores (goat 0.77%) and humans (0.03%) (Kavoi and Jameela, 2011). Compared to rodents, the accessory olfactory bulb is less well developed and appears as a much simpler structure with less lamination (e.g., Salazar et al., 1994). Whilst dogs possess a vomeronasal organ that comprises both sensory and non-sensory epithelium and expresses markers of neuronal activity (Dennis et al., 2003), it is unclear whether the vomeronasal organ serves any function in canids. The characteristic facial expression associated with processing

chemosensory stimuli by the vomeronasal organ, flehmen, is not observed in the dog but is present in the coyote, jackal, and bushdog.

The area covered by the olfactory epithelium is much larger in dogs than in humans (e.g., German shepherd 150 cm<sup>2</sup> cf. humans 3–5 cm<sup>2</sup>), moreover the receptor cells appear to be more densely packed in dogs (Dodd and Squirrel, 1980). As a consequence, dogs possess a significantly greater number of olfactory receptor cells than do humans, 220 m–2 billion cf. to 12–14 million (Miklosi, 2007). Other structures implicated in transducing chemosensory stimuli, for example, the trigeminal nerve, the septal organ of Masera, Grueneberg ganglion, are all present in the canids (McCotter, 1913; Pettigrew et al., 2009). However, whether these have any functional significance for olfactory behavior in these animals is unknown.

### 26.3.2 Olfactory Receptor Genes

Since the discovery of olfactory receptor genes (Buck and Axel, 1991), there has been considerable interest in exploring the olfactory receptor gene repertoire of different animals, including the dog; such information may contribute to our understanding of their olfactory abilities. Current analysis has identified around 1100 olfactory receptor (OR) genes in the dog, of which 20–25% are thought to be pseudogenes (Quignon et al., 2012). The overall number of OR genes is higher than identified in humans (600–900), but lower than that found in the mouse (1200–1400) or rat (1600). A similar percentage of pseudogenes (20–25%) are observed in dogs as in rats and mice; humans, by contrast, have more (~50%).

OR gene proteins may be classified into families and sub-families according to their amino acid characteristics. Dogs exhibit a greater number of sub-families compared to the rat and mouse (300 cf. 280 and 246, respectively, Quignon et al., 2006). Two hundred of these genes are Class 1, a high percentage compared to other species. It has been suggested that this may be significant in mediating the olfactory abilities of the dog (Olender et al., 2004).

In contrast to OR genes, only nine intact vomeronasal V1R genes have been observed in the dog (Young et al., 2005). This is a similar number to that identified in humans, but significantly fewer than the 100 plus found in rodents. It is suggested that this smaller number is linked to the reduced structures of the accessory olfactory bulb and vomeronasal organ found in the dog (compared to rodents) and the associated decrease in functionality of these organs (Quignon et al., 2006). The same V1R pseudogenes are found in both the wolf and dog, suggesting that the reduction in the number of V1R genes is not a result of

domestication (Young et al., 2010) and may be a feature of canids more generally.

Exactly how the olfactory system of canids accounts for their acute olfactory abilities has yet to be determined. The greater number and more densely packed olfactory receptors may have a role in detection thresholds. The greater repertoire of OR gene sub-families may enable a greater range of odors to be transduced. Although more research is required, some preliminary studies do support the links between structures and function suggested above. For example, the olfactory ability of dogs differs widely between breeds. Boxers, which have a less acute sense of smell than poodles, possess a higher percentage of OR pseudogenes (Quignon et al., 2006). Breeds generally noted for good olfactory abilities (e.g., German Shepherd, Belgian Malinois) exhibit greater OR gene polymorphism compared to breeds with poorer olfactory abilities (e.g., greyhound and Pekingese) (Robin et al., 2009). Trained detection dogs that possess a glycine/arginine substitution at one specific locus on the cOR52N9 gene exhibit poorer performance on explosive detection tasks (Lesniak et al., 2008), indicating the potential importance of specific genes for the detection of specific odors. However, much more work is needed before the link(s) between structure/genes and olfactory function is fully elucidated. It should also be noted that the emphasis to date has been on peripheral sensory receptor mechanisms. Little attention has been paid to how more central processing of olfactory information may contribute to the dog's olfactory abilities.

### 26.3.3 Sniffing

Whilst the effective transduction of odors to neural impulses is a vital process, the odors have to be received by the receptors. It appears that the mechanism of delivery has been optimized through the form of the dog's nasal structures and its sniffing behavior.

The olfactory epithelium, situated in a recess at the rear of the canine nose, is separated by the *lamina transversa* from the main airways through which air traverses during breathing. This position enables air to travel across the epithelium in one direction during inspiration (allowing the possibility of spatial coding) and no movement of air during expiration, thus providing longer access for the odor molecules to the receptors (Craven et al., 2010). Sniffing is independent from respiration. Dogs sniff at a much higher rate than they respire, and sniffing rate may increase upon encountering novel or weak odors. Whilst breed size affects respiration rate, the rate of sniffing (3–12 Hz) is similar across all breeds of dog. It would thus appear that the odors are delivered to the receptor cells in a manner that optimizes their transduction, facilitating both detection and discrimination (Lawson et al., 2012).

### 26.3.4 Glands

As well as possessing structures to detect odors, canids also produce odors that may be important for guiding their behavior. Odors are produced by waste products: urine and faeces, and also from a variety of glands distributed over the animal's body. Canids possess sebaceous, apocrine, and eccrine glands (Harrington and Asa, 2003) which can be found singly or in aggregations and emit odor-producing secretions which can be detected by others. In many cases, little is known about the role these odors play or the functional chemicals emitted, and much more work is needed to understand their significance for canid behavior. Here we concentrate on describing the sources of odors and will deal with their possible functions in more detail later.

Sweat (eccrine) glands are found on the footpads and apocrine glands between the toes (Nielsen, 1953). Thus, the animals may leave an odor cue every time the paw comes into contact with a surface or through the specific behavior of ground scratching which may accompany urine or faecal scent marking. Apocrine glands are also spread over the hair-covered skin in most carnivores and may impart a distinctive whole body odor, for example, as noted in African wild dogs (van Heerden, 1981).

The anal region of some canids has three distinct odor producing areas: the supracaudal gland, situated on the top of the tail; the circumanal glands, which surround the anus; and the anal sac, situated internally with ducts to the anal canal. These odor sources are described in the following three paragraphs.

The supracaudal (tail) gland, or "violet" gland in the fox, is comprised of both sebaceous and apocrine cells, although it is the former that is regarded as the main odor-producing component (Albone and Flood, 1976). Most canids possess this gland; although it may be present in the dog, it appears not to function and is absent in the African wild dog. In the red fox, it produces a sweet, pleasant 'violet'-scented odor. The odor is weaker in wolves and coyotes, but smells similar to that produced by the red fox. In the gray fox, the odor is described as "musky" (Fox, 1971). The odor can be easily distinguished from that produced by the fox's anal gland (see below), which is described as "rancid," in contrast to the "pleasant" smell produced by the supracaudal gland. Although this gland is present in wolves, individuals do not appear to investigate this area in conspecifics (Harrington and Asa, 2003).

Anal sacs are paired reservoirs with ducts that lead to the anus and are found in most carnivores. The sacs are surrounded by smooth muscle and it is believed that, to a certain extent, secretions from the anal sac are under voluntary control (Harrington and Asa, 2003). Secretions can accompany some defecations, but not all, and may occur

on their own in the absence of defecation, especially when the animal is acutely stressed. In wolves, it is the dominant males that leave the majority of anal sac scent on their faeces (Harrington and Asa, 2003). In skunks and pole cats, anal gland secretions are sprayed on others as a means of defense. In beagles, consistent individual differences in the odors of anal sac secretions are present. Thus, a sharp acrid odor is associated with light colored, less viscous, and more rapidly secreted anal sac secretions, whereas a dull, somewhat neutral or slightly pleasant, dog-like odor is associated with dark, pasty, and less rapidly secreted anal sac secretions (Doty and Dunbar, 1974a).

Circumanal glands are located around the anus in canids and are made up of single apocrine glands, sebaceous glands, and hepatoid glands (Shabadash and Zelikina, 2002). With the concentration of odor sources distributed around the anal region, it is not surprising that this area receives significant investigation when conspecifics meet.

In addition to the anal region, the head provides a concentrated source of odors, and the head and muzzle region are sites of interest and investigation between conspecifics. Wolves appear to pay more attention to the head region than do dogs. Apocrine and sebaceous glands are found in high concentrations in the ears, where they combine to produce cerumen (ear wax). Eccrine (sweat) glands are found on the skinless end of the nose and saliva may be distributed around the mouth and jaw area.

Fox (1971) suggested that there is an inverse relationship between the intensity of body odor, especially that produced by the supracaudal gland, and the level of sociality exhibited by the animal. More intense odors are produced by the least social species. Thus foxes, which are less social than wolves and dogs, produce a more powerful odor. One exception to this is the African wild dog, which is highly social and produces a strong odor, but this may result from apocrine secretions on the body as opposed to anal region odors. A more intense odor may be required in more solitary species, as the opportunity for exposure to conspecific odors is poorer and therefore odors need to persist for longer to serve their communication function.

### 26.3.5 Summary

Whilst the role of some aspects of the canid's olfactory system that contribute to its sensitivity are understood, much still remains to be elucidated. The role of the animal's odors in shaping its olfactory system has yet to be explored. It may be that the information produced by various secretions requires a greater olfactory sensitivity to fully detect the information and this has, in part, driven the development of the canid's olfactory system.

## 26.4 OLFACTORY-GUIDED BEHAVIOR

The fact that canids have excellent olfactory abilities and possess a variety of sources for producing odors suggests that scent plays a significant role in canid behavior. The following section reviews olfactory-guided behavior in the canids. We consider the development of olfactory behaviors, the use of odors in social recognition, and scent-marking behavior. Again, the review will highlight areas where further research is needed.

### 26.4.1 Early Development of Olfactory Behavior

Dogs are able to detect chemosensory substances before birth and respond to these odors postnatally (Wells and Hepper, 2006). Dogs exposed to aniseed via their mother's diet prenatally exhibit a preference for this stimulus immediately after birth (Wells and Hepper, 2006). This preference is specific to the "odor" experienced before birth. Such learning may be important for the acceptance of milk (Wells and Hepper, 2006). At birth, pups exhibit rooting behavior, but whether this is controlled by olfactory stimuli is unknown. Pups detect and respond to olfactory stimuli at birth (e.g., aniseed, fish scent), even though the olfactory nerves are poorly myelinated (Scott and Marston, 1950; Jones, 2007). Day-old pups are able to acquire conditioned responses to olfactory stimuli (e.g., Volokhov, 1959). The odor of amniotic fluid may be important for mothers to accept pups, since mothers reject offspring which have been washed, but accept those bathed in amniotic fluid (Abitol and Inglis, 1997). Odors thus play an important role in canid behavior, beginning before birth and this continues throughout the individual's life.

### 26.4.2 Social Recognition

The ability of conspecifics to recognize others by individual, group or kinship cues is widespread amongst animals. There is no reason to expect these abilities are not present in the canids; however, little attention has been devoted to this issue.

It is generally believed that canids are able to recognize individual conspecifics by odors. It has been speculated that individually identifiable odors may originate from the faeces, urine, feet, anal sacs/gland, supracaudal gland, and skin. However, very little study has explored odor sources of individuality other than that presented by the animal's urine. Interestingly, dogs spend more time investigating the urine from a colony mate than they do their own urine, and longer again when presented with urine from a dog outside their colony (Dunbar and Carmichael, 1981). They also over-mark their own urine less than urine from another dog

(Bekoff, 2001). Wolves are able to discriminate individuals by differences in their urine (Brown and Johnston, 1983) and also increase urine over-marking upon encountering urine marks from conspecifics (Peters and Mech, 1975). Red foxes investigate both the urine and anal sac secretions of unfamiliar foxes more than familiar foxes (Blizard and Perry, 1979), although whether this reflects individual recognition, or recognition of familiarity, is unknown. There is additional evidence that dogs produce individually identifying odors. Wells and Hepper (2000) found that dog owners were able to identify their own dogs from their odors deposited on blankets. Detection dogs are able to identify individual maned wolves by their faeces (Wasser et al., 2009).

Dogs are able to recognize their siblings and mother at 5 weeks of age (Hepper, 1986, 1994), most likely using odor cues. Further, dogs recognize their mother by olfactory cues, even after two years of separation, although they only recognize unfamiliar siblings from whom they have been separated for two years if they have been living with another sibling during that time (Hepper, 1994). Contradictory evidence was obtained from a study of dogs examining the mother's ability to recognize her pups using a retrieval task: one female tested retrieved only her own pups, whereas another female retrieved both her own and alien pups (Dunbar et al., 1981). In a simultaneous choice task, mothers investigated their own 5-week-old pups more than unrelated offspring (Hepper, 1994).

Bitches in heat elicit much more investigation from sexually experienced male conspecifics than when not in heat, indicating their odor, especially urine, reflects their reproductive status (Beach and Gilmore, 1949; Doty and Dunbar, 1974b). Moreover, females urinate more when in heat (Beach and Gilmore, 1949), perhaps advertising their receptive status.

It is apparent that much more research is needed to determine the social recognition abilities of the canids. In particular, it will be of interest to establish if there are any differences between species that live in social groups (e.g., hunting dogs, wolves) and those that are more solitary (e.g., foxes).

### 26.4.3 Scent Marking

One behavior that has elicited investigation in the canids is scent marking. Scent marking, that is, the deposition of an odor through defecation, urination, and/or glandular deposits, is common to all canids. It has been argued that scent marks may signify individual or group identity and/or some aspect of current status, for example, dominance, reproductive state, age. These in turn may serve to determine ownership of territory, mark food caches, maintain group cohesion, and signal status. Whilst the behavior of scent marking has been documented amongst canids, the

information presented by marks and how this “acts” on the recipient has been less well elucidated.

Scent marking is not performed equally by all individuals. In most canid species, the dominant individual or pair is responsible for more acts of scent marking than lower ranked individuals, for example, coyotes (Gese and Ruff, 1997), gray wolves (Peters and Mech, 1975), dogs (Lisberg and Snowdon, 2011) and Ethiopian wolves (Sillero-Zubiri and Macdonald, 1998). It is unknown whether the marks contain information of dominance directly or by association, that is, others learn the individual identity of the dominant male/female and associate their individual signature left in the mark with their dominance status.

Individuals in groups or packs mark more than lone individuals, for example, coyotes (Gese and Ruff, 1997) and wolves (Mech and Boitani, 2003). Lone male wolves have been observed defecating away from paths used by packs, whereas packs tend to deposit marks on trails, especially at junctions (Peters and Mech, 1975), presumably places where others can find them. Males urine mark more than females, for example, dogs and free-ranging dogs (Pal, 2003), dholes (Paulraj et al., 1992) and wolves (Peters and Mech, 1975).

Marking may also be influenced by context. A higher rate of marking is observed during the mating season when females come into estrous, for example, dholes (Paulraj et al., 1992) and free-ranging dogs (Pal, 2003), suggesting that this behavior has a role in the maintenance of the pair bond (Rothman and Mech, 1979). Indeed, newly formed pairs exhibit an increase in marking. An increased frequency of urine marking is observed when the scent of other conspecifics is present, for example, as in dogs (Hart, 1974) and wolves (Peters and Mech, 1975). Some canids mark food caches that have been emptied with urine, for example, red fox (Henry, 1977), Arctic wolf (Mech, 2006), wolf (Harrington, 1981), and coyote (Allen et al., 1999).

Whilst wolf packs mark frequently in their own territory, they do not mark in the territories of their neighbors (Mech and Boitani, 2003). Increased marking is observed around the periphery of the animals’/group’s territory, for example, wolves (Peters and Mech, 1975), free-ranging dogs (Pal, 2003), coyotes (Allen et al., 1999), and foxes (Arnold et al., 2011), suggesting a role in territory demarcation. Faeces may be deposited in latrines throughout the territory, for example, golden jackals (Macdonald, 1979a), dholes (Davidar, 1975), and Ethiopian wolves (Sillero-Zubiri and Macdonald, 1998).

Scent marking by urination in male canids is accompanied by a specific raised leg urination posture and often only small amounts of urine are expelled (see Figure 26.1). This posture may be important as the animal sometimes displays this pose without urinating. The raised leg position may also serve to raise the position of the mark on the vertical object, perhaps reflecting something about the scent marker and

**Figure 26.1** The characteristic ‘raised leg display’ posture adopted by male canids when depositing urine scent marks, here exemplified by the coyote (by permission J.W. Wall, jwallphoto.blogspot.com).

also to position the mark at nose height, thereby increasing the chances of detection. However, given the acute olfactory sense of the canid, this latter explanation seems unlikely and the function of raised leg urination is probably related more to its spatial position than odor. Canids, for example, red fox (Macdonald, 1979b), maned wolves (Macdonald, 1980), and black-backed jackals (Haywood and Haywood, 2010) deposit faecal marks on conspicuous, often raised, locations. Although the function of this is unknown, it is believed to increase the visual conspicuity of the mark.

One specific pattern of urine marking that is observed is “double marking,” in which a scent mark deposited by one individual of a dominant pair is quickly over-marked by the other, for example, Arctic wolves (Harrington, 2006), gray wolves (Rothman and Mech, 1979), and coyotes (Gese and Ruff, 1997). It is speculated that this aids in courtship, the formation and maintenance of pair bonds, mate guarding, and territory formation (Macdonald, 1985). These hypotheses require further examination.

Observations of scent marking by canids are abundant and some of the parameters that affect marking, for example, dominance, and its context, edge of territories, are well established. As more studies emerge, increased variability in scent-marking behavior is becoming apparent. For example, the ground scratching rates of wolves in Poland (Zub et al., 2003) are much higher than those reported for wolves in North America (Peters and Mech, 1975). Individual differences are observed in marking behavior (Wirant and McGuire, 2004) and differences are seen between the behavior of captive and wild animals. The information provided by scent marks remains somewhat of a mystery. It is clear that these odor marks have a function and present information to other conspecifics. The nature of this information has yet to be elucidated. Such information is essential if the functions of scent marking are to be

fully understood. Scent-marking behavior is ubiquitous in canids yet much remains to be discovered about how scent marks exert their function.

#### 26.4.4 Scent Rolling

A final behavior worth noting is scent rolling. Many canids roll in particularly pungent substances, such as rotten food or faeces (Reiger, 1979). Such rolling is often undertaken in a ritualistic manner. A number of possible functions have been suggested: to learn about the new odors; to camouflage and hide their own odors; to enhance their social standing; an evolutionary remnant of behavior that now serves no function; and, a comforting/reinforcing behavior. Much further work is needed to explore this. In African wild dogs, females roll in the urine of the males of packs they attempt to join (Frame et al., 1979). Presumably this enhances their acceptability, but exactly how remains to be determined.

#### 26.4.5 Summary

Odors are important in guiding the behavior of canids, from birth and throughout their lives. However, our understanding of the full range of behaviors influenced by odors and how they function in different canid species remains sparse and much further work is needed before the extent of the role of odor in canids is fully understood.

### 26.5 USES OF THE DOG'S NOSE

The olfactory abilities of dogs, combined with their trainability, have led to their use to detect and discriminate odors in a wide variety of settings and for a variety of purposes. The following section will review these uses. First, however, a number of issues relating to the performance of dogs on these tasks are considered.

#### 26.5.1 A Dog is Not Just a Dog

The use of dogs in applied settings is widespread, however factors that may affect their performance have yet to be fully explored. The performance of the dog will be influenced by two main factors: the individual animal and its training. These factors may singly, or in combination, influence how well the dog does on any particular task.

Different breeds of dog differ in their olfactory abilities, moreover, even within a particular breed, there are differences between individuals in their sensitivity and ability to discriminate odors. As yet, there has been no systematic study of breed or individual differences upon olfactory abilities within dogs. Related to this, is the dog's motivation to undertake the required task. Scott and Fuller (1965) assessed the interest of different breeds in locating

a live mouse in a 1 acre field. Beagles found the mouse in 1 minute, whilst fox terriers took 15 minutes. Scottish terriers never found the mouse and indeed it is reported that one even stood on the rodent but failed to notice it. Dogs will differ in their motivation and this also has to be factored in to assessments of performance.

The vast majority of detection dogs undergo training to ensure they are able to perform the required task. That said, one of the first reported instances of a dog detecting skin cancer was by an untrained animal (Williams and Pembroke, 1989). There are a number of issues surrounding training that should be considered. First, as with olfactory abilities, there are individual differences in the trainability of dogs (e.g., Maejima et al., 2007). Second, there is no standardized method for training dogs (e.g., Jezierski et al., 2010). Thus, the most appropriate procedure for obtaining optimum performance in dogs is unknown. Further, there is no standardized method for assessing performance (e.g., Rooney et al., 2007). Often organizations using dogs will have their own criteria, but these may vary between organizations and between applications.

Due to the potential variation introduced by these factors it is difficult to evaluate the meaning of a specific performance achievement (e.g., x% success rate) for any particular task. For example, if a dog is reported as being 80% successful, this does not necessarily reflect the absolute capability of *this* dog (e.g., training may have hindered its performance) or *all* dogs (e.g., this dog could have superior/inferior olfactory abilities). In the absence of standardized procedures for evaluating performance, the reported figures of success are little more than indications that, under some circumstances, a particular dog can complete, to some extent, the task required. Hence we do not report absolute success rates here. Comparisons within studies are reported where relevant as the same techniques (for good or bad) have been used and enable some conclusions to be drawn about relative performance.

The use of detection dogs is considered below under four main headings: forensic; economic, conservation, and health.

#### 26.5.2 Forensic Applications

It has been widely assumed that one of the earliest uses of dogs by man was for tracking prey, thus assisting hunting. A variety of canids are reported to use odors (amongst other senses) in their hunting (Fox, 1975). Indeed dogs have been specifically bred for their ability to follow an odor trail. Romans found the Celtic tribes of the UK using the Agassian, a small dog renowned for its ability to air scent. In 2012, The Federation Cynologique Internationale recognized over 70 breeds of scent hounds.

Dogs have exceptional abilities to follow a route travelled by an individual on foot (e.g., Wells and Hepper,

2003). Dogs may use one, or a combination, of three methods to follow an individual (Hepper and Wells, 2005). They may: *track*, where they follow the route of the individual with their head down and nose very close to the ground; *trail*, when they follow the route with their head down when moving with the wind, but with their head up when moving into the wind; or *air scent*, where they follow the route with their heads up sampling the air.

The odor cues used by dogs may originate either from the individual directly or from ground disturbance (Hepper and Wells, 2005). The fact that individuals can follow the trail of one individual when crossed by many others suggests that there are individual odor cues that are available to the dog to use (Kalmus, 1955). The literature, however, is conflicting. Some studies suggest dogs cannot track in the absence of odor from ground disturbance (e.g., Budgett, 1933), others that dogs cannot follow a trail in the absence of the individual's odor (e.g., Pearsall and Verbruggen, 1982).

Whilst dogs can follow a track, exactly how they do so remains poorly understood. Some studies have attempted to explore how dogs use odor information to detect the direction of a track. For example, Hepper and Wells (2005) found that there was sufficient information contained in five consecutive footprints to determine the direction of a track. An evaluation of the time to deposit the five footsteps indicated that it took approximately 1.9 seconds from the 1st to the 5th step. Assuming that the dog makes some comparison between the footsteps (e.g., based on the quality of odor), then there is a change in the olfactory information presented by a time difference of under 2 seconds that is detectable by dogs. What also seems vital for dogs to track is discontinuity in the olfactory signal. Whilst dogs can easily determine directionality from a track formed of discrete footsteps, they find it much more difficult from a continuous track (Steen and Wilson, 1990). This is similar to insect behavior. Moths, for example, are unable to locate the source of odors when presented with a continuous plume, but can do so when the odor plume presents intermittent information (Justus and Cardé, 2002).

The ability of dogs to discriminate individuals (e.g., Hepper, 1988) has led to proposals that such animals may be used to detect individual odor "fingerprints" from crime scenes and use this information to match to the owner of the scent and possibly the perpetrator of the crime (Schoon, 1996). Scent identification line-ups, in which the dog is required to match the odor obtained from a crime scene to one of a number of odors presented in a row, is now accepted as part of proceedings in a number of European Courts (Schoon and Haak, 2002).

The ability of the dog to detect human odor is also used by search and rescue dogs, ranging from locating lost hikers to individuals buried under avalanches or earthquake debris. Others have been trained to locate cadavers and

parts of bodies (e.g., Komar, 1999). Of all the detections that the dog can perform, we still consider one of the most impressive to be the location of bodies submerged underwater (e.g., Osterkamp, 2011).

It is worth mentioning here another issue to be addressed in assessing detection dogs' performance. In most cases, dogs work as part of a team, the other team-member being their handler. It is known that handlers influence the reliability of their dog's performance (e.g., Lasseter et al., 2003). Thus, a further complication in assessing how well dogs perform is to assess the role of the handler. It may be appropriate to consider that in tasks in which the dog performs "off-lead," the animal is considered the unit of assessment, however when the dog performs the task "on-lead," it is the dog and handler that is considered the unit of assessment.

The ability of the dog to be trained and recognize specific odors has led to it being used in a number of forensic settings to detect the presence of a particular trained substance. Such detections include explosives (Gazit et al., 2005) and even the scent of the trip wires that trigger mines (Hayter, 2003). Following the detonation of explosives, for example, IEDs, dogs are able to match human odors obtained from the blast debris to the humans depositing scent on the device pre-explosion (e.g., Curran et al., 2010). Dogs are able to discriminate accelerants that have been used in arson, despite the presence of additional burnt material at the scene (e.g., Gialamas, 1996). Dogs are used to detect drugs, counterfeit and smuggled goods, and mobile phones in the prison population, amongst others. Indeed, with appropriate training, dogs appear able to detect virtually anything, provided it emits an odor at a level that can be detected by the dog.

### 26.5.3 Economic Applications

Detector dogs have been used in a variety of ways to reduce economic costs arising from damage to buildings or crops and to improve productivity. For example, dogs have been trained to detect the presence of dry rot fungi and decay caused by fungi (Kauhanen et al., 2002) and termite infestations (Brooks et al., 2003). Both causes of damage may be difficult to detect early and by visual inspection and result in considerable economic cost if not treated. When the performance of dogs to detect termites was compared against an electronic odor-sensing device, dogs performed better (81% vs 48–62% successful detection), but only when there was more than 50 termites present (Lewis et al., 1997). Below this number, the dog's performance became poorer, possibly due to the lack of sufficient odor.

Dogs have also been used in agricultural settings to detect the presence of insects that may damage crops, for example, red palm weevil (Nakash et al., 2000) and parasites which cause damage to livestock, for example,

screwworm and its pupae (Welch, 1990) and nematodes (Richards et al., 2008). Dogs can also, more effectively than other methods, determine estrous in dairy cows, thereby enhancing breeding success (Fischer-Tenhagen et al., 2011). Finally, dogs have been trained to detect bed bugs (Pfiester et al., 2008), a cause of concern for travellers and individuals prone to allergic reactions.

#### 26.5.4 Conservation Applications

Detection dogs have found extensive use in conservation applications to detect the presence of other animals, a feat they perform more effectively than other methods. For example, Long et al. (2007) found that dogs were able to detect black bears, fishers, and bobcats from their faeces. Dogs detected more of these species than either hair snares or cameras; however they were more expensive to employ. Overall, however, the increased cost was more than made up for by increased detection rates and dogs were found to be the most cost effective method.

Dogs have been used to detect the presence of a wide variety of animals to enable assessment of their number in a particular area. This includes, for example, species large, Amur tiger (Kerley and Salkina, 2007), small, rats and mice (Gsell et al., 2010), and minute, fire ants (Lin et al., 2011). As well as detecting feces to provide estimates of numbers of animals, dogs have also been used to help humans detect and collect a sufficient quantity of fecal material to enable detailed testing to be undertaken to provide information on the health of the individuals, for example, Northern right whales (Rolland et al., 2006).

Dogs have been used to detect the presence of invasive species which may cause devastation to their new environment. For example, brown tree-snakes in Guam (Savidge et al., 2011), Quagga and zebra mussels in California (California Dept Fish and Game, 2009), and knapweed in Montana (Goodwin, 2010).

Finally, dogs may also be used to provide information about the effects of human changes to the environment on animal species. One area of concern has been the effect of wind farms on bird life. Dogs have been found to be far better at locating carcasses of birds around wind farms than humans, thus improving estimates of the impact of wind farms on the bird population (Paula et al., 2011).

#### 26.5.5 Health and Medical Applications

One area of considerable interest in recent years has been the use of the dog's nose as a diagnostic instrument for evaluating human health (Wells, 2007). An initial paper (Williams and Pembroke, 1989) reported the case of a border collie/Doberman cross-breed persistently sniffing at a mole on the patient's skin. Following investigation,

the mole was found to be a malignant melanoma. The dog had undergone no training and appeared to be attracted to something about the odor of the mole. Since then, other studies have reported the ability of dogs to detect melanoma (Wells, 2012).

Based on the assumption that the presence of cancer changes the odor signature of the individual in a manner that is consistent across patients with the same condition, studies have explored the ability of dogs to discriminate samples from patients with cancer from those without. Dogs are able to detect the presence of bladder cancer from urine samples (Willis et al., 2004), although it has been questioned as to whether this is due to detecting the odor arising from the cancer or other factors that increase the risk of cancer, for example, smoking (Leahy, 2007). Dogs have been reported to be able to detect prostate cancer from urine (Cornu et al., 2011), breast and lung cancer from breath samples (McCulloch et al., 2006), colorectal cancer from breath or stool sample (Sonoda et al., 2011), and ovarian cancer from tissue (Horvath et al., 2008).

A second line of research has explored whether dogs can predict the onset of serious medical conditions. Based on owners' accounts of their dogs' untrained behavior, Wells et al. (2008) report that pet dogs displayed behavioral changes when their diabetic owners became hypoglycaemic, in many cases before the patients knew they were becoming low in sugar. Similar reports of dogs' behavior changing prior to the onset of migraine attacks have also been documented (Marcus, 2012). Studies indicate dogs can be trained to detect the onset of an epileptic seizure (Strong et al., 1999). Whether these alerts are based on the dog detecting changes in the individual's odor, as opposed to some other cue (e.g., visual), is unknown.

#### 26.5.6 Summary

In summary, if it produces an odor the likelihood is that the dog can be trained to detect it and discriminate it from other odors. The key task is to correctly identify the odor for the dog. Despite many studies demonstrating that dogs undertake remarkable detections, the lack of standardization in, and standards of, training and appropriate evaluations of dog olfactory abilities preclude accurate assessment of the effectiveness of dogs, in general, performing these tasks. Further, great coverage is given when search and rescue dogs locate an individual alive following an appalling natural disaster. However, the fact that it is a natural disaster and a scene of devastation and confusion means it is virtually impossible to determine if dogs missed other individuals. Thus, assessing performance in the field may be difficult and this further emphasizes the need for standardized assessment and evaluation during training.

## 26.6 IMPROVING WELFARE THROUGH ODORS

Lately, some attention has been directed towards the use of so-called pheromones as a tool for enhancing animal welfare (see Doty, 2010, for a critique of the pheromone concept in mammals). Synthetic analogues of domestic species' facial secretions have been successfully produced to this end, with studies reporting efficacy in producing more normal patterns of behavior in animals who are exposed to them (e.g., Spielman, 2000). A "dog appeasing pheromone" (DAP, Ceva Sante Animale, France) has been reported to be useful in treating some behavior problems (e.g., firework phobia, travel-related excitement, separation anxiety) in pet dogs, although its effectiveness has been questioned (Frank et al., 2010). DAP has also been reported as useful in enriching the environment of captive canids. Thus, Tod et al. (2005) found a significantly reduced frequency of barking in sheltered dogs subjected to DAP exposure for 7 days, although maximum barking amplitude was not significantly altered.

Other odors have been used to provide enrichment for animals in captivity (e.g., cats and gorillas, Wells, 2009), but only one study has evaluated the use of odors for enriching the welfare of dogs (Graham et al., 2005). Odors were diffused into dogs' cages in a rescue shelter to assess whether they influenced the animals' behavior in ways suggestive of enhanced welfare. Lavender and chamomile encouraged more behaviors suggestive of increased relaxation (more resting and less barking), while peppermint and rosemary increased locomotion and barking. Given the significance of odors for canids, manipulation of their odor environment undoubtedly has the potential to improve their welfare. This is an area worthy of significant further study.

## 26.7 CANINE OLFACTION: A STUDY IN CONTRADICTION

Ever since man encountered canids, the acute olfactory sense of the wolf, and then the dog, has been recognized, selected for, and put to use. Recent years have seen the development of applications for the dog's nose, expanding from the earliest uses of tracking prey to the more recent detection of cancerous tumors. However, although the behavioral evidence is clear, our understanding of the factors underlying the canid's sense of smell and its functions is poor. Even basic questions, such as how good is the sense of smell across canids have yet to be answered. The challenge for future research is to explain what factors, both proximate and ultimate, have led to the acute sense of smell in the canid. We need to identify what information is provided by the olfactory cues left by canids, often in a stylised and ritualistic manner. This will not only enhance

our understanding of the olfactory world of the canid, but may also improve our opportunities to benefit from this sensory skill, thereby extending the cooperation that has been evident since *Homo* and *Canis* first encountered each other.

# Chapter 27

---

## Olfaction in Nonhuman Primates

MATTHIAS LASKA and LAURA TERESA HERNANDEZ SALAZAR

### 27.1 INTRODUCTION

Primates are traditionally considered as primarily “visual” animals with a poorly developed sense of smell. This view, however, is mainly, if not exclusively, based on an interpretation of neuroanatomical and recent genetic findings and not on behavioral or physiological evidence. In fact, an increasing number of studies now suggest that olfaction may play a significant role in regulating a wide variety of primate behaviors and that the olfactory capabilities of both human and nonhuman primates are not generally inferior to that of nonprimate species believed to have a keen sense of smell. This chapter therefore aims at summarizing the current knowledge about the anatomy, physiology, genetics, and behavior concerning the sense of smell in nonhuman primates.

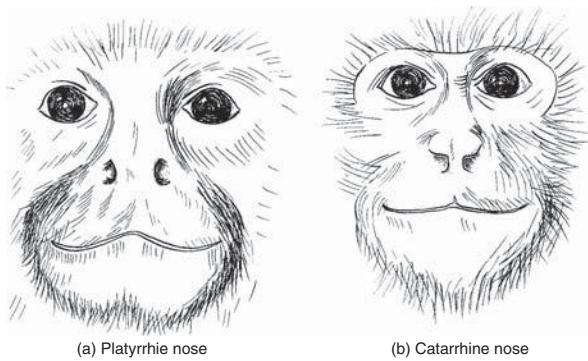

### 27.2 ANATOMY

The anatomy of the nose has been studied in a variety of primate species including members of all major groups within this order of mammals (Smith et al., 2007; see Chapter 2). The anatomy of the external nose of primates allows for a classification into two subgroups based on the shape of the nostrils: the strepsirrhines, meaning “curved nose,” which include the lemurs, lorises, and galagos, and the haplorhines, meaning “simple nose,” which include the tarsiers, New World primates, Old World primates, and hominoids. Strepsirrhines are characterized by the presence of a rhinarium, the moist and naked surface around the nostrils which is also present in a number of nonprimate mammals such as cats and dogs. The rhinarium is believed to play a role in olfaction, as its presence may increase the

probability of volatiles being absorbed by the thin layer of mucus that covers the rhinarium, thereby increasing the number of molecules that can be detected.

Another classification of primates also refers to a feature of their nostrils: the catarrhines, meaning “downward-nosed,” which include the Old World primates and hominoids have downward-pointing nostrils and a narrow septum whereas the platyrhines, meaning “flat-nosed,” which include the New World primates have outward-pointing nostrils and a wide septum (Figure 27.1). Both of these nose-based classifications are widely used in primate taxonomy.

The anatomy of the internal nose of primates shows all the features that are considered as typical for mammalian noses in general: the nasal fossae are paired passageways located on either side of a midline septum that connect the nostrils (that is: the external nasal openings) and the choanae (the internal nasal openings) leading to the pharynx. From the lateral nasal walls, turbinals invade and subdivide the nasal fossae, thus increasing their internal surface. Depending on the species, these projections may vary from simple ridges to highly elaborated scrolls. Comparative studies suggest that the turbinals of strepsirrhines have a more complex morphology than those of haplorhines (Smith and Rossie, 2006). Whereas most strepsirrhines have four ethmoturbinals in addition to a well-developed maxilloturbinal and nasoturbinal, the haplorhines have only between one and three ethmoturbinals and less-developed maxilloturbinals and nasoturbinals. Within the haplorhines there seems to be no further systematic trend towards a reduction in the complexity of the turbinals from New World primates over Old World primates to hominoids (Figure 27.2).

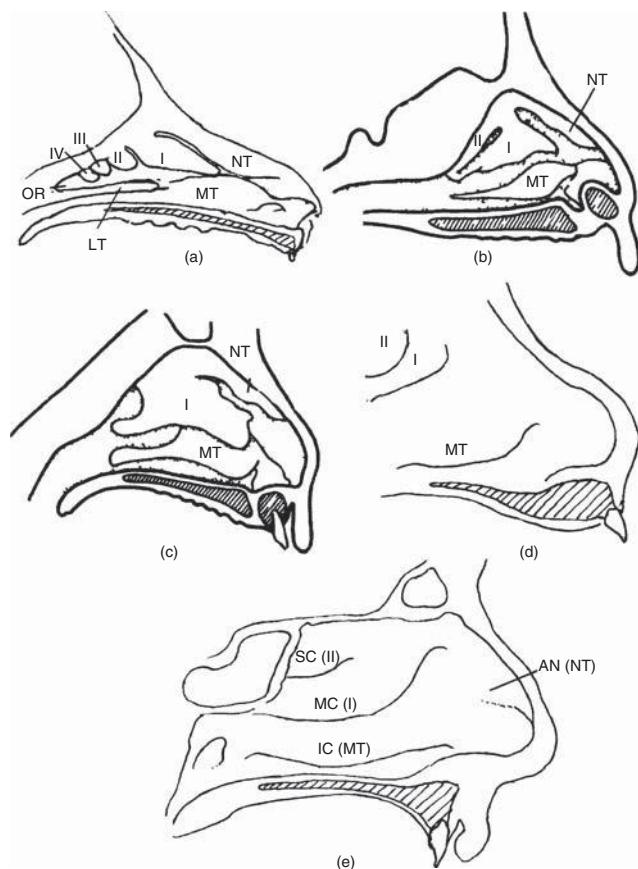

**Figure 27.1** (a) Platyrhine nostrils pointing outward and separated by a wide nasal septum. (b) Catarrhine nostrils pointing downward and separated by a narrow nasal septum. (Redrawn from Ankel-Simons, 2007).

The mucosa that lines the nasal fossae includes respiratory, stratified, and olfactory epithelia. The olfactory epithelium in primates is composed of the same elements (olfactory sensory neurons, supporting cells, basal cells) as that of nonprimate mammals (Loo, 1977). The proportion of olfactory epithelium relative to total nasal fossa area appears to be reduced in haplorhines compared to strepsirrhines. In the latter group, olfactory epithelium has been found to cover all ethmoturbinals whereas in the former group it is usually limited to the posterosuperior-most ethmoturbinals. However, recent detailed histological studies showed marked inter- and intraspecific variations in the extent of olfactory epithelium inside the nasal fossae. In some anthropoid primates, for example, olfactory epithelium has been found more anteriorly than previously described. Similar to the turbinals, there seems to be no further systematic trend within the haplorhines for a further reduction in the distribution of olfactory epithelium from New World primates over Old World primates to hominoids (Smith et al. 2004).

### 27.3 NEUROANATOMY

The comparative neuroanatomical studies of Stephan and co-workers on mammalian brains and brain structures provide data on the absolute and the relative size of the main olfactory bulbs in 45 species of primates representing all major groups within this order (Table 27.1). Several evolutionary trends can be deduced when comparing main olfactory bulb sizes between species:

1. There is a clear trend for a decrease in the relative size (but not in the absolute size) of the main olfactory bulbs from prosimians over New World primates and Old World primates to hominoids. However, this

**Figure 27.2** Variations in the lateral nasal wall of different primates. (a) Lemurs and most other strepsirrhines have four ethmoturbinals (indicated from anterior to posterior as I-IV). The ethmoturbinals II-IV are found entirely within the “olfactory recess” (OR) and are lined with olfactory epithelium. Note that the ethmoturbinals, nasoturbinal (NT) and maxilloturbinal (MT) are oriented in a more vertical arrangement in anthropoids (B.-E.), with some variation. Note a reduction in the number of ethmoturbinals and proportionally reduced NT in New World primates (B. Saimiri) and Old World primates (C. Macaca). In the apes, the ethmoturbinals are more vertically oriented, as shown in the gibbon (D. *Hylobates*) and especially in humans (E.). In some anthropoids, the NT may be absent or extremely reduced, as in the homologous aggar nasi (E. AN). IC, inferior nasal concha (MT homologue); MC, middle nasal concha; SC, superior nasal concha; MT, maxilloturbinal; hard palate (hatched lines). Specimens are drawn to similar sizes, not to scale. (Redrawn from Smith and Rossie 2006).

can mainly be attributed to a progressive increase in neocortex size across these primate groups.

2. Primates tend to have smaller main olfactory bulbs relative to total brain volume than basal insectivores such as hedgehogs and shrews which are considered to resemble the common ancestor of today's mammals. However, this too, can mainly be attributed to the massively increased neocortex in primates relative to basal insectivores.

**Table 27.1** Absolute and relative size of the main olfactory bulbs (MOBs) in primates.

Common Name	Scientific Name	MOB Volume (mm <sup>3</sup> )	Brain Volume (mm <sup>3</sup> )	MOB % of Brain
Gray mouse lemur	<i>Microcebus murinus</i>	43.0	1654	26
Greater dwarf lemur	<i>Cheirogaleus major</i>	158	6320	25
Fat-tailed dwarf lemur	<i>Cheirogaleus medius</i>	102	3000	34
White-fronted brown lemur	<i>Lemur albifrons</i>	207	22258	9.3

Humans	<i>Homo sapiens</i>	114	1266665	0.09

Data from Stephan et al. (1988)

3. Folivorous primates tend to have smaller main olfactory bulbs relative to total brain volume than frugivorous primates. Exactly the same trend can be found in other mammalian orders suggesting that dietary specialization is an important determinant of the size of the main olfactory bulbs.

A re-analysis of Stephan et al.'s data by Barton (2006) generally confirmed the above-mentioned evolutionary trends and additionally found activity period (whether a primate species is diurnal or nocturnal or cathemeral) to correlate with relative size of the main olfactory bulb. Further, the social/mating system (whether a primate species is

monogamous or polygynous) was found to correlate with the relative size of both the main and accessory olfactory bulbs. Some authors have argued that the absolute size of the olfactory bulbs should be indicative of a species' olfactory capabilities and have taken the available data as an argument for a "greatly reduced sense of smell in primates" relative to other mammals (Rouquier et al., 2000). However, if the simple reasoning according to which a larger olfactory bulb would necessarily be accompanied by a better sense of smell was true, then mice and rats should have a markedly poorer sense of smell than humans and most of the primate species listed in Table 27.1 as the absolute size of the olfactory bulbs is 8 and 24 mm<sup>3</sup>, respectively, in the two rodent species and 114 mm<sup>3</sup> in humans – a conclusion which is not exactly intuitive.

Other authors have argued that the relative size rather than the absolute size of the olfactory bulbs would allow for conclusions as to the olfactory capabilities of different species. Here, too, the simple reasoning that an increase in the size of non-olfactory brain structures would necessarily lead to a decrease in the efficiency of olfactory brain structures and thus to a decrease in olfactory capabilities is neither logical from a theoretical point of view nor supported by physiological data. In this context it is also interesting to note that nobody ever claimed that primates would have a "greatly reduced sense of hearing" although comparative studies also showed that the relative size of their subcortical auditory brain structures is clearly smaller than that of nonprimate mammals (Glendenning and Masterton, 1998).

The size of the olfactory epithelium is another neuroanatomical feature that has been suggested by some authors to be indicative of a species' olfactory capabilities. Unfortunately, no systematic data on olfactory epithelium sizes in nonhuman primate species are at hand. However, as a caveat concerning the plausibility of the idea that a larger olfactory epithelium would necessarily be accompanied by a better sense of smell it should be mentioned that the size of the human olfactory epithelium has been estimated to be around 5 cm<sup>2</sup> whereas that of the rat is only 4 cm<sup>2</sup> (Güntherschulze, 1979), leading to the interesting conclusion that based on this neuroanatomical feature humans should have a better sense of smell than rats. Comparisons of olfactory detection thresholds between species with known sizes of their olfactory epithelium do not generally support a correlation between olfactory sensitivity and epithelium size (Smith and Bhatnagar, 2004).

Using cranial endocasts of 150 species of mammals including 16 species of primates, Pihlström et al. (2005) measured total skull area as well as the area of the cribriform plate of the ethmoid bone, through which the axons of the olfactory sensory neurons reach the olfactory bulbs (Table 27.2). Based on a subsample of 15 nonprimate species, the authors found that the size of the cribriform plate is directly proportional to the size of the olfactory

**Table 27.2** Size of the cribriform plate in primates.

Common Name	Scientific Name	mm <sup>2</sup>
Potto	<i>Perodicticus potto</i>	41.5
Greater dwarf lemur	<i>Cheirogaleus major</i>	17.6

epithelium. As the authors believe that the size of the olfactory epithelium would be a reliable indicator of a species' olfactory performance (see previous paragraph on the trustworthiness of this notion), they conclude that the relative size of the cribriform plate would be a reliable indicator of olfactory capabilities, too. With regard to primates, they mention that humans, apes, and monkeys would have small olfactory organs in relation to skull size, while prosimians would have olfactory organs of a size that was typical for mammals of their body size.

## 27.4 NEUROPHYSIOLOGY

Using a combination of electrophysiological recordings, lesioning of circumscribed brain areas, and behavioral assays, Takagi and co-workers systematically studied the central olfactory projections in members of an Old World primate genus, the macaques (Takagi, 1986). They were able to establish that the basic architecture and central connections of the olfactory pathway in these nonhuman primates are very similar to those reported in rodents such as mice and rats. At least three additional important findings resulted from these studies:

1. The authors demonstrated the presence of an olfactory area in the neocortex of the macaques (Tanabe et al., 1975a). More specifically, they found that the lateral and posterior areas of the orbitofrontal cortex are involved in the processing of olfactory information.
2. The authors demonstrated the presence of a transthalamic olfactory pathway in macaques (Yarita et al., 1980). Whereas a neuronal connection between paleocortical areas involved in olfactory processing and

neocortical areas bypassing the thalamus had been well-established in a variety of animal models, the existence of a thalamic connection between paleo- and neocortex as part of the olfactory pathway had been a matter of debate for many years.

3. The authors demonstrated that the orbitofrontal cortex is involved in odor discrimination (Tanabe et al., 1975b). Among the neocortical neurons they recorded from, 50% responded to only one of eight odorants presented to the animals and none of the neurons responded to more than four of the eight odorants. Lesioning of these neocortical areas led to an impairment in olfactory discrimination performance at the behavioral level.

The high degree of homology between the central olfactory projections in rat and macaque monkey were also confirmed histologically using anterograde and retrograde neuronal tracers (Carmichael et al., 1994) as well as by functional PET imaging in alert animals (Kobayashi et al., 2002).

Rolls and co-workers continued to explore the specific functions of olfactory cortical areas in macaques (Rolls, 2004). They demonstrated that subpopulations of neurons in the primate orbitofrontal cortex that respond to odor stimuli are also involved in associative learning (Rolls et al., 1996) and in the perception of flavor, that is, the combined sensations of smell, taste, and touch in the context of food ingestion (Rolls, 2006). Further, they showed that physiological states such as hunger and satiety may affect the responsiveness of olfactory neurons in the orbitofrontal cortex of macaques (Critchley and Rolls, 1996).

Studies on central olfactory projections in nonhuman primates other than macaques are sparse. Using neuronal tracers, Liebetanz et al. (2002) found the architecture of the olfactory pathway in the common marmoset, a New World primate, to be similar to that in the macaque. Using functional magnetic resonance imaging, Boyett-Anderson et al. (2003) reported odorant-induced activation in awake squirrel monkeys, also a New World primate, in the same brain areas previously implicated in conscious human olfactory processing. Together, these studies suggest that the olfactory pathway and the brain areas involved in processing of olfactory information do not differ fundamentally between New and Old World primates, or between primates and non-primate mammals.

## 27.5 GENETICS

Olfactory receptor (OR) genes comprise the largest multi-gene family in mammalian genomes. Bioinformatic analyses of the draft genome sequences of various mammals

revealed that both the total number of functional OR genes and the fraction of OR pseudogenes may differ considerably among species. Gilad et al. (2004) sequenced 100 randomly chosen OR genes in 19 primate species and found that the fraction of OR pseudogenes in Old World primates and the howler monkey was significantly higher than in New World primates (Table 27.3). From this observation they hypothesized that OR genes in primates lost their functionality due to the acquisition of full trichromatic vision, which is only found in Old World primates and the howler monkey.

However, using high-coverage whole-genome sequences, Matsui et al. (2010) analyzed the complete OR gene repertoires of seven primate species (Table 27.4) and found no significant differences in the number of functional OR genes and in the fraction of OR pseudogenes between New World primates and Old World primates and hominids. From this the authors concluded that the degeneration of OR genes in primates cannot simply be explained by the acquisition of trichromatic vision.

Analyzing the evolutionary processes underlying the between-species differences in OR gene repertoires, Dong et al. (2009) reported dramatic variations and dynamic turnovers in the evolution of OR genes in primates with evidence for both relaxed selective pressure on some OR

**Table 27.3** Fraction of OR pseudogenes in primates, based on 100 randomly chosen OR genes.

Data from Matsui et al. (2010)

genes and positive selection for other OR genes in the same species. From this the authors concluded that OR gene repertoires in primates may have evolved in such a way to adapt to their respective chemical environments. This idea is supported by findings from comparative studies that assessed olfactory capabilities such as threshold sensitivity or discrimination performance and found that the frequency of occurrence of odorants in a species' chemical environment or the behavioral relevance of odorants may affect their detectability and discriminability (Laska et al., 2005a, 2005b). Additional evidence for unusually rapid processes in the evolution of primate OR genes is provided by a comparison of the repertoires of functional OR genes between humans and chimpanzees. Within only 6 million years since their last common ancestor about 25% of their functional OR genes are now species-specific (Go and Niimura, 2008).

Some authors have argued that the number of functional OR genes and the fraction of OR pseudogenes should be indicative of a species' olfactory capabilities and have taken the limited data available so far as an argument for a "greatly reduced sense of smell in primates" relative to other species (Rouquier et al., 2000). However, if the simple reasoning according to which a high number of functional OR genes would necessarily be accompanied by a keen sense of smell and a low number of such genes by a poor sense of smell was true, then dogs would have to be considered having markedly poorer olfactory capabilities than rats as the former has only 822 functional OR genes whereas the latter has 1259 (Nei et al., 2008) – a conclusion which is not exactly intuitive. Thus, it should be emphasized here that there is no physiological evidence whatsoever supporting the hypothesis of a correlation between the size of the olfactory receptor repertoire and olfactory performance. Rather, comparative studies of olfactory performance in species with known numbers of functional OR genes generally fail to support the idea of "more functional OR genes equal a better sense of smell" (Kjeldmand et al., 2011).

## 27.6 BEHAVIOR

The traditional belief that primates would be primarily "visual" animals with a poorly developed sense of smell prevented behavioral studies specifically addressing the role of olfaction in regulating primate behavior for a long time. However, there is now accumulating evidence for olfactory involvement in a variety of behavioral contexts including foraging and food selection, predator avoidance, social communication, and reproduction in nonhuman primates.

With regard to the role of olfaction in foraging and food selection, numerous anecdotal reports described free-ranging primates of all major groups within this order of mammals to smell at potential food prior to deciding for or against its consumption. Experimental studies demonstrated that nocturnal mouse lemurs are able to find hidden fruit using olfactory cues alone (Siemers et al., 2007). Similarly, nocturnal owl monkeys, but not diurnal capuchin monkeys, succeeded in finding hidden fruit based on olfactory cues alone (Bolen and Green, 1997). However, Ueno (1994a) showed that capuchin monkeys are at least able to discriminate between food odors. Diademed sifakas have been shown to use olfactory cues to forage for the inflorescences of subterranean parasitic plants (Irwin et al., 2007). Laska et al. (2007a) studied the food selection behavior in captive squirrel monkeys and spider monkeys. They found that both species use olfactory, gustatory, and tactile cues in addition to visual information to evaluate novel food, whereas familiar food items were mainly assessed visually prior to consumption. The importance of olfactory cues for food selection was further indicated by the finding that familiar food which was experimentally modified by adding a non-matching odorant was treated, that is, sniffed at as if it was unfamiliar (Laska et al., 2007a). Interestingly, dichromatic and trichromatic wild spider monkeys were found not to differ in their use of olfactory cues when assessing potential food items (Hiramatsu et al., 2009). The odor of potential food has also been demonstrated to serve as an effective cue in

food avoidance learning by nonhuman primates. Squirrel monkeys and common marmosets learned to reliably avoid unpalatable food based on olfactory cues alone after only one or a few trials and showed retention of the significance of these olfactory cues for up to four weeks (Laska and Metzker, 1998).

Information about the edibility of food is also transferred between individuals by using olfactory cues: in three species of Old World primates, mandrills, drills, and olive baboons, animals were found to consume the same type of food as a conspecific after they had sniffed at the conspecific's mouth. This information transfer by actively sniffing at the mouth of an eating conspecific occurred most often between young and older animals suggesting olfactory learning about edibility of food (Laidre, 2009).

With regard to the role of olfactory cues for predator avoidance, Buchanan-Smith et al. (1993) demonstrated that cotton-top tamarins respond differentially to the fecal odors of sympatric predators and non-predators. They concluded that the discrimination of predator and non-predator odors was innate in this primate species as their animals were captive-born and the observed behavioral responses were unaffected by whether or not the parent animals were wild-caught or captive-born. Similarly, olfactory predator recognition has been demonstrated in both wild (Kappel et al., 2011) and captive-born (Sündermann et al., 2008) mouse lemurs. Interestingly, the odor of owl feces, that is, of an aerial predator, was not avoided by the mouse lemurs, whereas this was not the case for the odor of fossa feces, that is, of a terrestrial predator. This difference may be explained either by a lack of predator-typical volatiles in owl feces or by a lower behavioral significance for olfactory recognition of aerial predators compared to terrestrial predators.

Gisela Epple and co-workers were the first to systematically study olfactory social communication in nonhuman primates. Using a combination of behavioral, chemo-analytical, and endocrinological approaches, they demonstrated that marmosets and tamarins, a group of New World primates, strongly rely on olfactory cues in the regulation of their social behavior. They described a variety of scent-marking behaviors (Epple, 1986), analyzed the chemical composition of scent gland secretions (Belcher et al., 1986), unraveled the informational content and the behavioral functions of scent-marks (Epple et al., 1993), and thus contributed significantly to our understanding of the role of chemical signals in the control of social behavior in nonhuman primates. Further, they demonstrated that, similar to nonprimate mammals, the scent-marks of marmosets and tamarins contain information about species, social group, gender, age, reproductive status, social rank, health status, individual identity, and genetic relatedness of the odor donor (Epple et al., 1989).

Whereas specialized scent glands are a common feature of prosimians and New World primates, their presence in Old World primates and hominoids appears to be rare. However, it should be noted that several species of Old World primates, such as mandrills (Setchell et al., 2010), guenons (Loireau and Gautier-Hion, 1988), velvet monkeys (Freeman et al., 2012), and even hominoids such as gibbons (Geissmann 1987), have been reported to possess fully functional specialized scent glands and to perform scent-marking behaviors. Recent studies have shown that the secretion of the sternal gland of the mandrill contains information about its producer's major histocompatibility complex and thus about its individual genetic quality which is thought to play a crucial role in mate choice and kin selection (Setchell et al., 2011). Primate species possessing specialized scent glands often display conspicuous scent-marking behaviors which may include, but are not restricted to, nasal rubbing, throat rubbing, chest rubbing, back rubbing, suprapubic rubbing, and anogenital rubbing, depending on the localization of the scent glands on the body (Figure 27.3).

These behaviors may be performed to deposit scent gland secretions either on a substrate such as branches, or on a conspecific, or on parts of the odor donor's own body. An example for this latter case are the ring-tailed lemurs which impregnate their bushy tails with the secretions of their antebrachial (that is: forearm) glands and then engage in ritualized "stink-fights" which serve to establish a stable hierarchy within a social group and to limit the degree of physical aggression (Kappeler, 1998).

Other primate species that are lacking specialized scent glands may nevertheless use olfactory cues for social communication, for example by employing urine as a signal. A wide variety of primate species including galagos, slender loris, mouse lemurs, capuchins, squirrel monkeys, owl monkeys (Andrew and Klopman, 1974), woolly monkeys (Milton, 1985), howler monkeys (Jones, 2003), and moustached tamarins (Heymann, 1995) engage in urine washing. This conspicuous behavioral pattern consists of urination onto the palm of the hand with subsequent distribution of the urine either onto the soles of the feet, or onto the fur, or onto the substrate, usually a branch. Interestingly, some of the species mentioned above do have specialized scent glands, but nevertheless display urine washing in certain behavioral contexts.

The variety of information that has been identified in the scent marks of nonhuman primates has also been demonstrated to serve a variety of functions including the advertisement of presence, the establishment and maintenance of social rank (e.g., Kappeler, 1998), territorial defense (e.g., Palagi and Dapporto, 2007), recognition of group members (e.g., Braune et al., 2005), advertisement of sexual receptivity (e.g., Clarke et al., 2009), synchronization or monopolization of reproductive activity (e.g.,

**Figure 27.3** Scent-marking behaviors in callithrichid monkeys. Sternal marking (Goeldi's monkey), anogenital marking with simultaneous sniffing of marking site (moustached tamarin), suprapubic marking (Geoffroy's tamarin). Redrawn from Heymann (2003).

Barrett et al., 1993), establishment and maintenance of an inbreeding barrier (e.g., Charpentier et al., 2010), directed altruism (e.g., Boulet et al., 2009), and social bonding (e.g., Kaplan et al., 1977), to name but a few.

## 27.7 PHYSIOLOGY

The systematic experimental assessment of olfactory performance in nonhuman primates has begun only two decades ago. Measurements of olfactory sensitivity and discrimination ability, as well as of olfactory learning and memory performance under controlled conditions, are clearly necessary to address the apparent discrepancy between (a) anatomical and genetic findings that suggest primates have a poorly developed sense of smell and (b) behavioral findings that suggest the sense of smell plays a crucial role in regulating primate behavior.

Laska and co-workers developed behavioral tests based on operant conditioning paradigms and using established psychophysical procedures which made it possible to assess key aspects of olfactory performance in squirrel monkeys and spider monkeys, two New World primate species, and in rhesus macaques, an Old World primate species. Figures 27.4 and 27.5 illustrate the behavioral tests.

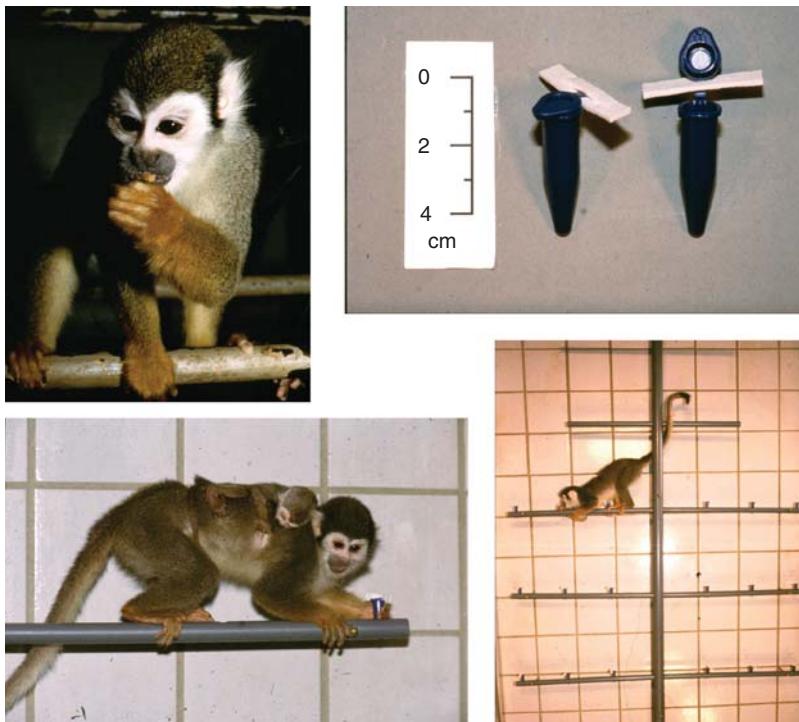

By the time this chapter was printed, Laska and co-workers have published olfactory detection thresholds for 74 odorants in spider monkeys, for 61 odorants in

squirrel monkeys, and for 60 odorants in rhesus macaques (Table 27.5). These numbers are considerably higher than the numbers of odorants that have been tested so far with any other nonhuman species.

Two tentative conclusions can be drawn from these olfactory detection threshold data:

1. Within-species comparisons suggest that olfactory sensitivity may correlate with the behavioral relevance of the odor stimuli. All three primate species tested were found to be particularly sensitive for odorants occurring in the contexts of food selection, predator avoidance, social communication, and reproduction. This is in line with findings from non-primate species which also suggest that the behavioral relevance of odor stimuli may affect their detectability.
2. Between-species comparisons suggest that the olfactory sensitivity of all three primate species is not generally inferior to that reported in species presumed to have a keen sense of smell, but in several cases matches or even surpasses the olfactory sensitivity of mice, rats, or dogs. This, in turn, suggests that neither anatomical features such as the absolute or the relative size of olfactory brain structures nor genetic features such as the number of functional olfactory receptor genes are reliable predictors of a species' olfactory sensitivity.

For the sake of completeness it should be mentioned that Glaser and co-workers (1994) determined the olfactory detection threshold for one odorant in the pygmy

**Figure 27.4** Olfactory conditioning method used with squirrel monkeys. *Upper left hand:* picture of a squirrel monkey (*Saimiri sciureus*). *Upper right hand:* Eppendorf® cups equipped with absorbent paper strips. The Eppendorf® cups serve as manipulation objects (“artificial nuts”) that are either baited with a piece of peanut or not, depending on the odorant applied on the absorbent paper strip. *Lower right hand:* experimental set-up. An “artificial nut tree” is used to present numerous “artificial nuts”, half of them baited with a piece of peanut and bearing an odorant used as rewarded stimulus, and half of them empty and bearing an odorant used as unrewarded stimulus. *Lower left hand:* a squirrel monkey inspecting an “artificial nut” on a branch of the “artificial nut tree”. (A detailed description of the method is given in Laska and Hudson, 1993b).

**Figure 27.5** Olfactory conditioning method used with spider monkeys. *Upper left hand:* picture of a spider monkey (*Ateles geoffroyi*). *Upper right hand:* the two-choice apparatus used, viewed from the animal’s side. It consists of two manipulation boxes of which one is baited with a Kellogg’s® honeyloop while the other is empty, depending on the odorant applied on the absorbent paper strip attached to the box. *Lower right hand:* a spider monkey smelling at one of the absorbent paper strips bearing an odorant used either as a rewarded stimulus or as an unrewarded stimulus. *Lower left hand:* a spider monkey indicating his decision for one of the two simultaneously presented odorants by opening the corresponding manipulation box. (A detailed description of the method is given in Laska et al., 2003a).

estr-1,3,5(10),16-tetraen-3-ol		0.63 / 63.3 mM	6.3 / 63.3 mM

Data from Hernandez Salazar et al. 2003; Joshi et al. 2006; Laska and Seibt 2002a, 2002b; Laska et al. 2000, 2003b, 2004, 2005a, 2005b, 2005c, 2005d, 2006a, 2006b, 2006c, 2007b, 2009; Løtvedt et al. 2012; Wallén et al. (2012)

The first value in each data pair refers to the lowest individual threshold, and the second value to the highest individual threshold determined with a given odorant.

Threshold values for the steroids are given in liquid concentrations ( $\mu$ M and mM) rather than in gas phase concentrations (log ppm) as no experimentally determined vapor pressures are available for these odorants.

marmoset. Using an operant conditioning procedure and an automated olfactometer, they found that this smallest of all primate species is able to detect vanillin at concentrations as low as –3.68 log ppm. Unfortunately, no further studies on olfactory capabilities in this primate species and using this method were published.

Studies on olfactory discrimination capabilities in squirrel monkeys using structurally related monomolecular odorants showed that this New World primate species possesses a well-developed ability to distinguish between members of homologous series of aliphatic acetic esters (Laska and Freyer, 1997), n-carboxylic acids (Laska and Teubner, 1998), 1-alcohols, n-aldehydes, and 2-ketones (Laska et al., 1999b). However, the squirrel monkeys failed to discriminate between some odorants that differed from each other by only one carbon atom, whereas mice and Asian elephants tested on the same odor pairs did not.

Squirrel monkeys were also found capable of discriminating between binary odor mixtures that vary only slightly in the concentration ratios of their components (Laska and Grimm, 2003), and between complex odor mixtures from which only one or a few components have been removed (Laska and Hudson, 1993a). Further, squirrel monkeys are able to discriminate between urine odors of individual conspecifics, irrespective of the gender of and the test animal's familiarity with the odor donor (Laska and Hudson, 1995). Ueno (1994b) reported that tufted capuchin monkeys are able to discriminate between the urine odors of five different species. The ability of both squirrel monkeys and pigtail macaques to discriminate between the odors of the (+)- and (–)-forms of enantiomers, that is, of optical isomers, was

found to be comparable to that of human subjects but inferior to that reported in mice and Asian elephants tested on the same set of stimuli (Laska et al., 1999a, 2005b).

With regard to olfactory long-term memory, Laska et al. (1996) demonstrated that squirrel monkeys show excellent retention of the reward value of previously learned odor pairs up to 15 weeks and above-chance level performance up to 30 weeks, the longest interval tested with this species. Similarly, pigtail macaques and spider monkeys showed no signs of forgetting of previously learned odor pairs after three and four weeks, respectively, the longest intervals tested with these two species (Hübener and Laska, 1998; Laska et al., 2003a).

Measurements of olfactory learning capabilities yielded mixed results in nonhuman primates: with regard to the speed of initial task acquisition, that is, mastering of the very first odor pair presented to the animals, squirrel monkeys needed 450–750 stimulus contacts for reaching a pre-set learning criterion, spider monkeys needed 660–720, and pigtail macaques 960–1800 stimulus contacts using the operant conditioning paradigms mentioned above (Hübener and Laska, 2001; Laska and Hudson, 1993b; Laska et al., 2003a). These numbers are comparable to those reported in South African fur seals (480–880), but are considerably higher than those reported in mice, rats, dogs, and Asian elephants which all needed <150 stimulus contacts to learn to criterion their very first odor pair. This suggests that nonhuman primates may not be as prepared as non-primate mammals to acquire the basic concept underlying olfactory discrimination paradigms. It should be mentioned, however, that gray mouse lemurs, a

prosimian primate, needed only 160–560 stimulus contacts to acquire a two-odorant discrimination paradigm using an operant conditioning procedure and apparatus similar to one employed with mice and rats (Joly et al., 2004).

The number of stimulus contacts needed to master subsequent odor pairs rapidly decreased in all four primate species to a level comparable with that reported in mice, rats, dogs, and Asian elephants. Thus, the speed of learning intramodal transfer tasks using olfactory stimuli displayed by nonhuman primates is not inferior to that of non-primate species believed to strongly rely on their sense of smell.

## 27.8 THE VOMERONASAL SYSTEM

The vomeronasal organ (VNO) has been demonstrated to play a role in sociosexual chemical communication in a wide variety of vertebrates (see Chapter 51, this volume). In mammals, the organ is situated at the anterior base of the nasal septum and consists of two elongated, liquid-filled and blindly-ending tubes whose inner surface is lined with a neuroepithelium which receives chemical stimuli via openings in the nasal cavity, or the oral cavity, or in both. The VNO has been found to be anatomically present and fully developed in all prosimians and New World primates studied so far (Smith et al., 2011). In contrast, Old World primates and hominoids seem to lack a fully developed VNO, at least postnatally (Smith et al., 2001). Recent reports of a VNO being anatomically present in postnatal humans (Meredith, 2001) and chimpanzees (Smith et al., 2002) suggest this structure to be vestigial and non-functional in these hominoids as a neuroepithelium as well as a neuronal connection to the brain seem to be absent. It should be emphasized, however, that in the majority of primate species known to have a fully developed VNO, physiological evidence of its functionality is lacking (but see Schilling et al., 1990). Nevertheless, behavioral studies suggest the VNO to be functional in at least some of these species (Evans, 2006). Similarly, studies reporting behavioral and/or hormonal changes as a consequence of VNO removal suggest the organ to be functional in primate species such as the grey mouse lemur (Aujard, 1997) or the common marmoset (Barrett et al., 1993).

The axons of the vomeronasal chemosensory neurons project to the accessory olfactory bulbs (AOBs), the first relay station of the vomeronasal pathway. The systematic neuroanatomical studies of Stephan and co-workers on the comparative size of mammalian brains and brain structures provide data on the absolute and the relative size of the AOBs in 45 species of primates representing all major groups within this order of mammals (Table 27.6). All 31 species of prosimians and New World primates studied were found to possess AOBs whereas this structure

was absent in all 14 species of Old World primates and hominoids studied.

Several evolutionary trends can be described when comparing AOB sizes between species:

1. Prosimians tend to have larger accessory olfactory bulbs relative to total brain volume than New World primates.
2. Within the prosimians, nocturnal species tend to have larger accessory olfactory bulbs relative to total brain volume than diurnal species. This is consistent with the idea that nocturnal species might rely to a higher degree on olfactory signals in the context of reproduction compared to diurnal species.
3. No interdependency between the size of the main olfactory bulbs and the size of the accessory olfactory bulbs was found. This is consistent with the idea that the main and the accessory olfactory systems serve different functions, that is, process olfactory information in different behavioral contexts.
4. No sex differences in the size of the accessory olfactory bulbs were found in any of the primate species studied. This is remarkable given that the vomeronasal organ is thought to be involved in the behavioral context of reproduction and given that sex differences in the production and deposition of scent marks as well as in flehmen-like behaviors have been reported in several species of nonhuman primates.
5. No correlation between the size of the accessory olfactory bulbs and dietary specialization was found. This is consistent with the idea that the vomeronasal organ is involved in the behavioral context of reproduction but not in the context of foraging and food selection.

Flehmen, that is, the curling of the upper lip in response to the detection of certain odorants has been reported in a variety of mammals that possess a vomeronasal system and is thought to facilitate the access of signaling chemicals secreted by conspecifics to the vomeronasal organ. The behavior is thought to play a role in the social and reproductive context. Flehmen-like facial expressions have been described in some prosimian species such as the ring-tailed lemur (Bailey, 1978) and in New World primates such as marmosets (Epple et al., 1993), but not in Old World primates and hominoids. When sniffing the urine of female conspecifics, some New World primate species such as howler monkeys (Van Belle et al., 2009) and owl monkeys (Wolovich and Evans, 2007) have been reported to show rhythmic tongue protrusions reminiscent of those in lizards and snakes. Since this behavior in reptiles has been linked with vomeronasal organ function it has been suggested that these rapid oscillating protrusions of the tongue are also involved in the perception of odorants via the vomeronasal organ in New World primates. Consistent with this idea,

**Table 27.6** Absolute and relative size of the accessory olfactory bulbs (AOBs) in primates.

Common Name	Scientific Name	AOB Volume (mm <sup>3</sup> )	Brain Volume (mm <sup>3</sup> )	AOB % of Brain
Gray mouse lemur	<i>Microcebus murinus</i>	1.6	1654	0.970

## The Role of Saliva in Taste Transduction

RYUJI MATSUO and GUY H. CARPENTER

### 28.1 INTRODUCTION

Saliva is the first digestive fluid in the alimentary canal, and is produced by three pairs of major salivary glands (parotid, submandibular, and sublingual) and by hundreds of minor salivary glands (labial, lingual, buccal, and palatal) spread over most parts of the oral mucosa. This fluid usually coats the surface of teeth and oral mucosa and has multiple functions, including the maintenance of taste and somatosensory functions of the oral cavity.

The role of saliva in taste was first documented by McBurney and Pfaffmann (1963), who showed that salivary constituents (sodium and chloride) could affect taste sensitivity to NaCl by human psychophysical experiment. Gurkan and Bradley (1988) recorded the taste nerve (the glossopharyngeal nerve) response in rats and have suggested that saliva not only acts as a solvent of taste substances, but also interacts in some way with the receptor mechanism. On the basis of these studies, many human psychophysical and animal behavioral and electrophysiological studies have been employed and provided evidence that saliva can widely affect the oral sense including the five basic tastes and the taste of fat, starch, astringency, and tactile sensation.

Since Ludwig (1850) and Bernard (1856) discovered the secretory role of nerves to salivary glands, it has been known that salivary secretion is dependent on reflex activity. The salivary reflex is regulated by the autonomic nerves innervating salivary glands. Whilst we are awake there is a resting flow of saliva by all glands into the mouth. The most copious flow of saliva is produced during eating

with inputs from taste, chewing, and smell, and to a lesser degree the texture of the food. Activation of the autonomic nerves is initiated by multiple sensory afferents, including taste bud activation, mechanoreceptors in the gingivae and bare nerve endings in the mucosa as well as the olfactory bulbs in the nasal cavity. These stimuli for salivation are conveniently called gustatory, masticatory, olfactory, and oesophageal salivary reflexes (Hector and Linden, 1999). This reflex saliva, or stimulated saliva, particularly assists in the breakup and bolus formation of food ready for swallowing. Resting saliva, in contrast, is more suited to the tasting of foods by having a different composition to reflex-stimulated saliva.

Unstimulated, or resting, saliva is secreted in the absence of apparent sensory stimuli related to eating, but is actually the greatest contributor to total salivary secretion during the diurnal cycle (Sreebny, 1989). Although this saliva is produced at rest it is still an active secretion process and is rich in glycoproteins, including mucins and IgA, mainly excreted from the submandibular and sublingual salivary glands (approximately 60–70%). Although the parotid glands are the largest salivary glands in humans they have a very low resting flow but contribute the greatest amount to whole mouth saliva (the sum of all salivary secretions into the mouth) during reflex activation. Whereas the submandibular and sublingual glands have large quantities of mucins, the parotid has none. Mucins have the properties of high viscosity and strong adhesiveness to oral tissues and are often perceived as molecules that create the thickness and elasticity of whole mouth saliva. The viscosity of resting saliva is two to three times

that of stimulated saliva induced by chewing paraffin wax in healthy adults (Rantanen and Meurman, 1998). These findings imply that resting saliva contributes to maintaining the health of the oral cavity by lubricating and protecting oral tissues, and acting as a barrier against chemical and mechanical irritants. In patients with decreased salivary flow (xerostomia), whether caused by prescribed drugs, disease or following head and neck irradiation, the result is clinically significant oral discomfort that may manifest as increased caries, susceptibility to infection of the oral mucosa, or altered oral sensation (Hershkovich and Nagler, 2004; Mese and Matsuo, 2007).

In normal healthy subjects, saliva constantly coats the oral mucosa, protecting taste receptors from their external environment, but most also mediate the initial events in taste transduction (Spielman, 1990; Bradley, 1991; Matsuo, 2000; Bradley and Beidler, 2003). To reach and stimulate taste receptors, taste stimuli initially have to dissolve in saliva and then pass through the salivary layer towards the receptor. The fluid layer is composed of various organic and inorganic substances, some of which can stimulate taste receptors and/or chemically interact with taste substances. These reactions eventually affect perceived taste intensity and/or quality.

Food contains various substances. Oral sensory receptors distinguish food chemicals into the five fundamental taste qualities of sweet, salty, sour, bitter, and umami. Other tastes, such as astringency, metallic and fatty sensations, are probably detected by oral mechanoceptors and bare nerve endings within the mucosa.

## 28.2 MILIEU OF SENSORY RECEPTORS IN THE ORAL CAVITY

### 28.2.1 Composition of Saliva

Saliva is a mixture of saliva from three pairs of major glands and hundreds of minor glands, all of which have a

different profile of proteins. Some proteins are universal to all glands, such as the secretory component, the transporter of IgA (the main antibody in saliva). Mucins (Muc 5b and Muc 7 gene products) are common to the submandibular, sublingual, and most minor glands, but are not expressed by the serous glands, parotid, and von Ebner's glands. Basic PRPs (proline-rich proteins) appear to be exclusive to the parotid glands, whilst acidic PRPs appear in submandibular and parotid glands. Furthermore, the relative contribution of each gland to saliva varies between resting and stimulated states. Hence, the composition of saliva can vary greatly within a person and vary even more among individuals due to genetic polymorphisms. For example, the proline-rich proteins, which form nearly 70% of parotid total protein, are encoded by only six or so genes but can be rearranged and have so many post-transcriptional modifications that a family of nearly 30 separate proteins appear in saliva (Maeda, 1985; Azen and Maeda, 1988).

Compared to reflex-secreted stimulated saliva, resting saliva is ideally modified for the initial tasting of foods. Although salivary secretion involves the active secretion of chloride ions into the ducts, to be followed by sodium ions and water, it has a low salt content as the low flow rate allows the striated ducts to reabsorb most of the sodium and chloride ions. This energy-demanding process changes the primary saliva, which is initially isotonic with serum, into a hypotonic solution (Table 28.1). The benefit to taste is that, because taste buds become adapted to their ionic environment, the taste threshold for salt is much lower than it would be if the ion reabsorption process did not occur. In addition, resting saliva has low buffering ability since the secretion of both bicarbonate ions and carbonic anhydrase, the main buffering agents in saliva, is related to flow rate. Thus, in unstimulated resting saliva, the low buffering capacity (although proteins do provide some buffering capacity) allows the taste buds to detect low concentrations of protons that create the sour taste sensation.

**Table 28.1** Electrolytes, pH, and osmolality of human saliva.

	Resting Saliva	Stimulated Saliva	Source of Saliva
$\text{Na}^+$	2.7 mEq/l	63.3 mEq/l	parotid
	3.3 mEq/l	45.5 mM/l	
$\text{K}^+$	46.3 mEq/l	18.7 mEq/l	parotid
	13.9 mEq/l	17.8 mM/l	
$\text{Cl}^-$	31.5 mEq/l	35.9 mEq/l	parotid
	12.0 mEq/l	23.4 mM/l	
$\text{HCO}_3^-$	0.60 mEq/l	29.7 mEq/l	parotid
$\text{pH}$	5.47	6.48	parotid
	6.73	—	
Osmolality	85.7 mOsm/kg	136.9 mOsm/kg	parotid

Data for parotid gland are cited from Shannon et al., 1974, and those for the submandibular gland are from Ferguson and Fort, 1974, and Ferguson and Botchway, 1979.

**Table 28.2** Salivary proteins related to oral senses and their main functions.

Proteins	Main Function	Effect on Oral Sense
Mucins	lubrication and pellicle formation	emulsifying of fats/oils, and tactile
Amylase	starch digestion	taste of carbohydrate and glucose, and tactile
Lipase	fat digestion	taste of fatty acids
Carbonic anhydrase	buffering action	acid taste
Proline-rich proteins	pellicle formation	astringency
Histatin	anti-bacterial action	astringency
Statherin	remineralization of teeth	lowering of surface tension

A further modification of saliva that facilitates the initial tasting of foods is the low surface tension. This is a feature of resting and stimulated saliva which allows the rapid interaction of the tastant with taste buds. The low surface tension of saliva is generated by the proteins within saliva and, in particular, surface active proteins such as statherin (Proctor et al., 2005a) (Table 28.2).

For many tastants, for example, salt and acids, saliva will be the solvent used to convey the ions to the taste buds. It is surprising then that an aqueous solution, such as saliva, is readily able to detect tastes locked up in an oil/fat liquid. The interaction of oil in water emulsions stabilized by different emulsifiers is a subject of considerable interest. Oil is well known to become emulsified by saliva, probably by interaction with mucins (Silletti et al., 2007). The deposition of oil onto the tongue surface, studied by *in vivo* confocal microscopy (Adams et al., 2007) and simpler paper sampling methods (Pivk et al., 2008) again relates to the emulsifying behavior of saliva. Further interactions of emulsions stabilized with different proteins reveals that the nature of the interaction with the oral mucosa governs taste and the mouthfeel of the food (Vingerhoeds et al., 2008; Vingerhoeds et al., 2009). Whey protein-stabilized emulsions did not readily interact with the tongue and formed creamy-type sensations, whereas lysozyme-stabilized emulsions formed almost astringent-like sensations and remained on the tongue.

### 28.2.2 Salivary Layer on the Mucosal Membrane

Saliva exists in the mouth as a heterogeneous (Sas and Dawes, 1997) thin film (Pramanik et al., 2010) that coats and interacts with the mucosa to form a highly lubricating layer (Bongaerts et al., 2007). The structure of the oral mucosa varies from non-keratinized squamous cells in the buccal region to keratinized gingivae and papillae on the dorsum of the tongue. The thickness of the salivary film varies from 5 µm on the hard palate to 25 µm on the tongue, as calculated by measuring the amount of saliva

per unit area (Pramanik et al., 2010). The thickness of saliva in different areas of the mouth probably reflects a number of variables, including local flow rates, salivary viscoelastic properties, and the surface roughness of the mucosa. The dorsal surface of the tongue, for example, has the thickest film, probably because of the papillae forming pronounced ridges. On the hard surfaces in the mouth, salivary proteins readily and specifically interact with the mineral components of teeth. The acquired enamel pellicle (Dawes et al., 1963) is a subset of salivary proteins that rapidly bind to calcium phosphate salts within teeth, mostly *via* post-translational modification of the protein, that is, a phosphate group. The most abundant salivary proteins in acquired enamel pellicles include statherin, acidic proline-rich proteins, and histatins (Jensen et al., 1992; Li et al., 2004). Modelling teeth with hydroxyapatite, mucins were also found to form strongly lubricating layers (Cardenas et al., 2007; Hahn Berg et al., 2003; Halthur et al., 2010). The presence of statherin, a calcium carrier, enhances the local concentration of calcium around teeth and thus prevents the dissolution of teeth (Hay and Bowen, 1996). The other proteins presumably play a role in managing the microflora that also bind to teeth.

As well as the enamel pellicle there is also evidence of a mucosal pellicle, that is, a select group of salivary proteins that are bound, to varying degrees, to oral mucosal cells. Initial observations (Bradway et al., 1989; Bradway et al., 1992) suggested that mucins, amylase, cystatin S, and acidic PRPs were present. The absorption of mucins to any surface in the mouth would be important for lubrication (Stokes and Davies, 2007). Once absorbed, the film can be modified by the ionic composition of saliva. In a study of absorbed mucins to control surfaces mimicking the oral mucosa, the absorbed mucin layer was found to vary in thickness between a low and high ionic strength solution (e.g., resting vs. stimulated saliva). This mucin film collapsed in a completely deionised environment, suggesting that static repulsion between molecules can influence film hydration/thickness (Macakova et al., 2010). It would be interesting to know whether the salivary film ever collapses

*in vivo.* A study of dry-mouth patients indicated that the salivary film was still present but thinner (Pramanik et al., 2010), perhaps suggesting a collapse of the mucosal pellicle, leading to the loss of lubrication and feelings of dryness. Over these pellicles (enamel and mucosal) flows the fluid phase of saliva. The flow starts from the opening of the ducts leading from the major glands (sublingual and buccal areas) and travels over all surfaces, at varying speeds, towards the throat for swallowing (or spitting out). This flow of saliva is important for the clearance of food and bacteria from the mouth and so maintains a normal healthy mouth.

### 28.2.3 Saliva and Taste Pore

#### 28.2.3.1 Taste Buds and Flow of Salivas are.

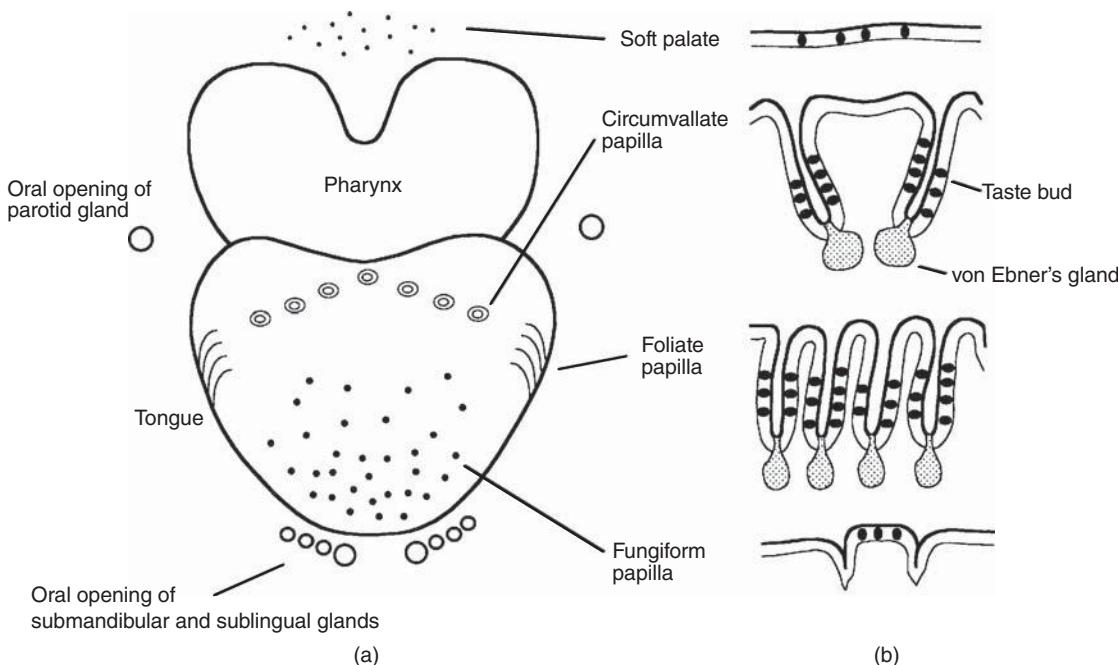

Taste buds, consisting of taste receptor cells, are unevenly distributed in the oral cavity. Many taste buds are located in the epithelial folds of the foliate and circumvallate papillae, and a smaller number are situated in the mucosa of the fungiform papillae and soft palate (Figure 28.1). It is likely that taste buds in various areas are exposed to different fluid environments, since secretions produced by each salivary gland differ in composition and, moreover, they are not always well-mixed or well-distributed around the mouth.

Lingual minor salivary glands on the posterior tongue, von Ebner's glands, drain saliva into the grooves of the circumvallate and foliate papillae. Saliva from von Ebner's

glands may exclusively fill the cleft and can effectively rinse away taste stimuli, as demonstrated by electrophysiological recordings of taste responses from circumvallate taste buds (Gurkan and Bradley, 1988).

Parotid saliva is secreted into the mouth from the oral opening of the main excretory duct at the buccal mucosa near the upper molar teeth. The main duct of the submandibular gland and several small ducts of the sublingual glands open onto the sublingual mucosa of the floor of the mouth. Due to this anatomical feature, parotid and submandibular/sublingual saliva is not evenly distributed throughout the mouth (Dawes and Macpherson, 1993). Mixed saliva collected from posterior regions of the mouth contains the greatest proportion of parotid saliva, whereas saliva from anterior regions contains the least under both stimulated and unstimulated conditions in humans (Sas and Dawes, 1997); a similar result was observed in rats (Matsuo et al., 1994). When a dye was infused into the mouth through the duct of the parotid or submandibular gland, the anterior and posterior parts of the tongue were mainly stained by infusion from the submandibular and parotid ducts, respectively. These findings imply that submandibular/sublingual saliva contributes to maintaining the external milieu of taste buds in the fungiform papillae more than parotid saliva.

#### 28.2.3.2 Milieu in the Taste Pores. Taste receptor sites are located on microvilli or club-shaped apical

**Figure 28.1** Locations of oral openings of the major salivary glands and taste papillae (a), and taste buds in the soft palate and taste papillae (b). (From Matsuo, 2000).

processes that emerge from taste cells. The apical membrane is exposed to the oral cavity in the taste pore (about 20 µm in diameter) at the top of the taste bud (Segovia et al., 2002). Taste pores are usually filled with mucous fluid that is derived from saliva and perhaps secretions from taste bud cells (Brouwer and Wiersma, 1980). Histochemical analyses of rabbits revealed that the taste pore content has a different carbohydrate composition from that of mucous substances overlying the adjacent epithelium, and that the composition of taste pore materials differs between fungiform and circumvallate/foliate taste buds (Witt and Miller, 1992). These findings suggest that secretions from taste buds immediately contact with the taste receptor. One such substance may be amylase, secreted from taste buds of the circumvallate papillae, as described later.

## 28.3 ROLE OF SALIVA IN TASTE

Taste substances should be dissolved in the salivary fluid layer to reach and stimulate taste receptors. During the process, saliva may affect taste substances by solubilization, diffusion, dilution, and chemical interaction. Some salivary components also affect the taste receptor and can alter its sensitivity by acting as stimulants and by affecting the affinity of the receptor to taste substances. Moreover, salivary digestive enzymes interact with certain components of food and produce tastants probably other than the five basic taste modalities. However, it is known that these salivary actions vary among animal species due to differences in taste transduction mechanisms and salivary compositions.

Based on recent molecular genetic studies on G protein-coupled receptors in various animals, it is suggested that species difference in taste receptor function intimately relates to taste behavior and feeding ecology (Li et al., 2005, 2009; Jiang et al., 2012). For example, cats and lions (obligate carnivores) lack the sweet taste receptor and are indifferent to sweeteners. Dogs (omnivore) and sheep (herbivore) do not show preferences to some of natural sugars including maltose (Ferrell, 1984; Glaser, 2002; Ginane et al., 2011), whilst rats and mice (omnivores) recognize and prefer most natural sugars including maltose (Li et al., 2002; Damak et al., 2003). On the other hand, it is well known that species have differences in salivary glands (e.g., Young and van Lennep, 1978) and salivary constituents (e.g., Erickson, 1964; Young and Schneyer, 1981). For example, in cats and dogs the zygomatic gland is prominent enough to be considered as the fourth major salivary gland, and in sheep the parotid gland is exceptionally large perhaps reflecting habitually ingesting dry food. Interestingly amylase is in low concentration or absent from the saliva of animals lacking the sweet taste receptors (e.g., cats) and those showing indifference to maltose (e.g., dogs and sheep). These findings suggest that, in evolution

of dietary habits, the function of taste and saliva might be designed to be suitable for detection, mastication, and digestion of food. Laboratory animals such as rats, mice, and hamsters secrete saliva of different concentration of ionic salts, amylase activity, and pH. There is a possibility that such variations may reflect species difference in taste sensitivity or taste transduction.

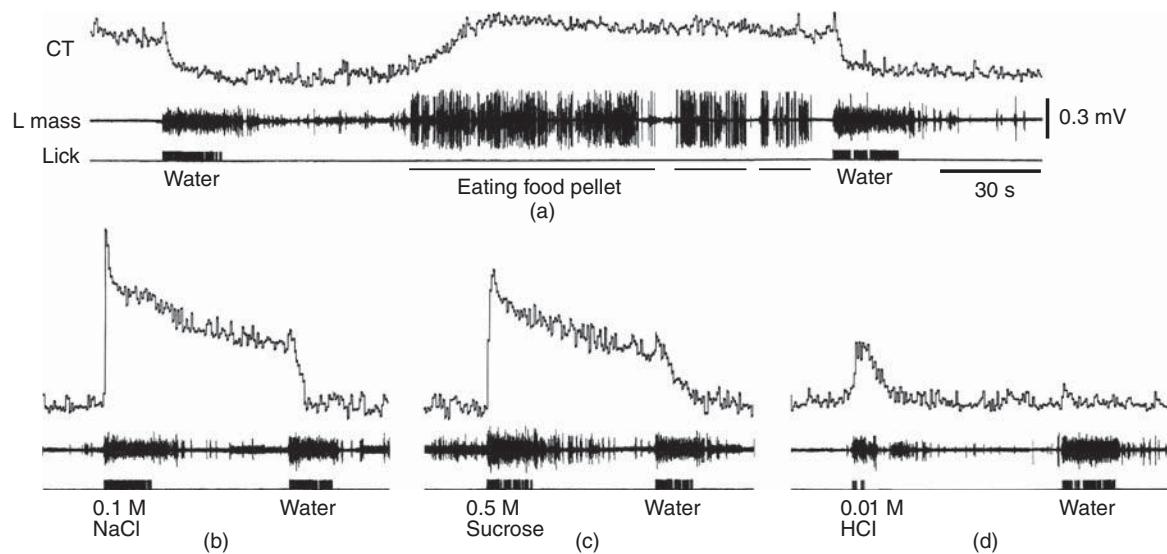

### 28.3.1 Saliva as a Solvent

The process of the dissolution and diffusion of taste substances in the pre-receptor fluid layer can influence the onset times of taste responses after the intake of food and beverages. Once taste substances dissolve into ions and molecules in the salivary layer, their movement to taste receptors by diffusion is relatively rapid, as shown by studies on taste response latencies (Beidler, 1961; Kelling and Halpern, 1993). Thus, the process of dissolution rather than diffusion may govern most of the pre-receptor time. The typical effect of solubilization can be observed after the intake of dried solid food and aqueous taste solutions (Matsuo et al., 1994). As seen in taste responses of the chorda tympani innervating the taste buds of the fungiform papillae in rats, a far longer time to reach the peak response was induced by eating food pellets than that induced by licking a taste solution (Figure 28.2). This suggests that chewing reduces the size of food particles and mixes them with saliva, gradually increasing the concentration of taste stimulants in the salivary layer.

### 28.3.2 Salty Taste

Of the salivary constituents of human mixed saliva, the principal ions of  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Cl}^-$ , and  $\text{HCO}_3^-$  can reach concentrations above their taste-detection threshold (see Table 28.1). These ions constantly stimulate the apical membranes of taste receptor cells. Eventually, taste receptor cells are adapted to such salivary components, and we are normally unaware of this background taste. In particular,  $\text{Na}^+$  and  $\text{Cl}^-$  may largely contribute to the adaptation or the basal activity of taste receptor cells, since  $\text{Na}^+$  and  $\text{Cl}^-$  ( $\text{NaCl}$ ) induce greater taste responses than other salivary ions ( $\text{KCl}$ ,  $\text{KHCO}_3$ , or  $\text{NaHCO}_3$ ). Sodium can enter taste receptor cells through epithelial sodium channels, the putative  $\text{Na}^+$  receptor, built into their apical membranes. Moreover, the tight junctions between the apical tips of taste bud cells and/or the epithelium are permeable to  $\text{Na}^+$  and  $\text{Cl}^-$ ; the permeated  $\text{Cl}^-$  may contribute to evoking stronger saltiness (Ye et al., 1993; Roper, 2007).

It is well documented that salivary  $\text{Na}^+$  and  $\text{Cl}^-$  can influence the detection of sodium chloride, the principal salty tastant, contained in food and beverages by the process of self-adaptation. Psychophysical studies in human (McBurney and Pfaffmann, 1963; Delwiche and

**Figure 28.2** Taste responses of the rat chorda tympani while eating a food pellet (A), licking 0.1 M NaCl (B), 0.5 M sucrose (C), and 0.01 M HCl (D). Each set of recordings is digitally summed chorda tympani discharge (CT), electromyographic activity of the left masseter muscle (L Mass), and lick signal (Lick). (From Matsuo et al., 1994).

O'Mahony, 1996; Bartoshuk, 1978) and animal experiments (Matsuo and Yamamoto, 1992; Rehnberg et al., 1992; Matsuo et al., 1994) have shown that salivary ions elevate the taste threshold and decrease the supra-threshold intensity of NaCl.

### 28.3.3 Sour Taste

Sour taste is elicited by acid, of which the proton and/or protonated molecular forms of organic acids in aqueous solutions are the ligand for sourness. Acids can stimulate both taste and trigeminal sensory receptors. In particular, non-dissociated acid molecules may enter the lingual epithelium and liberate protons. These protons could reach and stimulate the trigeminal free nerve endings innervating the epithelium, including the taste bud (Yamasaki et al., 1984; Bryant and Moore, 1995). In humans, acids are a powerful simulator evoking reflex salivation. A copious flow of saliva will dilute the taste stimulant. Moreover, saliva acts as a buffer by neutralizing acids with its components of bicarbonate, phosphate, and amphoteric proteins and enzymes. Bicarbonate is the most important buffering system of saliva. Since the concentration of bicarbonate and pH of saliva increase as the flow rate of saliva increases, the buffering action works more efficiently during stimulated high flow rates than during unstimulated low flow rates.

In animal experiments using rats, electrophysiological recordings of the taste nerve (chorda tympani) showed lower responses to HCl solution in the presence of saliva or bicarbonate salts on the tongue surface than in the absence of saliva (Matsuo and Yamamoto, 1992; Matsuo et al.,

1994). In humans, the pH of HCl solution increased after subjects sipped and expectorated the solution (Christensen et al., 1987). Human subjects who have greater sensitivity to acids tend to show a higher salivary flow rate, and eventually their perceived taste intensity will be decreased by dilution and buffering of the acid stimuli (Christensen et al., 1987; Lugaz et al., 2005).

### 28.3.4 Sweet Taste

Salivary effects on sweet taste differ among animal species, reflecting differences in the salivary composition and taste receptor mechanism. In rats, sweet taste responses were recorded from the chorda tympani under anesthetized and unanesthetized conditions, and the results showed that the magnitude of sweet responses in awake animals, or when the tongue was adapted to saliva in anesthetized animals, was about twice that obtained when the tongue was adapted to distilled water (Matsuo and Yamamoto, 1992; Matsuo et al., 1994). The response to licking 0.5 M sucrose solution is comparable to that of 0.1 M NaCl solution (Figure 28.2). The second-order taste relay neurons, the rostral nucleus of the solitary tract, also showed a large response magnitude when awake rats licked sucrose solution, partly because of the effect of saliva (Nakamura and Norgren, 1991). This enhancement is common to sweet compounds having various chemical structures, including sugars such as mono- and di-saccharides, amino acids, and artificial sweeteners such as saccharin and cyclamate (Matsuo and Yamamoto, 1990). This salivary effect can be mimicked by artificial saliva containing  $\text{HCO}_3^-$  and solutions with the pH adjusted to 8–10; meanwhile, sweet taste

responses were suppressed when the tongue was adapted to solutions of pH 3–4 (Matsuo and Yamamoto, 1992). A possible explanation for these findings is that salivary pH can change the charge distribution on the putative receptor, T1R2-T1R3 heterodimers of G protein-coupled receptors, and the allosteric H<sup>+</sup> binding of sweeteners with the receptor molecule is optimal at about pH 9.

In hamsters, no enhanced sucrose responses in the chorda tympani occur in the presence of saliva on the tongue (Rehnberg et al., 1992), but suppression of sucrose responses under acidic conditions of the tongue surface is suggested (Formaker et al., 2009). The lack of sweet taste enhancement in hamsters may be because the pH values of whole saliva are higher in hamsters (8.5–9.0) than rats (7.5–8.4) (Erickson, 1964), and chorda tympani responses to sweet taste stimuli are naturally much stronger in hamsters than rats (Ogawa et al., 1968).

In dogs (Kumazawa and Kurihara, 1990) and rats (Matsuo and Yamamoto, 1992), sweet taste responses can be slightly enhanced by the presence of Na<sup>+</sup> on the tongue at a low concentration equivalent to salivary levels, although the molecular mechanism of this effect is not known. In humans, psychophysical experiments reveal that the epithelial Na<sup>+</sup> channel blocker, amiloride, suppresses sweet taste-perceived intensity, suggesting the enhancement of sweet taste by Na<sup>+</sup> (e.g., Schiffman et al., 1983). Amiloride, however, can bind to the human sweet taste receptor and acts as its inhibitor (Imada et al., 2010). The effect of salivary Na<sup>+</sup> or pH on sweet taste intensity is not yet known in humans.

### 28.3.5 Umami Taste

Representative umami taste substances are 5'-mononucleotides, such as inosine 5'-monophosphate (IMP) and guanosine 5'-monophosphate (GMP), and some amino acids including glutamate whose sodium salt was the first umami substance identified. One candidate umami receptor is a heterodimer of G-protein-coupled receptors, T1R1-T1R3. This receptor may relate to the synergy reported for glutamate and nucleotide monophosphates in behavioural and nerve-recording studies (Roper, 2007; Zhan et al., 2008); for example, the taste intensity of a mixture of glutamate and IMP is larger than the sum of the individual taste intensities. This synergy is a unique characteristic of umami taste and also appears with mixtures of IMP and various amino acids in addition to glutamate. Among such umami amino acids, glutamate, glycine, proline, and serine are the main amino acids found in human saliva. A psychophysical study indicates that the low concentration of salivary glutamate is enough to generate a synergistic taste-enhancing effect in the presence of IMP (Yamaguchi, 1991). It is possible that IMP and/or GMP in foods can also boost taste intensities of other salivary amino acids,

since human saliva contains more glycine, proline, and serine than glutamate (Pobozny et al., 2006).

### 28.3.6 Bitter Taste

Saliva can act as a depressor of bitter taste, as suggested in animal experiments, but has not been tested in human psychophysical experiments. In rats, the neural activity from the chorda tympani was almost negligibly small when the rat licked a bitter solution, quinine-HCl, with normal levels of saliva present on the tongue (Matsuo et al., 1994). In anesthetized rats, the quinine response was smaller when the tongue was adapted to collected saliva rather than to deionized water. This suppressive effect was mimicked by adaptation of the tongue with solutions containing the predominant electrolytes of rat saliva, but not with dialyzed rat saliva (Matsuo and Yamamoto, 1992). A similar result has been reported in recordings from the chorda tympani of hamsters, using artificial saliva containing various ions (Rehnberg et al., 1992). Hence, salivary electrolytes may suppress the bitter taste transduction at the receptor level; however there is no explanation of this effect because of the wide diversity of bitter compounds and little knowledge of the molecular mechanism of bitter stimulation.

As for the bitter taste from the foliate and circumvallate papillae, a protein secreted from von Ebner's gland was a candidate carrier of bitter taste substances (Schmale et al., 1990). This salivary protein belongs to the lipocalin superfamily including odorant-binding proteins. Since these proteins can bind a variety of hydrophobic molecules, it was initially postulated that the von Ebner protein might bind lipophilic compounds, most likely of bitter substances, and carry them to or concentrate them at, taste receptor sites; however, the protein did not bind any of the various lipophilic bitter stimuli (Schmale et al., 1993). Thus, the von Ebner protein may be involved in non-taste-related activities such as protection against harmful lipophilic dietary chemicals, facilitation of lingual lipase activity (Kock et al., 1994), or general protection of epithelia such as fluids from tears, the nasal mucosa and tracheal mucosa; an identical protein has been found in these fluids (Redl, 2000). To define the role of von Ebner protein, it may be necessary to elucidate the ligand-binding specificity or the three-dimensional structure.

### 28.3.7 Taste Produced by Amylase

Amylase is the major digestive enzyme secreted by the parotid and von Ebner's glands, which breaks down starch and glycogen into di- and mono-saccharides, that is, maltose and glucose. Recently, another source of lingual amylase has been found in taste buds of the circumvallate papillae by a histochemical study of rats (Merigo et al., 2009); that is, amylase immunoreactivity is observed in

the epithelium lining the top of the taste buds and in the taste pore and, moreover, in some taste bud cells. This finding suggests that the taste bud cells may secrete amylase and collaborate in carbohydrate digestion with the concerted action of salivary amylase, and sugars generated by digestion, especially in the taste pore, may stimulate taste receptors. This potential role of amylase probably contributes to the detection of the ‘taste’ of starch, which is commonly assumed to be tasteless. In animal experiments, it has been postulated that the starch taste is detected by two types of carbohydrate taste receptors: one for the sweet taste of sugars and another for the taste of polysaccharides (e.g., Sclafani and Mann, 1987). Unfortunately, the latter receptor has not been discovered.

In addition to taste, the digestion of starch by amylase may result in the modification of texture sensations, that is, increased melting and decreased thickness sensations of starch-based food. An *in vitro* experiment has demonstrated that human whole saliva markedly reduces the viscosity of custard desserts within a few seconds (de Wijk et al., 2004). Such action of salivary amylase will effectively progress while amylase is mixed properly into the food bolus by mastication.

### 28.3.8 Taste Produced by Lipase

Salivary lipase secreted only by von Ebner’s glands breaks down emulsified dietary fat, triacylglycerides, in the salivary layer to free fatty acids and monoacylglycerol. The free fatty acids liberated in the oral cavity likely act as signalling molecules for the detection of fat taste, since triacylglycerides are tasteless, but recent human psychophysical evidence has suggested that various free fatty acids have a taste whose quality is probably different from the five basic tastes (Chalé-Rush et al., 2007; Stewart et al., 2010). Some candidate receptors for free fatty acids have now been isolated from taste cells of foliate and circumvallate papillae in rodents, and one in humans (Mattes, 2011).

The activity of lipase in stimulated whole saliva is sufficient to break down fat and produce free fatty acids at concentrations over their taste detection thresholds in humans (Stewart et al., 2010). This is supported by an experiment in rats indicating that fat digestion occurs within 1–5 s in the circumvallate papillae, and the amount of the generated free fatty acids is enough to be detected in the mouth. Moreover, a lipase inhibitor diminished the preference for triacylglycerides but not for free fatty acids (Kawai and Fushiki, 2003).

### 28.4 ROLE OF SALIVA IN ASTRINGENCY

Tannins are naturally occurring secondary metabolites of some plants and are found in the human diet, in the greatest

amounts in (green or black) tea and red wine. Although adding an interesting astringent sensation when consumed in larger quantities, tannins are harmful since they bind the enzymes and proteins necessary for the normal uptake of nutrients (Manach et al., 2005). Salivary proteins, histatins, and proline-rich proteins (PRPs), which make up nearly 70% of all parotid salivary protein (Kauffman and Keller, 1979), bind very well to dietary polyphenols/tannins (Baxter et al., 1997; Bennick, 2002; Wroblewski et al., 2001). The high affinity of these proteins to tannins are thought to have a protective effect since animals that lack proline-rich proteins do not survive on high tannin diets (McArthur et al., 1995). Although dietary polyphenols can cause tooth staining (Carpenter et al., 2005; Proctor et al., 2005b), their role in causing astringency generates most interest. Astringency, at least at low levels, adds refreshment to a drink. Although tannins are known to interact with salivary proline-rich proteins and histatins, it is not understood how this leads to a dry puckering sensation of the entire mucosa. A common view is that astringency is due to the loss of lubrication of the salivary film. Recent studies have suggested that whilst there is a loss of interfacial rheology of saliva following interactions with polyphenols (Rossetti et al., 2008) it could not account for the astringency of all astringent compounds tested. The possible interaction of proline-rich proteins already bound to buccal cells, as part of the mucosal pellicle, was explored in a recent report by the author (Nayak and Carpenter, 2008). We speculated that if proline-rich proteins and histatins are involved in astringency, then washing the mouth out with water (to reduce the levels of these proteins) prior to the ingestion of a tannin solution should reduce the perception of astringency; in fact, astringency increased. This reinforces the view that saliva acts principally as a barrier to astringency. Analysis of the proteins precipitated by the tannin solution after several oral rinses revealed proline-rich proteins and mucins, presumably adhering to the mucosa. This would suggest that any food/chemical that disrupted this adherent layer of protein would cause an astringent feeling. Detergents, for example, sodium/lauryl sulphate, or metal ions such as, copper (Hong et al., 2009), or whey proteins (Vardhanabhuti et al., 2010) can all cause astringent sensations without obvious interactions with or precipitation of salivary proline-rich proteins; hence, the continued research for mechanisms underlying the physiology of astringency.

### 28.5 LONG-TERM RELATIONSHIP BETWEEN SALIVA AND ORAL SENSES

Besides the initial process of sensory stimulation, saliva has roles in the long-term protection of the oral mucosa

and maintenance of the health and integrity of the taste function. Taste cells are continuously replaced with new cells about every nine days (Zeng and Oakley, 1999). Saliva contains candidates for trophic factors of regeneration. One candidate is zinc and/or a zinc-binding protein, carbonic anhydrase (gustin), which has been postulated as a trophic factor that promotes the growth and development of taste buds (Henkin et al., 1999, 2010). This hypothesis is based on the treatment of patients with taste disorders by zinc supplementation; however, other clinical studies (Matson et al., 2003; Osaki et al., 1996) and reviews (Bradley and Beidler, 2003; Matsuo, 2000) cast doubts on zinc therapy and such hypotheses. No physiological basic study has been performed on the effects of salivary zinc and/or carbonic anhydrase on the renewal of taste buds. The other candidate is epidermal growth factor (EGF), which has been widely studied as one of the major accelerators of wound healing (e.g., Jahovic et al., 2004; Noguchi et al., 1991). As for taste buds in rats, supplemental EGF in drinking water can prevent the loss of taste buds in the fungiform papillae after removal of the submandibular and sublingual glands (Morris-Wiman et al., 2000). This suggests that salivary EGF may always act as a growth factor for maintaining the normal renewal of taste buds. Taste bud cells, like epithelial cells, arise from stem cells near the basal area of the local epithelium (Stone et al., 1995) and therefore, the role of EGF in taste buds involves the oral epithelium.

Sjögren's syndrome patients having chronic failure of salivary gland function display only decreased taste threshold sensitivity (Weiffenbach et al., 1995); however, animal models of severe hypo-salivation (removal of the major salivary gland) exhibited more measurable taste impairments, such as poor performance in taste discrimination tests, hyperkeratosis of the tongue epithelium, shrunken and disorganized taste buds (Cano and Rodriguez-Echandia, 1980; Nanda and Catalanotto, 1981), loss of taste buds (Morris-Wiman et al., 2000), and decreased responses of the taste nerve (Matsuo et al., 1997). Moreover, relating to the renewal of taste buds, taste sensitivity can be modified by one-week manipulation of the external milieu of the taste buds (Matsuo et al., 1997). In contrast with such a role of saliva in taste, long-term alteration of oral sensitivity can affect saliva and salivation; for example, increased salivary PRP by feeding a tannin-containing diet (Mehansho et al., 1992; Jasman et al., 1994), the effect of food texture (Kurahashi and Inomata, 1999) and starchy food (Perry et al., 2007) on amylase synthesis, and the effect of food texture on the size of the salivary gland (atrophy or hypertrophy) (Proctor, 1998); hence, saliva and oral sensitivity have the characteristic of affecting each other. We should be aware of this reciprocal relationship in studies on the taste acuity of older persons or individual differences in taste sensitivity.

## 28.6 CONCLUDING REMARKS

More than 99% of saliva is water, which acts as a solvent used to convey taste substances to the receptor. Only less than 1% of saliva is inorganic ions and organic molecules. Nevertheless, some inorganic salts can stimulate taste receptors and affect the taste threshold and supra-threshold intensity of taste. The organic constituents (proteins) themselves cannot stimulate taste receptors; however, some of them may affect the initial process of oral sensory transduction *via* the digestion of starches and fats, emulsification of fats/oils, lowering of surface tension, and chemical interaction with food, for example, tannins. Saliva also forms the milieu of taste receptors and can influence the sensitivity of renewed taste receptors. To maintain these roles of saliva, a sufficient amount of resting saliva is necessary. The flow rate of resting saliva positively correlates with that of stimulated saliva (Rantanen and Meurman, 1998), bite force (Yeh et al., 2000), and the sizes of parotid and submandibular salivary glands (Ono et al., 2006). These findings suggest that, for the secretion of sufficient resting saliva and maintenance of oral senses, it is necessary to maintain the ability to produce sufficient stimulated saliva, which requires sound salivary glands, neural circuits, and chewing capability.

# Chapter 29

---

## Anatomy of the Tongue and Taste Buds

MARTIN WITT and KLAUS REUTTER

### 29.1 INTRODUCTION

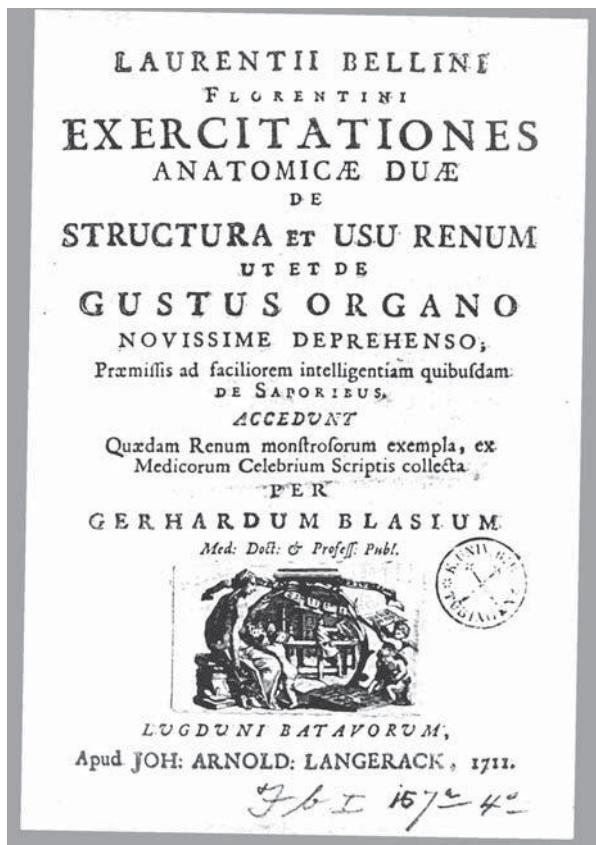

*“... Many papillae are evident, I might say, innumerable, and the appearance is so elegant that they catch the view and thoughts of the observer, and control him for a long time and not without enjoyment ... All this delights the curious mind, when observing with an engyscope; and if anyone asks to what they are similar, I am unsure whether I should compare this huge number of papillae first with grapes or fruits of the bay, or innumerable mushrooms emerging between fine, densely standing blades of grass ...”*

These are the first detailed and enthusiastic words on papillae and their “membranes” in human tongues by Lorenzo Bellini (1665) (Figure 29.1), who knew that Marcello Malpighi (1628–94) had reported on lingual papillae the year before. Malpighi discovered mucosal elevations associated with nerve fibers, naming these elevations “papillae,” as the morphological substrates for gustatory sensation (Figure 29.2).

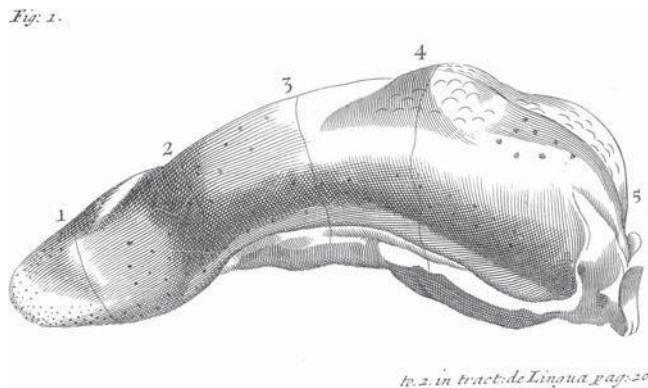

The peripheral taste apparatus includes the gustatory sensory organs or taste buds and their innervation, and the specific papillae within which taste buds are assembled. What one needs to know about taste buds in relation to how one perceives tastants depends on the approach to taste perception. One aim of this chapter is to provide a sufficient knowledge on peripheral gustatory anatomy as a basis for understanding other chapters of this book. Some structural details about the human peripheral taste system are well known, but it is also worthwhile to provide comparative anatomical information to fill in the gaps or understand and establish basic principles. The fundamental question of how tastants are perceived has been addressed for more than two millennia, and the majority of concepts, theories, and experimental “proofs” that have been proposed have since given

way to present-day concepts. This chapter incorporates this rich history which sculpted our contemporary views of gustatory anatomy and physiology.

Aristotle (384–322 BC), applying Platonic concepts, argued that taste sensation was carried from the tongue via the blood, to the liver or heart, which was the common seat of the soul and all sense perception [De sensu 438b 26; On youth and old age, 469a 5–13; cited after Siegel (1970)]. Galen’s (Claudius Galenus, 129–201 AD) anatomical analyses challenged this notion: his detailed studies on the innervation of the tongue describe correctly the different functions of the three principal nerves supplying the tongue (lingual, glossopharyngeal, and hypoglossal nerves), and demonstrate their origin at the base of the brain. Galen posited that the lingual nerve communicated gustatory sensations, a concept yet resonant in contemporary neurobiology. One strand of nerve fibers corresponding to cranial nerve IX (CN IX or glossopharyngeal nerve) of present terminology (rediscovered in humans by Panizza, 1834) was already known to Galen as the principal gustatory nerve of the tongue. CN IX also carries some motor fibers to the pharynx. Galen also noted excretory ducts of the lingual and sub-mandibular glands (in ox). The particular structure of the tongue surface was initially described by Casserius (1609) and, later by Malpighi (1686) and Bellini (1665) (reviewed by Jurisch, 1922). Further evidence for the significance of the papillary epithelium and its cells came from observations in taste organs of the frog (Fixsen, 1857, Waller, 1847, 1849). Taste buds were identified initially on the barbels and skin of fishes by Leydig (1851) and described as “*becherförmige Organe*” (goblet-shaped organs), whose function he associated with tactile sensitivity. Schulze (1863) subsequently suggested they were chemosensory structures. Similar organs in mammals were described as *Schmeckbecher* (taste goblets)

**Figure 29.1** The cover sheet of Lorenzo Bellini's book that summarizes examinations on the anatomy of the kidney and the taste organ. (Langerack, Leiden, 1711).

**Figure 29.2** Depiction of a bovine tongue by Marcello Malpighi (1686) showing “patches” where papillae were observed. Note the concentration of fungiform papillae (dots) on the tip of the tongue. The drawing of vallate and foliate papillae is still rather vague.

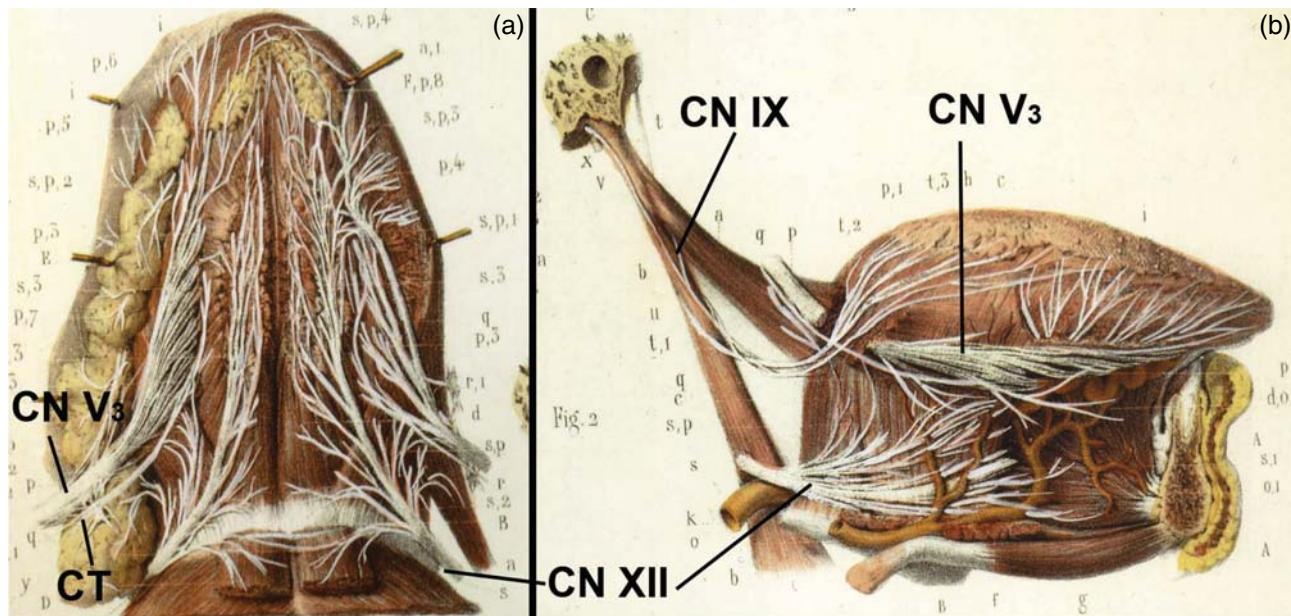

(Lovén, 1868) and *Geschmacksknospen* (taste buds) or *Geschmackszwiebeln* (“taste onions”) (Schwalbe, 1868). Herrick (1904) translated “Geschmacksknospen” as “taste buds.” Their location within lingual papillae, the latter already associated with the loci of taste perception, lent credence to their identity as taste sensor organs.

Nineteenth-century studies focused on cytological features, nerve supply (Figures 29.3 and 29.5), and the development of taste buds. While the nerve-dependent nature of taste sensation was known since Galen’s time, its significance for sensory organ physiology blossomed in the mid-1800s. With development of the neuron doctrine (see Koelliker, 1844), previously described “ganglion globules” (*Ganglienkugeln*: Ehrenberg, 1833) could now be acknowledged as part of a specialized cellular system (cell theory of Schleiden and Schwann) (Schwann, 1839). Two major prerequisites favored the expansion of scientific knowledge in the nineteenth century: (1) replacement of the often speculative natural philosophy by the experimentally based natural sciences, mainly represented by Francois Magendie (1783–1855) in France and Johannes Müller (1801–58) in Germany, and (2) technical advances which included improved microscopes (K. Zeiss, 1816–88, together with Ernst Abbé, 1840–1905, and E. Leitz, 1843–1920) as well as use of histological techniques, for example, introduction of chromic acid for histological examination of neural tissue (Hannover, 1840), allowing for the distinction between cells and fibers. Further, gold chloride staining facilitated discriminating finely ramifying nerve fibers (Gerlach, 1858). Helmholtz (1842) observed a direct continuity between nerve cells (globuli gangliosi) and their fibers in vertebrates. The demand for the neuron doctrine in vertebrates was established by Koelliker (1844). Introduction of the methylene blue staining method facilitated observations that *fine nerve* fibers in the frog taste disc widened with varicosities, penetrated the gustatory epithelium and approached the sensory cells “with extremely sharp small knobs, [which] ... connect taste cells not continuously, but *per contiguitatem*” (Ehrlich, 1886). This pioneering observation of secondary sensory cells in a taste organ that was clearly different from primary sensory cells, as had already been described in the olfactory epithelium, albeit without the understanding of the “contact” nature of taste bud cells and their innervating afferents, as later described ultrastructurally, was opposed by Retzius (1892). Using the Golgi silver impregnation method (Golgi, 1873), Retzius attributed a sensory function only to free nerve endings (Figure 29.5b). Later, Krause (1911) clearly demonstrated that the finest nerve fibers enter the taste bud and ascend to the taste pore, but do not merge with taste bud cells whose basal processes end near the basal cells.

## 29.2 LINGUAL PAPILLAE AND TASTE BUD DISTRIBUTION

### 29.2.1 Nongustatory Papillae

Approximately 60 years before taste buds were identified as gustatory organs, an illustration of the human tongue

**Figure 29.3** These illustrations of Bourgery and Jacob (1839) show the human tongue including nerve and blood supply, as well as the lingual muscle system. In spite of precise macroscopical observations on the innervation of glands and muscles, it still represents indirectly the (nowadays revised) morphological concept of gustation in the early nineteenth century, according to which the principal taste nerves are the lingual (*p* in (a) and (b); CN  $V_3$ ) and glossopharyngeal (*t* in (b); CN IX) nerves. The chorda tympani, although depicted near the submandibular ganglion (*q* in (a) and (b); CT), does not reach the lingual dorsum. Ebner's glands are not known to the authors. (a): *D*, submandibular gland with *q*, chorda tympani and submandibular ganglion and *p*, lingual nerve; *s*, hypoglossal nerve (CN XII); *E*, sublingual gland; *F*, Nuhn's gland. (b): *C* styloid process; *b*, stylopharyngeus muscle, the leading muscle for *t*, glossopharyngeal nerve (CN IX), which overlaps partly with the innervation area of the lingual nerve; *k*, lingual artery; *p*, lingual nerve, interrupted to show the glossopharyngeal nerve; *q*, part of the chorda tympani nerve; *s*, hypoglossal nerve (CN XII); *X*, trunk of the facial nerve. (See plate section for color version.)

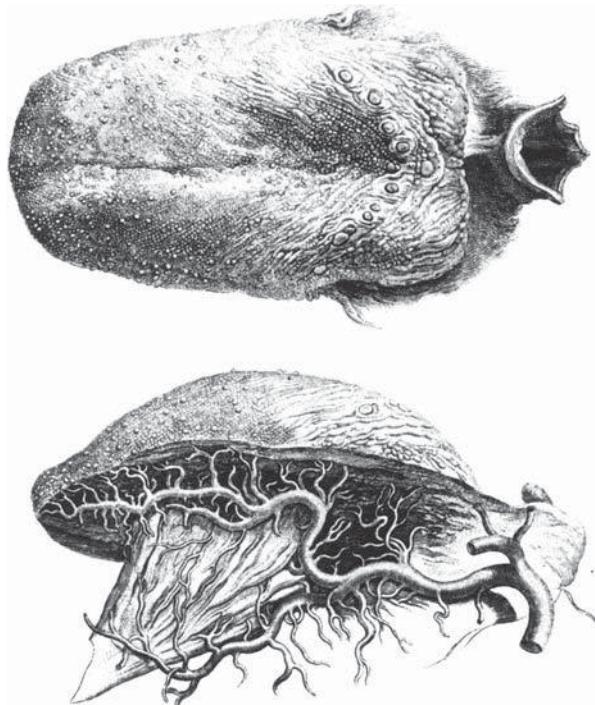

by Sömmering (1806) (Figure 29.4) accurately showed the regional distribution of lingual papillae. A line called the sulcus terminalis (an ontogenetic remnant, see below), which is located posterior to the vallate papillae, separates the body of the tongue from the lingual root. It may be seen that the sulcus terminalis extends laterally to the pharyngeal wall from the foramen caecum (also an ontogenetic remnant) near the midline (see Figures 29.4 and 29.11). The root of the tongue is covered by a papilla-free smooth epithelium, and beneath this epithelium lie mucous glands and a reticular connective tissue filled with lymphatic follicles which lead to the designation of “lingual tonsil.” Ducts of intralingual salivary glands (Ebner, 1873) empty into the troughs of vallate and foliate papillae (see below).

The dorsal surface of the tongue is covered with filiform and conical papillae from the sulcus terminalis to the tongue tip. Filiform papillae are the most prevalent type, while the number of conical papillae may vary. Both types of papillae are sparse along the lingual margin and abundant in the middle regions. Conical papillae have a cylindrical base, and taper to a sharp point at their apex. Filiform papillae (L. *filum* = thread) have a pyramidal shape, and a narrow tail of cornified cells extending from their apical

tips as a pennant. The fila are part of the fibrous mat on the tongue’s surface in the hypertrophic condition called “hairy tongue.”

## 29.2.2 Gustatory Papillae

Taste buds occur in distinct papillae of the tongue, the epithelium of the palate, oropharynx, larynx (epiglottis), and the upper esophagus. Taste buds of most vertebrates are bulb-shaped structures which are composed of about 50–120 bipolar cells (see Figures 29.9 and 29.10). With the exception of basal cells, the slender taste bud cells arise from an interrupted basal membrane and converge with their apical protrusions, the microvilli, into the mucus-filled taste pit. Together, these cells form the organ’s sensory epithelium. The nuclei of the cells are located in the lower third of the taste bud, which is approximately the region where most afferent nerve fiber terminals are distributed. Sensory cells possess transmembrane receptors and/or ion channels for specific taste stimuli at apical and lateral portions of the cell membrane. Taste buds are demarcated from

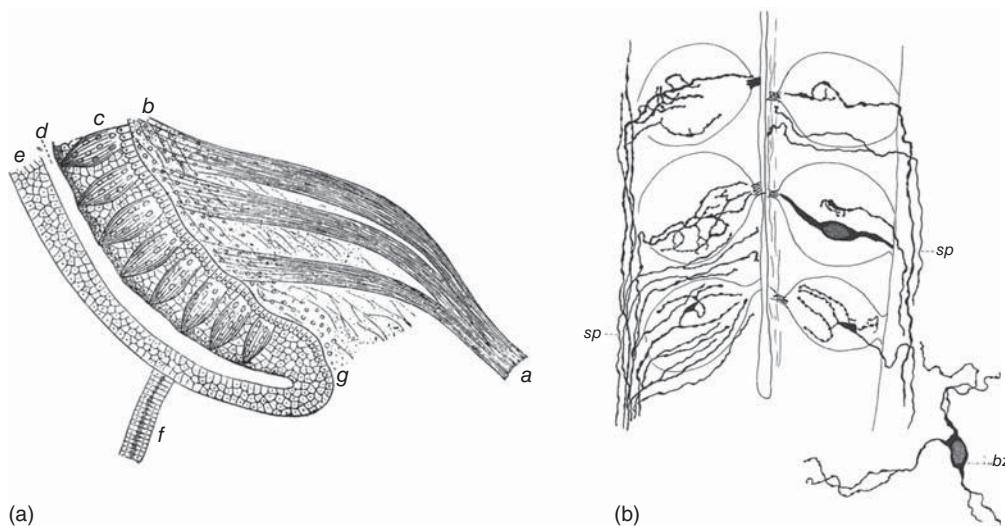

**Figure 29.4** The first precise depiction of a human tongue by Samuel Sömmering (1806). (Above) The anterior part (left side) of the tongue shows numerous fungiform papillae. Behind the V-like arrangement of vallate papillae (right side), the lingual tonsils and the entrance to larynx with the epiglottis are visible. (Below) Lateral view of the tongue shows the left lingual artery and its ramifications into gustatory papillae, which appear as red dots after injection of the artery with a red dye (observation of Sömmering).

surrounding nongustatory epithelial cells by specialized epithelial cells (marginal cells).

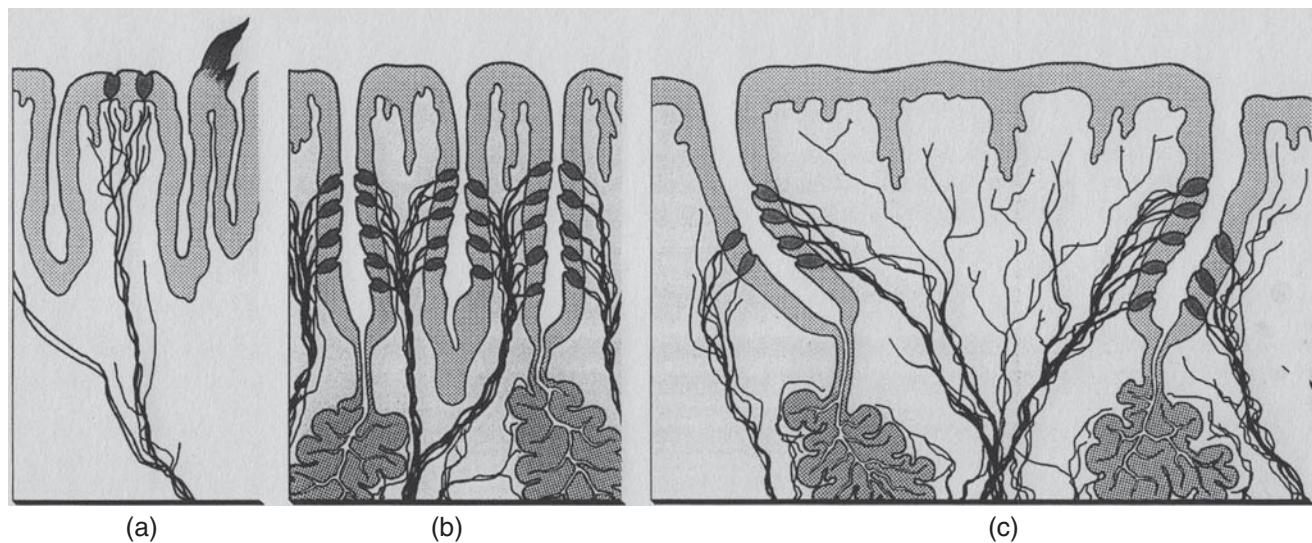

#### 29.2.2.1 Distribution of Lingual Taste Buds.

The pattern of taste bud distribution over the tongue surface is similar among humans and other mammals. Lingual taste buds are found exclusively within gustatory papillae, that is, those bearing taste buds. Similar types of gustatory papillae are located on homologous regions of adult mammalian tongues. The gustatory papillae include the vallate, foliate, and fungiform papillae. As the term suggests, typical fungiform papillae are mushroom-shaped, with a slender neck and an enlarged head (Figures 29.6–29.8). But the majority of fungiform papillae vary in form and the filiform papillae are intermingled among them. Shortly after the published discovery of taste buds in humans (Lovén, 1868; Schwalbe, 1868), the first systematic investigations on the distribution of human taste buds within the oral cavity were carried out by the medical student Hoffmann (1875). He emphasized that taste buds are more sparse within foliate papillae and the soft palate including the uvula. Hoffmann concluded that the development of taste perception is dependent on the number of taste buds on a particular location.

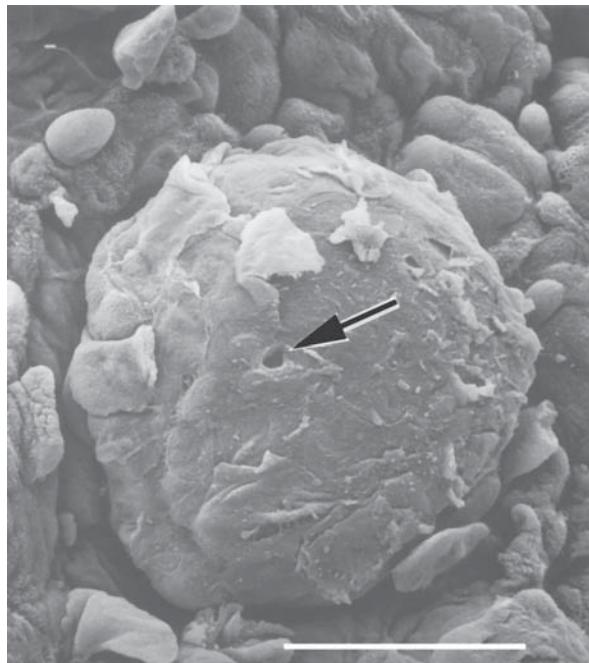

Of the approximately 4,600 total taste buds in all three lingual fields in humans, vallate buds comprise about 48% (2200), foliates about 28% (1280) and fungiforms 24% (1120). However, taste bud numbers vary greatly among individuals (Miller and Reedy, 1990a), with some adults possessing a total of only 500 taste buds

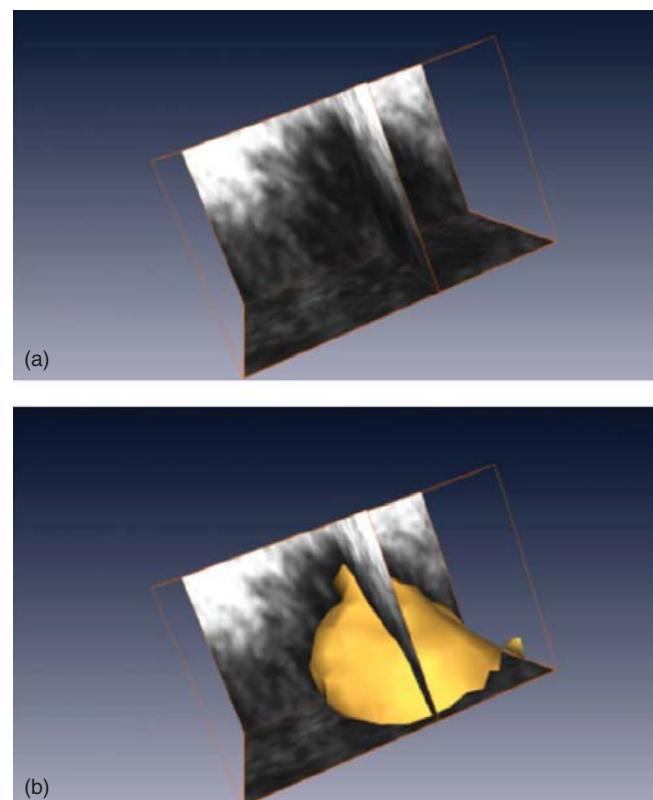

**Figure 29.5** (a) First description of a mammalian taste bud (vallate papilla of the swine) by Schwalbe (1868). Minor bundles and fibrils of nerves are lost in the “*interior of taste goblets*”. Note the incorrect arrangement of basal cells. According to Schwalbe, two cell types, pin cells (*Stiftchenzellen*), and rod cells (*Stabzellen*), might mediate different taste sensations. (b) Distinguished observation of intra- and intergemmal nerve terminals in the rabbit foliate papillae by Retzius (1892) using the Golgi silver impregnation method. Taste buds are directed to the trench of the papilla. Retzius also depicts a slender bipolar “sensory” intragemmal cell and a multipolar cell (bz) (right side). Direct contacts between nerve fibers and taste cells were not noticed. Retzius believed that exclusively nerve fibers rather than taste cells were responsible for gustatory sensations.

**Figure 29.6** (a)–(c). Schematic drawings of taste bud-bearing, mammalian lingual papillae (longitudinal sections). (a) Fungiform papilla (papilla fungiformis) with two apically situated taste buds and their innervation. On the right side, a (taste bud- free) filiform papilla. (b) Foliate papillae (pp. foliatae). (c) Vallate papilla (p. vallata). In B and C, the taste buds are directed to the lateral trenches of the papillae. Serous Ebner glands drain to the trenches. Dermal connective tissue is rich in nerve fibers; below the taste buds they form subgemmal plexus.

**Figure 29.7** Human fungiform papilla during development, week 15. Only one taste pore is visible (arrow). Scale bar = 50  $\mu\text{m}$ .

**Figure 29.8** *In vivo* confocal laser scanning microscopy of a human fungiform taste bud. (a) 3D-reconstruction of a single bud. (b) The taste bud contours were delineated that allows the calculation of the taste bud volume. From Srur et al. (2010). (See plate section for color version.)

(Linden, 1993). The taste bud density of *foliate* papillae seems to be constant in life (Hou-Jensen, 1933), but age-related differences have been reported for *vallate* papillae, which are more numerous and containing more taste buds in younger individuals (Jurisch, 1922). There are also more marginal fungiform papillae during the late fetal and newborn period, but they usually lack taste buds and are referred to as “sucking papillae” (Habermehl, 1952; Yamasaki and Takahashi, 1982).

**29.2.2.2 Vallate Papillae.** Vallate papillae, first comprehensively described by Haller (1766) and Sömmering (1806), lie directly anterior to the sulcus terminalis and extend in a V-shaped line across the root of the tongue (Figures 29.4 and 29.12). They are round and measure between 2 and 8 mm in diameter. The pores of taste buds open into the trenches around the bases of each vallate papilla (Figure 29.6). The papillae are innervated by an enormously large nerve fiber plexus originating from CN IX (see below) compared to foliate or fungiform papillae. The number of vallate papillae per human tongue varies between 4 and 18 ( $n = 2,264$  tongues), with an average of  $9.2 \pm 1.8$  papillae (Münch, 1896). Ninety-eight percent of all tongues have a central median papilla (Figure 29.4). The presence of three or four lateral papillae on each tongue half was observed most often (20%). Atrophic changes were observed in papillae of some men  $> 40$  years old and some women  $> 55$ –60 years old, though Jurisch (1922) reported that the number of vallate papillae did not appear to change systematically as a function of age. The average numbers of taste buds per papilla are summarized in Table 29.1.

**29.2.2.3 Foliate Papillae.** Foliate papillae in humans were first reported by Albinus (1754) and histologically described by Höngschmied (1873), but did not become the focus of scientific attention in humans until the

twentieth century. These papillae, located bilaterally along the posterolateral margins of the tongue surface, consist of parallel rows of ridges (folia) and valleys which lie adjacent to the lower molar teeth. Ducts located between the folia transmit secretions from mostly serous lingual glands within the root of the tongue.

Scanning electron microscopy of human foliate papillae and transmission electron microscopy of their resident taste buds was reported by Svejda and Janota (1974) and Azzali et al. (1996). The number of taste buds in human foliate papillae was reported by Hou-Jensen (1933) and Mochizuki (1939) (see Table 29.1). Confusion in finding taste buds within the folds of human foliate papillae reflects papilla structure. As many as 20 parallel ridges and furrows are found on the posterolateral margin of the human tongue. The rostralmost furrows (lateral rugae) contain no glandular ducts or taste buds, and their epithelia are more cornified than that between foliate papillae (Hou-Jensen, 1933). Fungiform papillae can be found on the tops of these lateral rugae. Although human foliate papillae were thought to be “rudiments” (in comparison to the well developed rabbit foliate papillae), Mochizuki (1939) calculated an average of 1300 taste buds per tongue, which exceeds the number of fungiform taste buds [800 buds: Braus, 1940; <1000 buds: Miller and Bartoshuk, 1991]. Indeed, contiguous taste buds within the same cleft may form a more functional unit, since they share access to a common taste stimulus pool. Foliate papillae are innervated by branches of the glossopharyngeal nerve (CN IX), but the more anterior portion also receives nerve fibers from the chorda tympani (Oakley, 1970; Pritchard, 1991).

**29.2.2.4 Fungiform Papillae.** Due to their morphological heterogeneity, fungiform papillae have been variously described as papillae clavatae, capitatae, lenticulares, obtusae, majores, and mediae (Haller, 1766; Sömmering, 1806). These papillae can be easily identified

**Table 29.1** Distribution of taste bud numbers within the oral cavity of adult humans.

\*per papilla.

as pink elevations about 0.5 mm in diameter on the anterior portion of the living human tongue. Notwithstanding its convenient location, the fungiform taste bud population has been difficult to quantify since fungiform papillae vary in appearance and are distributed over a large area of tongue surface. The anterior portion of the tongue extends from the line of vallate papillae to the tongue tip (Figures 29.4 and 29.12). This region contains about 30 cm<sup>2</sup> of surface area, depending on the size of the person, and the fungiform papillae are spread unevenly over it. The number of taste buds differs among fungiform papillae, and there are large variations among human subjects in fungiform taste bud distribution. Most papillae on the 5 mm margin of the tongue tip are shorter than those on more posterior regions. Following the surface in a posterior direction from the midline of the tip toward the back of the tongue, fungiform papillae become progressively larger in size, being largest in the more posterior lingual regions.

Small, rounded papillae are present on the margin. Some of them contain taste buds, while others are comparable in size to filiform papillae but lack fila. Some papillae on the margin of the tip are elongated like conical papillae, and these, generally, lack taste buds. Fungiform papillae vary in size and shape: some are short and cuboidal, and others are tall with expanded heads like mushrooms. Among papillae on the margin of shorter height and smaller diameter (<0.5 mm), the distinction between filiform and fungiform papillae becomes obscure. Fungiform papillae occasionally have projections on their apices like small fila on filiform papillae.

Taste buds have been quantified in terms of tongue surface areas, referred to as “taste bud density,” or number of taste buds per cm<sup>2</sup> of tongue surface. There are about 145 gustatory (fungiform) papillae per lateral half of the tongue, with about 30 papillae per cm<sup>2</sup> on the tip, but only about 3 papillae per cm<sup>2</sup> on the posterolateral area. There are about 30 large fungiform papillae in the posteromedial region, for an estimated total of about 320 fungiform papillae per tongue (Miller and Reedy, 1990b; Shahbake et al., 2005). On 320 fungiform (gustatory) papillae, an average of about 3.5 taste buds per papilla has been estimated, for a total of 1120 fungiform taste buds (Miller and Reedy, 1990a, 1990b) (Table 29.1).

Most investigators who study human fungiform papillae report the existence of papillae without taste buds, which rarely occurs in other mammals (Mistretta and Baum, 1984). Studies in humans show, depending on the methods used, that fungiform papillae lacking taste pores comprise 1–67% of the fungiform population per subject (Arvidson and Friberg, 1980; Cheng and Robinson, 1991; Miller and Reedy, 1990a; Segovia et al., 2002). This wide range may reflect how investigators decide which papillae are “fungiform.” Children possess a higher density of fungiform papillae, which correlates well with

increased sensitivity for sucrose (Segovia et al., 2002). Modern non-invasive imaging techniques, for example, confocal laser microscopy, allow the *in vivo* visualization of fungiform taste buds and their dynamics over a certain period of time, even buds that have not yet presented a taste pore (approx. 10%; Just et al., 2005; Srur et al., 2010) (Figure 29.8).

### 29.3 EXTRALINGUAL TASTE BUDS

There are “extralingual” taste buds in regions of the oral, pharyngeal, and laryngeal cavities. Interestingly, Magendie (1820) and Carus (1849) erroneously associated the teeth with taste perception. Verson (1868) described the first “goblet-like organs” within the dorsal epithelium of the epiglottis, and Davis (1877) and Wilson (1905) observed taste buds in and the elicitation of taste perception from the human larynx. Lalonde and Eglitis (1961) counted more than 2,500 taste buds on the epiglottis, soft palate, laryngeal pharynx, and oral pharynx of one human neonate. Taste buds are evident in the epiglottis of one neonatal specimen (Rabl, 1895), and esophagus in human fetuses (Ponzo, 1907) and adults (Burkl, 1954; Schinkele, 1942). Taste buds are also found near the openings of sublingual salivary gland ducts in some other primates (Hofer et al., 1979), and near the ducts of the molar glands in rodents (Iida et al., 1983). In chickens and quail, taste buds in nonlingual parts of the oral cavity are almost always associated with salivary gland ducts (Ganchrow and Ganchrow, 1987). Miller and Smith (1984) estimate that about 25% of the hamster’s total taste buds are extralingual, and Mistretta and Baum (1984) accounted for a similar proportion of extralingual taste buds in the rat. It is not known whether extralingual taste buds are functionally different from those on the tongue. Taste buds of the epiglottis and/or uvula could be involved in initiation of upper airway reflexes (Bradley et al., 1983) and in the pharyngolaryngeal water response, possibly mediated by receptors signaling the absence of chloride ions (reviewed by Lindemann, 1996). Similarly, taste buds of the larynx seem not to play a role in gustation but detect chemicals that are not saline-like in composition, for example, CO<sub>2</sub> (Bradley, 2000; Nishijima and Atoji, 2004). Apparently, structure and immunohistochemical properties of taste buds are remarkably conserved despite their different locations and innervation patterns (Kinnamon, 2011).

### 29.4 SALIVARY GLANDS OF THE TONGUE

*Lingua sicca non gustat* (A dry tongue does not taste). This declaration of Haller (1766) refers to the dependence of

taste ability on solutions, within which tastants are dissolved and transported to the taste bud. Extralingual saliva is secreted by small, mostly mucous glands embedded in the epithelium of the cheek and palate. More saliva is produced by the serous parotid gland and the muco-serous sublingual and submandibular glands (Figure 29.3), whose secretory ducts open at the tongue frenulum just underneath its tip. Intralingual saliva originates from the mucoseroous anterior lingual glands [glands of Blandin and Nuhn, (Tandler et al., 1994), Figure 29.3], and deep posterior serous salivary glands (Ebner) located in the submucous connective tissue below the foliate and vallate papillae of the tongue (Ebner, 1873; Riva et al., 1999). Their excretory ducts lead to the deepest sites of the papillary furrows (Figure 29.6). The gland lobules lie deeply in large patches of connective tissue which, in turn, are separated from each other by muscle fiber bundles. In addition, adjacent to Ebner glands in vallate papillae lie mucous (Weber's) glands (Nagato et al., 1997), which in humans open into the crypts of the lingual tonsils (Zimmermann, 1927). Neither Weber's nor Blandin-Nuhn glands lie in close proximity to taste buds and their particular significance for taste perception is unknown because of the difficulties in collecting saliva from these glands (Tandler et al., 1994).

There is biochemical and histochemical evidence that the saliva of Ebner's glands, as well as that of other non-lingual salivary glands, has more functions than that of a serious "washing solution." Binding proteins such as Ebnerin (Li and Snyder, 1995) are supposed to modulate sensations. Schmale et al. (1990) isolated a protein from rat Ebner's glands that is structurally similar to odorant binding proteins in Bowman's glands of the olfactory mucosa. The gland is under autonomic control (Fukami and Bradley, 2005; Gurkan and Bradley, 1987). Interestingly, a recent report seems to point at a dependency of the hypoglossal nerve on sympathetic innervation of posterior lingual glands in hamsters (Cheng et al., 2009). For reports on specific ligand-receptor interaction with taste qualities, see Azen et al. (1990), Schmale et al. (1993), Spielman, (1990), Toto et al. (1993), and Chapter 31 of this volume.

## 29.5 BLOOD SUPPLY TO GUSTATORY PAPILLAE

The mammalian tongue receives its blood supply from the lingual artery, which is usually a branch of the external carotid artery (Figures 29.3 and 29.4). Study of the tongue's vascular system historically parallels that of the lingual papillae. For example, Albinus (1754), Sömmering (1806) (Figure 29.4) and Arnold (1839) performed intravascular injections in order to visualize the papillary surface. More recently, distribution of the blood supply

to different regions of the tongue and different types of lingual papillae has been described by Hellekant (1976). Each type of gustatory papillae is supplied by a characteristic capillary configuration (rat: Ohshima et al., 1990; cat, rabbit: Ojima et al., 1997a-c) and fine capillary networks are found adjacent to taste buds. The capillary loops of larger papillae in rats and dogs often show a constriction, maybe sphincter-like structures, but rarely arteriovenous anastomoses (Hu et al., 1996; Selliseth and Selvig, 1993). Taste stimuli injected systemically elicit responses in gustatory nerves as the bolus passes through the tongue (Bradley, 1973).

## 29.6 SOLITARY CHEMOSENSORY CELLS

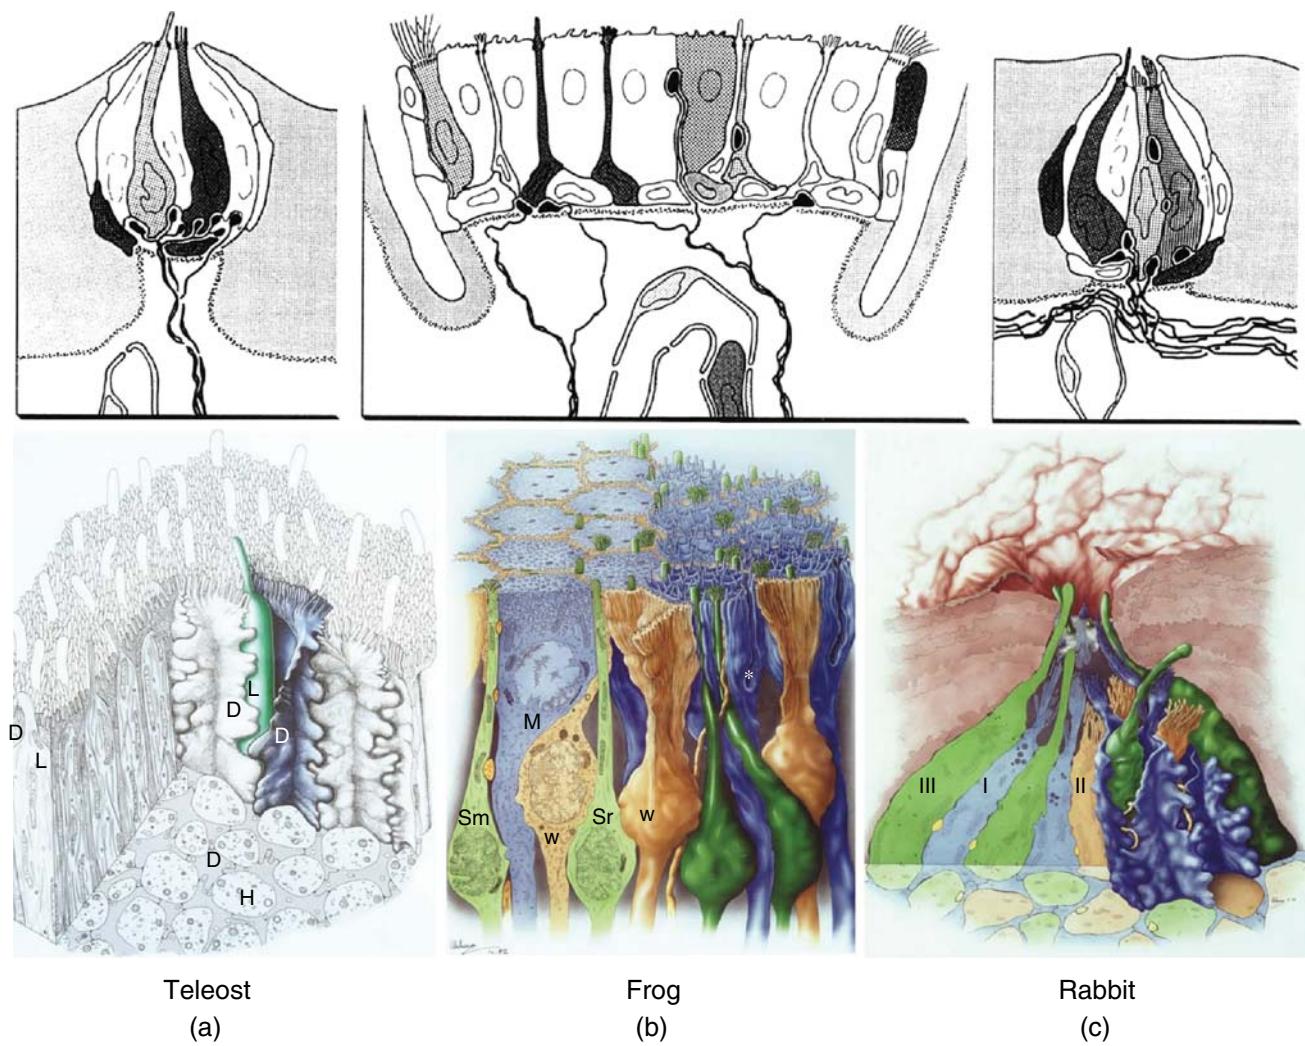

In addition to taste buds and free nerve endings, the solitary chemosensory cells (SCC) comprise another chemosensory system in vertebrates. They are not assembled in clusters, but are dispersed across the surface of the animal. SCC are related to taste bud cells in the sense that the former are secondary sensory cells with a slender, bipolar phenotype (Finger, 1997). "Classical" SCC have been studied first in teleosts (Whitear, 1992). The evolutionary benefits of these cells are still in question: In sea robins (*Triglo*), they are, beside taste buds, involved in finding food; in rocklings (*Gaidropsarus*) they are assumed to be important for predator avoidance (Kotschal, 1996). Since the arginine-like receptor in catfish taste buds also occurs in SCC, Finger (1997) suggests that taste buds might include SCC within them. During development of fish, SCC seem to precede the development of taste buds. In mammals, however, SCC-like cells have been observed only transiently, during development. In newborn rats, single gustducin-immunopositive cells are seen in locations where later-developing vallate papillae will appear (Sbarbati et al., 1999). Individual slender cells, immunopositive for cytokeratin 20 (Witt and Kasper, 1999), an intermediate filament protein that is exclusively present in taste bud and epidermal Merkel cells (Moll, 1993; Zhang and Oakley, 1996; Zhang et al., 1995), are seen occasionally during early ontogenesis of the human tongue. Gustatory epithelia *sensu strictu* of adult mammals have not yet been reported to possess SCC. However, alpha-gustducin-immunoreactive SCC occur in the nasal mucosa of mice and have been interpreted as sentinels in the anterior nasal air passages (Finger et al., 2003). Taste receptors (Tas1R, Tas2R) in SCC along with their synaptic connectivity to CGRP-positive polymodal pain fibers of the trigeminal nerve indicate a role in detection of irritants and foreign substances by triggering trigeminally-mediated reflexes (Tizzano et al., 2011).

## 29.7 CELL TYPES OF VERTEBRATE TASTE BUDS

Peripheral taste organs differ in number, size, and shape in different vertebrate taxa, according to their importance for the particular species. For the sake of brevity, the following overview is restricted to some functionally well-characterized vertebrate species. Details are available in reviews by Reutter and Witt (1993) or Chaudhari and Roper (2010). Figure 29.9 shows a scheme representing the organization of cells in fish, frog, and mammalian taste buds.

### 29.7.1 Taste Buds of Lower Vertebrates – Cell Types

**29.7.1.1 Fish.** In fish, and especially in some teleosts that are well-adapted to the dark, the taste organ is significantly more important for food intake than in amphibians and mammals. Thus, these fish, like the *Siluridae*, possess many more taste buds than representatives of the latter classes (Atema, 1971; Finger et al., 1996; Miller and Bartoshuk, 1991). The fish taste bud is generally pear-shaped and similar to that of mammals (Figure 29.9). Electron microscopic studies of teleost taste buds have

**Figure 29.9** (a)–(c) Longitudinal sections of taste organs from representatives of three different vertebrate classes. (a) Fish (bullhead, Teleostei), (b) Amphibian (frog, Anura), (c) Mammal (rabbit). In the schematic drawing, each sensory epithelial cell type is represented once with a distinct grey-step. The organs lie in squamous epithelium of different height, on top of dermal papillae which are also of different height. Each dermal papilla contains nerve fibers and a capillary vessel. (Below) 3D reconstructions of the respective apical taste bud portions. In all species, glia-like cells (blue in teleost and rabbit; sepia in frog “wing” cells) enwrap sensory cells. Sensory cells (green; sepia in rabbit as type II receptor cell). Nerve fibers entangle all cells, but synapses are seen only with type III cells in rabbit and microvillar (Sm) and rod-like receptor cells (Sr) in frog. (See plate section for color version.)

attempted, somewhat incompletely, to relate the ultrastructure and functions of taste bud cell types (for reviews see Jakubowski and Whitear, 1986; Reutter, 1986; Reutter and Witt, 1993). This is also apparent in the nonuniform usage of nomenclatures. Most authors refer to elongated “light” and “dark” taste bud cells, as well as “intermediate” and “degenerative” cells (Connes et al., 1988; Desgranges, 1965; Reutter, 1971, 1978; Welsch and Storch, 1969; Whitear, 1970). Generally, light cells are supposed to be “sensory” (receptor) cells, while the dark cells are regarded as “supporting” or “sustentacular” cells (e.g., Desgranges, 1965; Hirata, 1966; Whitear, 1970). However, Reutter (1992) considers the dark cells also as sensory because they exhibit synaptic contacts with nerve profiles or with basal cells. These observations, however, are not supported by the work of Grover Johnson and Farbman (1976) and Jakubowski and Whitear (1986). According to these authors the differentiation “light” and “dark” in combination with functional terms such as “supporting cells” and “sensory (receptor) cells” are misleading and should be avoided. According to Hirata (1966), Merkel (1880) and Reutter (1973) the taste bud may also have mechanoreceptive functions, particularly in view of the morphology of basal cells (Reutter, 1971, 1986) or serotonergic Merkel-like cells (Zachar and Jonz, 2011). While the existence of synaptic contacts of light and dark taste bud cells has not yet been finally proven, the different lengths of their microvilli perhaps suggest functional differences: The light taste bud cells have a single long microvillus reaching far into the mucous layer of the taste bud surface, the receptor area. By penetrating this layer, longer microvilli may be exposed to quite different “perireceptor events” (Getchell et al., 1984) than the small microvilli of dark taste bud cells that do not penetrate the mucous layer (Reutter, 1980; Witt and Reutter, 1990).

In larvae of lampreys, representatives of fish-like jawless vertebrates (Petromyzontidae), taste bud cells were characterized by Retzius (1893) using the Golgi silver impregnation technique. Recently, Barreiro-Iglesias et al. (2010) reported three different cell types including serotonergic bi-ciliated cells, basal cells, and sustentacular cells.

Ultrastructural (Reutter and Witt, 1993) and neurochemical (Ferrando et al., 2012) investigations in non-teleostean fish reveal clearly that taste buds differ within the main vertebrate taxa, which is partly represented in the differential expression of G protein-coupled receptors (Oka and Korschning, 2011). Further, in different systematic groups of fish the taste buds do not follow only one structural design. Thus, taxon-specific taste buds or cell types do not exist. Similar differences among mammalian taste buds point to a similar inevitable conclusion regarding particular phenotypes: There are only species-specific taste bud types, and a general “model” seems

difficult to find among vertebrates. This underlines the thesis that morphological phenotypes and the structural organization of taste bud cells do not necessarily reveal a general bauplan, but rather, reflect specific environmental conditions and/or feeding behaviors (Reutter and Witt, 1999).

The influence of environmental differences has been studied in two closely related teleosts, one of which is sighted (*Astyanax mexicanus*) and the other of which is a blind cave fish (*Astyanax jordani*). Whereas taste bud morphology is rather similar, the cave fish compensates for blindness by significantly more gustatory axon profiles (Boudriot and Reutter, 2001) and an expanded expression of Prox 1 gene in developing taste buds (Jeffery et al., 2000; Varatharasan et al., 2009).

**29.7.1.2 Amphibians.** The taste organs of post-metamorphic Salientia (=Anura), unlike piscine and mammalian taste bud bulb-like formations, are relatively large disk-like epithelial differentiations of the dorsal lingual and palatal mucosa (Figure 29.9). Waller (1847, 1849) and Engelmann (1872) called these structures “Geschmacksscheibe” or “taste disc.” In contrast to Salientia, the taste buds of the urodeles [= Caudata, e.g., mudpuppy (*Necturus*), newt (*Triturus*) or Axolotl (*Ambystoma*)] have a bulb-like shape (Cummings et al., 1987; Delay and Roper, 1988; Fährmann, 1967; Farbman and Yonkers, 1971; Toyoshima et al., 1987; Toyoshima and Shimamura, 1987). The cellular elements of the taste disc, or “Endscheibe” (Merkel, 1880), of the frog were subject to numerous investigations and received various designations: After Waller (1847, 1849) had first distinguished between *papillae conicae* (=*P. filiformes*) and *papillae fungiformes*, Fixsen (1857) described two different cell types, the so-called “*cellulae cylindricae*” and “*cellulae fusiformes*,” the processes of which pass through the whole sensory epithelium to reach the connective tissue core of the papilla. Engelmann (1872) and Merkel (1880) further developed the terminology: Merkel distinguished between “*cylindrical cells*” (Cylinderzellen) situated on the epithelial surface and surrounding “*wing cells*” (Flügelzellen), the nuclei of which lie deeper in the epithelium. After Graziadei and DeHan (1971) had described only two cell types (“associate cells” and “sensory cells”) in electron microscopy, the close relationship between “rod cells” (Stäbchenzellen) and cylindrical cells (Merkel, 1880) was recently re-introduced by von Düring and Andres (1976). In addition, the latter authors first described basal cells and Merkel cells of the frog taste disc, which are the only cells that do not contact the epithelial surface. The taste disc in adult frogs contains up to eight cell types (Reutter and Witt, 1993): mucus cells, wing cells, two types of sensory cells (cylindrical and rod-like type), two types of basal cells [stem and

Merkel cell-like basal cells (Zancanaro et al., 1995)], and marginal cells and ciliated cells (Toyoshima et al., 1999) (Figure 29.9). The cell types and the history of the nomenclature are described in detail by Jaeger and Hillman (1976), Reutter and Witt (1993), Witt (1993), Osculati and Sbarbati (1995), and Li and Lindemann (2003).

Tadpoles possess so-called premetamorphic papillae which bear bud-like taste organs at their tops. During metamorphosis, these structures wholly disappear and are replaced by fungiform papillae with large taste disks (Nomura et al., 1979; Żuwała, 1997; Żuwała and Jakubowski, 1991). Tadpole taste discs consist of sensory and supporting cells, and basal cells are lacking.

Taste buds of the mudpuppy (*Necturus*, Urodela) are similar to those of fishes. They are composed of dark and light cells and possess serotonergic Merkel cell-like basal cells which are synaptically connected with either nerve fibers or dark and light cells (Delay et al., 1994, 1993; Delay and Roper, 1988).

**29.7.1.3 Reptiles and Birds.** Lingual taste buds in reptiles have been described in turtles (Iwasaki et al., 1996; Korte, 1979), tortoises (Pevzner and Tikhonova, 1980), and some lizards (Uchida, 1980). Lizards (Gekkonidae or Anguidae), as well as snakes, have virtually no taste buds on the tongue, but rather on the buccal floor and oral epithelia of the mandible and maxilla (Toubeau et al., 1994). In shape, reptilian taste buds resemble those of mammals. There are up to five different types of taste bud cells, classified into light and dark cells and as types 1,2,3,A,B, or as types I, II, II, and basal cells (Reutter and Witt, 1993).

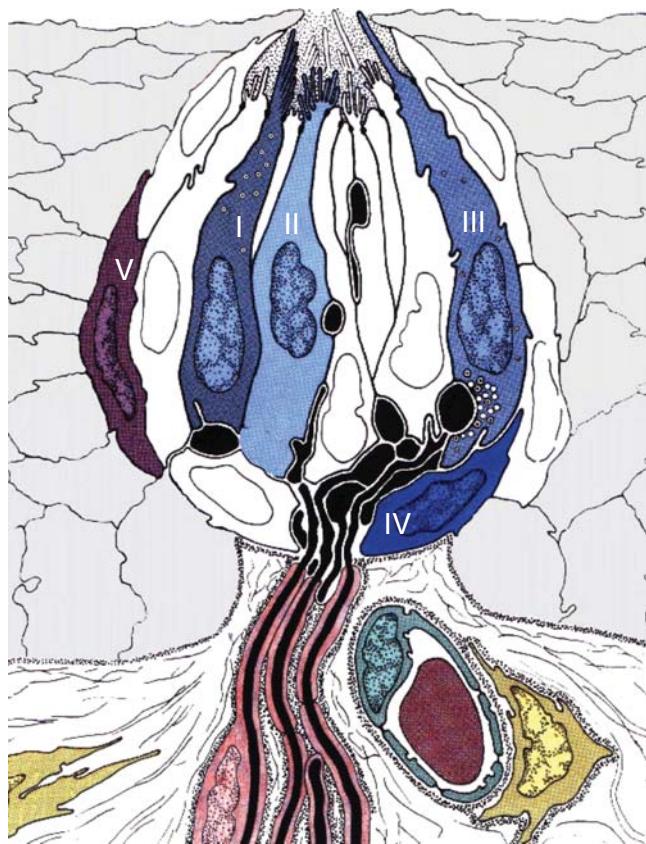

Reptiles and birds belong to the same superclass, and one might expect a similar organization of avian taste buds. However, the few examples of bird taste buds show great variability among species. Buds in grain-eating birds appear in the posterior part of the tongue, near the pharynx, and in the distal palatal mucosa (Ganchrow et al., 1991; Ganchrow and Ganchrow, 1987; Saito, 1966; Sprissler, 1994). Unlike mammals, avian taste buds do not reside within lingual bud-bearing papillae. In addition, taste buds contain tubular-like channels circumscribed by elongated cells grouped in a rosette configuration, with the channel lumen continuous apically with the taste pore (Berkhoudt, 1985; Ganchrow et al., 1993). Taste buds in chicken are richly innervated (Ganchrow et al., 1986), contain gustducin in a subset of taste cells (Kudo et al., 2010), and synapses are seen between all cell types (light cells and dark cells) and nerve fibers (Reutter and Witt, 1993; Sprissler, 1994). Stornelli et al. (2000) observed four cell types in duck taste buds: light cells, dark cells, intermediate cells, and basal cells.

## 29.7.2 Mammalian Taste Buds – Cell Types

Early histological investigators of mammalian taste buds described two types of elongated, fusiform cells in taste buds of human vallate papillae (Schwalbe, 1868): “supporting” and “taste cells,” the latter divided into Stiftchenzellen (*pin cells*) and Stabzellen (*rod cells*) with differences in contrast and brightness (Figure 29.5).

Classification into “light” and “dark” taste bud cells was also used in early electron microscopic analyses (Engström and Rytzner, 1956). Farbman (1965) considered dark, fusiform taste bud cells of human fungiform papillae as sensory cells (type I), whereas other investigators such as Paran et al. (1975) described a type II-cell that contains numerous vacuoles and mitochondria, especially in apical areas. This latter cell is not believed to be sensory. Cottler Fox et al. (1987) speculated that the different electron densities are due to irreproducible fixation artifacts. In general, ultrastructural and immunohistochemical criteria are considered more important for the classification of cells than the evaluation of the electron density of the cytoplasm. Moreover, present understanding in mammalian taste bud cytology leads to using a rather heterogeneous nomenclature, based on morphological and functional differences across species.

The basis for the current nomenclature was established by the Murrays and colleagues (Murray, 1986; Murray and Murray, 1967, 1971; Murray et al., 1969) in taste bud cells of the rabbit foliate papillae. However, these cell types differ in some respects from rodent taste buds (Kinnamon et al., 1985, 1993, 1994; Pumplin and Getschman, 2000; Pumplin et al., 1997, 1999). Thus, Royer and Kinnamon (1988) observed considerable deviations in the cytoarchitecture of murine foliate taste buds compared to that of other mammals. For example, they did not find type III cells, and all bud cells had synaptic connections with nerve fibers. Most current information on chemoreception of taste stimuli and information transfer to primary afferent axons have been established in mice (Dando and Roper, 2009; Huang et al., 2009; Roper, 2006), but there are significant species differences (Ma et al., 2007), and the precise organization of the taste bud in humans remains to be determined (Azzali, 1996, 1997; Paran et al., 1975; Witt and Reutter, 1996). An example for a more generalized taste bud is depicted in Figure 29.10. Work of the last two decades has revealed that taste stimuli are received by type II receptor cells (Tomchik et al., 2007), while type III (presynaptic) taste cells are the only ones that contain synaptic proteins and form synapses with nerve fibers (Kinnamon et al., 1988). The information transfer from type II (receptor) cells to type III (presynaptic) cells is mediated through ATP and pannexin hemichannels (reviewed by Chaudhari and Roper, 2010) or directly

**Figure 29.10** Mammalian taste bud in longitudinal section, idealized schematic drawing according to electron microscopical findings. Each cell type is depicted once. Following Murray's nomenclature, cells of type I, II and III are elongated and form the buds sensory epithelium proper. Apically, these cells end with different types of microvilli within the taste pit and may reach the taste pore. Type I cells are glia-like, type II cells comprise receptor cells for bitter, sweet, and umami stimuli. Synapses are only found at the bases of type III (presynaptic) cells. Type IV cells are basal cells, type V marginal cells. Nerve fibers within the short dermal papilla are slightly myelinated, and within the taste bud they form an unmyelinated plexus. Note the basal lamina between dermis (which contains a capillary) and the epithelium.

from type II cells to nerve fibers, as gustatory afferents also contain purinergic receptors P2X2 and P2X3 for the interaction with ATP (Finger et al., 2005). A survey representing the most important substrates associated with taste cell types in vertebrates is shown in Table 29.2.

**29.7.2.1 Type I Cells (Glia-Like Cells).** These cells are the most frequent. They are spindle-shaped and have a basal process that envelops the axons in a Schwann cell-like manner. Type I cells protrude with brush-like, long microvilli (1–2 µm) into the taste pit. These cells ensheathe type II and type III cells with cellular protrusions and may insulate them (Figures 29.9 and 29.10). Apically, they contain large granules, 100–400 nm in diameter (Murray,

1986). The nuclei of type I cells are irregularly shaped. According to Murray and Murray (1971) and Murray (1986) these cells have a secretory (supporting cells) and possibly phagocytotic function, and probably produce the amorphous material of the taste pit (e.g., (Farbman, 1965; Menco, 1989; Ohmura et al., 1989; Witt, 1996). Type I cells are involved in neurotransmitter clearance and ion redistribution, similar to the function of glia cells in the central nervous system. They contain GLAST, a glutamate transporter (Lawton et al., 2000), as well as enzymes degrading extracellular ATP (Bartel et al., 2006). Some type I cells possess the K<sup>+</sup> channel ROMK that may eliminate accumulated extracellular potassium ions to retain the excitability of type II and type III cells (Dvoryanchikov et al., 2009).

**29.7.2.2 Type II Cells (Receptor Cells).** Most of these cells are located in the periphery of the taste bud. They are fusiform, but do not possess enveloping processes, or granules. Their cytoplasm is moderately electron-dense, and nuclei are round to oval. Synapses are not observed (Farbman et al., 1985, 1987). Toyoshima and Tandler (1987) describe a modified endoplasmic reticulum with specialized sub-surface cisterns adjacent nerve profiles. In mice, vallate and foliate “light” (type II-) and “dark” (type I- and type II-) taste bud cells exhibit synaptic contacts with nerve fibers, thus suggesting a gustatory function. However, type I- and type II- cells do not form synapses with the same nerve fibers (Kinnamon et al., 1985, 1988; Royer and Kinnamon, 1988). These cells are equipped with G-protein coupled receptors and tuned to sweet, bitter, and umami, but not to sour and salty taste (Matsunami et al., 2000; Tomchik et al., 2007).

**29.7.2.3 Type III Cells (Presynaptic Cells).** Taste buds contain only 5–7% of type III cells. They have unbranched basal and apical processes. Their apical portion protrudes with a single large microvillus into the taste pit and may reach the taste pore. Type III cells are the only cells that have synaptic contacts with intragemmal nerve fibers. Near the cell nucleus there are numerous dense-cored vesicles (80–140 nm in diameter) which are involved in neurotransmitter synthesis (GABA, serotonin, norepinephrine) (Fujimoto et al., 1987; Hokfelt et al., 1980; Huang et al., 2005; Nada and Hirata, 1977). Type III cells contain several synaptic proteins and are therefore termed “presynaptic cells” (DeFazio et al., 2006). Their apical process apparently possesses channels for sour taste reception (Huang et al., 2008).

**29.7.2.4 Type IV Cells (Basal Cells).** Type IV cells (Murray, 1973; Murray et al., 1969) include basal cells (Nemetschek-Ganssler and Ferner, 1964) or “pre-gustatory cells” (Scalzi, 1967). These are relatively small

**Table 29.2** Survey of selected substances (transmitters, channel or transporter proteins) associated with certain types of taste bud cells in various species.

Taste Bud Cell Type	Substance/Transmitter	Species	Reference
Basal Cells	5HT (serotonin)	catfish	Reutter, 1971
basal cells	5Ht, Glu, GABA	necturus	Kim and Roper, 1995; Nagai et al., 1996
basal cells	5HT	frog	Jain and Roper, 1991
I	Glutamate/aspartate transporter (GLAST)	mouse	Lawton et al., 2000
I	Ecto-ATPases	mouse	Bartel et al., 2006
I	Epithelial Na <sup>+</sup> channel (ENAC)	mouse	Lin and Kinnamon, 1999; Vandenebeuch, Clapp, and Kinnamon, 2008
I	K <sup>+</sup> channel ROMK	mouse	Dvoryanchikov et al., 2009

undifferentiated cells that lie at the taste bud's base, which do not form processes that reach the pore. They contain numerous bundles of intermediate filaments (Royer and Kinnamon, 1991), and differ from Merkel cell-like basal cells of fishes and amphibians. Type IV cells are considered to be undifferentiated stem cells of their bud cell progeny (Chaudhari and Roper, 2010; Murray, 1973; Murray, 1986; Roper, 1989). In embryonic and adult vallate taste buds of mice, basal cells also express the transcription factors Hes6 and Mash-1, the latter possibly being involved in specification of a type III lineage (Seta et al., 2003, 2011). Using genetic lineage tracing in murine taste buds, Miura et al. (2014) found sonic hedgehog (*shh*) in most basal cells, which indicates a fate as postmitotic, immediate precursors of all three cell types rather than a stem cell.

Some authors report on “intermediate cells” (e.g., Kinnamon et al., 1985). It has been pointed out (Farbman et al., 1985; Roper, 1989) that differences in the electron density of the cytoplasm could also reflect different stages in the maturation of the same cell type which indicate different states of function.

#### **29.7.2.5 Type V- Cells (Marginal Cells).**

“Marginal cells” (also “perigemmal cells,” and, in extension of Murray’s nomenclature, “type V cells”) have been described (Beidler and Smallman, 1965; Farbman, 1980; Gurkan and Bradley, 1987; Reutter and Witt, 1993). However, they have nothing in common with the secretory marginal cells of taste organs in fish and frog, and may possibly be taste bud stem cells (Beidler and Smallman, 1965; Farbman, 1980) which express particular non-taste receptor proteins, for example, CD44 isoforms (Witt and Kasper, 1998) during human taste bud ontogenesis.

### **29.7.3 Molecular Markers of Taste Bud Cells**

One of the most intriguing challenges for suggesting possible functional properties of taste bud cells is to identify subsets of these cells by morphological features as well as molecular properties, many of which can be traced even in enriched primary taste bud cell cultures (Kishi et al., 2001, 2002; Ozdener et al., 2006). Histochemical evidence on the neurochemical nature of taste cells have identified the panneuronal markers, neuron-specific enolase (NSE) and protein gene product 9.5 (PGP 9.5) (Astbäck et al., 1997; Montavon et al., 1996; Yee et al., 2001; Yoshie et al., 1988), carbohydrate- binding proteins, the lectins (Witt and Miller, 1992; Witt and Reutter, 1988). Immunoelectron microscopic studies have tried to match functional parameters with those of conventional electron density. For example, cell adhesion molecules (Nolte and Martini, 1992; Smith et al., 1993, 1994) and several blood-group

antigens (Pumplin et al., 1997, 1999; Smith et al., 1999) characterize subsets of type II taste bud cells. A subset of the (light) type II cell contains partly the G protein gustducin (Menco et al., 1997; Ruiz-Avila et al., 1995), which is involved in the perception of sweet and bitter taste (Tomonari et al., 2012; Wong et al., 1996).

Choline acetyl transferase, an enzyme involved in the synthesis of the neurotransmitter acetylcholine, has been identified in rat type II cells (Menco et al., 1997). Whereas the putative neurotransmitter serotonin is confined to basal cells of fish taste buds (Reutter, 1971) and Merkel cell-like basal cells of amphibian taste organs (Delay et al., 1997; Hamasaki et al., 1998; Toyoshima and Shimamura, 1987), serotonin in mammals has been described in type III cells in the rabbit (Fujimoto et al., 1987; Kim and Roper, 1995) and human taste buds (Azzali, 1997). This led to the hypothesis that these cell types were equivalent in both taxa (Kim and Roper, 1995). Lindemann (1996) suggests the term “serotonergic cells” instead of type III cells (<10% of all cells).

Generally, neuropeptides are located in intragemmal nerve fibers rather than in particular bud cells. An exception is vasoactive intestinal peptide (VIP) that has been detected in a subset of rat type II cells (Herness, 1989; Shen et al., 2005), and in light taste bud cells in the carp (Witt, 1995) by electron microscopy. Though most of these markers are expressed only in differentiated cells and are not evident after nerve dissection (Smith et al., 1993; Whitehead et al., 1998), their functional correlation with taste perception data is mostly unknown.

To avoid the present Babylonian confusion of tongues with regard to taste bud cell nomenclature, present research directions try to associate electrophysiologically-characterized, isolated taste bud cells with a particular cell type based on its specific substrate expression. Modern cell biological approaches, for example, introduction of green fluorescent protein chimeras *in vitro* (Landin et al., 2005) or calcium imaging after application of specific stimuli (Caicedo et al., 2000), have contributed to a solution of this problem.

Several authors report on morphological and immunohistochemical differences between vallate/foliate and fungiform taste buds within the same species. For example, mouse taste bud cells of fungiform papillae contain more synapses and presynaptic vesicles than those of vallate papillae (Kinnamon et al., 1993), and the number of taste bud cells containing group H blood antigen and gustducin is three times higher in vallate than in fungiform papillae (Smith et al., 1993). The coexpression pattern of taste receptors (T2R and T3R) and gustducin differs between fungiform and vallate taste buds in mice (Kim et al., 2003). In rabbit, lectin carbohydrate profiles of both taste bud populations differ as well (Witt and Miller, 1992). The reasons and significance of these differences between fungiform and vallate/foliate taste cells are not clear, but

factors determining their varying phenotype could include a different local saliva composition (Schmale and Bamberger, 1997; Schmale et al., 1990; Shatzman and Henkin, 1981) or morphogenetic conditions of local epithelium (Smith et al., 1999).

Evidence for communication between taste cells, apart from purinergic transmission (Finger et al., 2005), includes the presence of cell adhesion molecules (Nolte and Martini, 1992; Smith et al., 1993), heparin-binding proteins (Wakisaka et al., 1998), and membrane receptors that influence the intracellular signal transduction cascades. For example, the hyaluronan receptor, CD44, was identified in a subset of human fetal taste bud cells (type V, marginal cells) and most of adult human taste bud cells (Witt and Kasper, 1998). This transmembrane protein is linked to a series of actin-associated microfilaments, for example, ezrin and ankyrin, which are located in microvilli of type I cells and might influence the function of ion-translocating membrane proteins (Höfer and Drenckhahn, 1999). In light of efferent neural control, taste bud cell communication may be mediated via local axon reflexes between sensory cells (Caicedo et al., 2000; Reutter and Witt, 2004).

## 29.8 DEVELOPMENT OF THE HUMAN PERIPHERAL TASTE SYSTEM

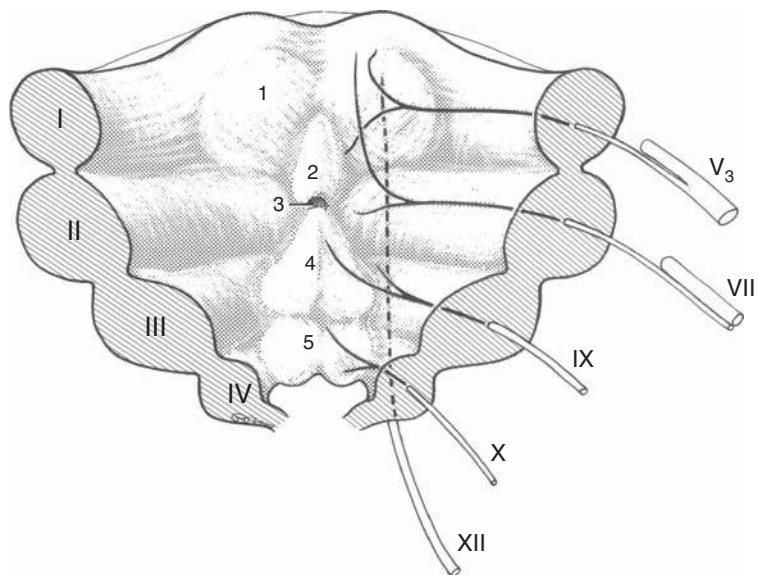

Morphogenesis of the mouth cavity is characterized by the development of the tongue anlage which appears prior to, and is a prerequisite of, the formation of gustatory papillae.

At the embryonic age of 4 weeks, the first structure of the tongue anlage to appear is the tuberculum impar which is situated between the first (mandibular) and second (hyoid) branchial arches (Figure 29.11). Then, anterolateral to the tuberculum impar, the paired lingual swellings (which derive from the medial parts of the mandibular arches) fuse with the tuberculum impar. The tongue's base is formed by the hypobranchial eminence (copula of *His*) forming within the third and fourth branchial arches. The border between the caudal part and the body of the tongue is demarcated by a V-shaped rim, the sulcus terminalis (Bradley, 1972; Witt and Reutter, 1997). The innervation pattern of cranial nerves, which later supplies particular lingual regions, reflects the early innervation of branchial arches (see Figure 29.11): The pretrematic nerve of the first branchial arch is the lingual nerve (from CN V<sub>3</sub>); that of the second arch, the chorda tympani (from the intermedio-facial nerve); and that of the third arch constitutes later lingual rami of the glossopharyngeal nerve (for details see textbooks on embryology, for example, Hinrichsen, 1990; Williams et al., 1989).

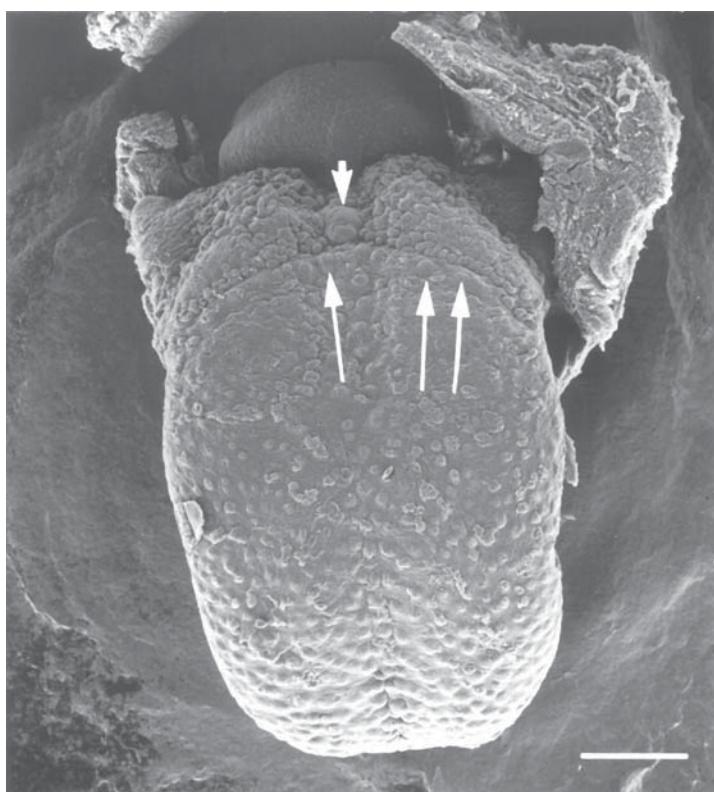

The first detailed developmental studies on the surface appearance of the tongue were carried out by Froriep

(1828), and continued histologically by Tuckerman (1889), Gråberg (1898), and Hellman (1922). Hermann (1885) described the stages of karyokinesis in developing taste buds. It was unclear to Hermann if supporting, or neuroepithelial, cells were being replaced. Vallate papillae start to develop earlier than fungiform papillae, and begin with the appearance of a central midline papilla just behind the foramen caecum around the sixth postovulatory week. From week 7 on, there develop many hillock-like epithelial elevations on the tongue's dorsum, as seen with scanning electron microscopy (Figure 29.12). Some of these elevations are precursors of fungiform papillae and are especially densely distributed near the midline and the lateral ridges of the tongue (Habermehl, 1952; Hersch and Ganchrow, 1980; Witt and Reutter, 1997). Analysis of serial sections of the tongue encompassing this critical developmental age (weeks 6–8) demonstrates that not every dermal elevation will be the target of nerve fibers. First, around week 7–8, nerve fibers, migrating towards the periphery, form a large intragemmal plexus. Our own studies show that there are no taste bud anlagen without approaching nerve fibers (Witt and Reutter, 1996; Witt and Kasper, 1998), but recent studies revealed the nerve-independent development of taste buds and their preforming papillae (Barlow, 2003; Ito and Nosrat, 2009; Nosrat et al., 2012; Stone et al., 1995; Thirumangalathu et al., 2009). Also, taste bud primordia without dermal papillae are evident, as well as individual bipolar epithelial cells resembling solitary chemosensory cells. These individual cells are immunopositive for cytokeratin 20, a marker for lingual taste bud cells (Witt and Kasper, 1999; Zhang and Oakley, 1996). Temporal correlation, which would suggest dependence of taste bud development on nerve ingrowth, has not as yet been seen.

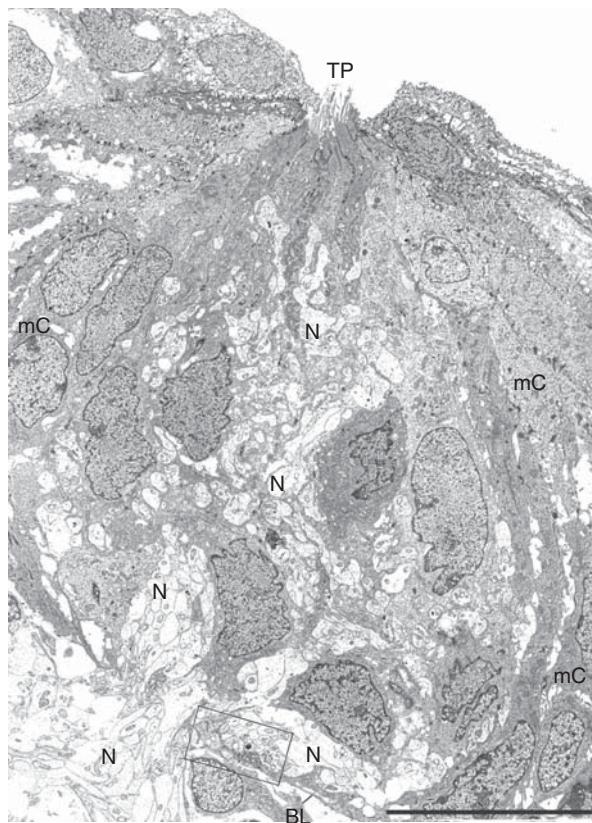

Lingual taste bud primordia first occur around the 7th and 8th postovulatory weeks (Bradley, 1972; Bradley and Stern, 1967). Taste pores, commonly acknowledged as a sign of taste bud maturity, appear between the 10th and 14th week. The presence of a taste pore is not always associated with a fully mature taste bud because the bottoms of early taste pits may be covered by flat epithelial cells (Witt and Reutter, 1997). However, transmission electron microscopical studies show that early taste bud primordia (week 8) synaptically contact nerve fibers, suggesting the potential for neurotransmission precedes the exposure of saponin molecules to the apical surface of the taste bud cell. At its base, the developing human taste bud (weeks 12–15) contains processes of dark and light cells, as well as processes resembling type III cells (exhibiting synapses with nerve fibers). At their apical ends, taste bud cells cannot be distinguished by their electron density (week 15, Figure 29.13). There are cells with long, slender microvilli, but, in contrast to adult taste buds (Azzali, 1997), there are no type I cells.

**Figure 29.11** Development of the human tongue, 5<sup>th</sup> postovulatory week. The schematic drawing was done by compiling Hinrichsen's (1990) and our own data. – By horizontal section the floor of the forecoming buccal cavity of a human embryo is removed and viewed from dorsally. The floor relief is derived from the branchial arches I (mandibular arch), II (hyoidal arch), III (3<sup>rd</sup> pharyngeal arch) and IV (4<sup>th</sup> pharyngeal arch), and by their derivatives which are 1- the paired lingual swellings, 2- the impar tubercle and 4- the hypobranchial eminence. These three structures form the tongue anlage. Between 2 and 4, the anlage of the thyroid gland invaginates, and as its remnant the 3- foramen caecum is left. 5- is the anlage of the epiglottis. The branchial arches, as well as the tongue anlage, are innervated by the cranial nerves V<sub>3</sub> (mandibular nerve), VII (facial nerve), IX (glossopharyngeal nerve) and X (vagal nerve). (CN XII -hypoglossal nerve- invades the tongue anlage as well, and innervates its muscular system). Later, the lingual nerve (from V<sub>3</sub>) and the chorda tympani (running with VII) join each other and to supply the anterior two- thirds of the tongue with somatosensory and gustatory nerve fibers, whereas IX and X carry taste fibers for the posterior third of the tongue, the epiglottis and the pharynx.

**Figure 29.12** Scanning electron micrograph of a human embryonic tongue, 7th postovulatory week. Fine dots in the dorsal surface demarcate later fungiform papillae. Anlagen of vallate papillae (arrows) lie in front of the sulcus terminalis. Short arrow indicates the median vallate papillae, which originates first. Scale bar: 0.5 mm.

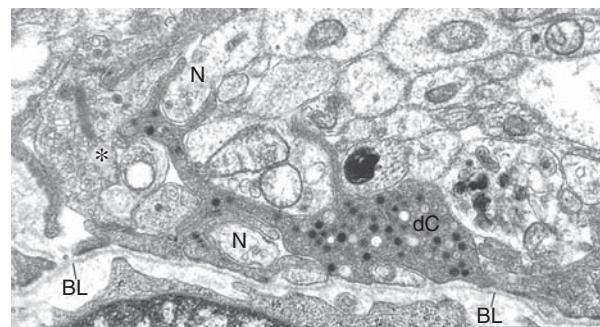

**Figure 29.13** Transmission electron micrograph of a human fungiform taste bud during development (week 15). The taste pore (TP) is already open, and some elongated cells stick into the taste pit. However, differences between cell types in the apical portion of the taste bud cannot be made yet. There is no mucus in the taste pit. Approximately two-thirds of the taste bud are filled with ramifications of nerve fibers (N). A part of the basal portion is outlined with a rectangle (see Figure 29.14). mC = marginal cell, BL = basal lamina; scale bar: 10  $\mu\text{m}$ . with typical dark granules believed to secrete the mucous material that fills the taste pit (Witt and Reutter, 1996).

## 29.9 INNERVATION OF THE HUMAN TONGUE AND TASTE BUDS

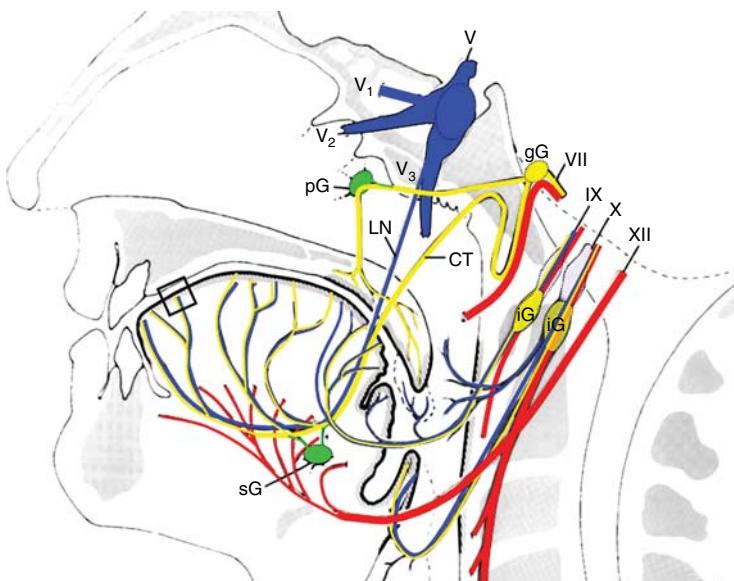

The tongue is innervated by (1) motor nerve fibers constituting the hypoglossal nerve (CN XII), which supplies the inner (intrinsic) and the hyoidal tongue muscles; (2) somatosensory nerve fibers, composed of divisions of the trigeminal (CN V<sub>3</sub>) and glossopharyngeal (CN IX) nerves; (3) autonomic nerve fibers which stem from the intermedio-facial nerve (CN VII), the glossopharyngeal nerve, and the vagus nerve (CN X); and (4) sensory (gustatory) nerve fibers that transmit taste information centrally

**Figure 29.14** Basal portion of a developing human taste bud, week 15 (detail from Figure 29.13). Numerous processes of an electron-dense cell (dC) rich in dense cored vesicles surround nerve fibers (N), but synapses and signs of release of the vesicular contents are not observed. One cell process is filled with dense-cored and clear vesicles (asterisk). BL = basal lamina. Bar = 1  $\mu\text{m}$ . From Witt and Reutter (1996), with permission of John Wiley & Sons.

from taste buds, namely (a) the chorda tympani, a branch of the intermediate nerve (generally considered a part of the facial nerve, CN VII), (b) the greater (=superficial) petrosal nerve, also part of the intermedio-facial complex, (c) glossopharyngeal nerve (CN IX), and (d) vagus nerve (CN X) (summarized in Figure 29.15).

Classical research papers of the nineteenth century explored the clinical consequences in taste perception associated with diagnostic features of the cranial nerves. These papers have formed the bases for the neurological examination. Two prominent themes were explored: (1) Which cranial nerves are associated with functional attributes of the taste system? (2) How is taste perception affected by neurological diseases? In physiological experiments, Magendie (1820) dissected the lingual nerve of living, unanaesthetized animals and observed loss of taste, but intact movement and sensation of palate, gingival, and buccal mucosa. Panizza (1834) performed dissection of the glossopharyngeal nerve resulting in loss of taste. Alcock (1836) described the role of the chorda tympani and the sphenopalatine (pterygopalatine) ganglion. Lussana (1869, 1872) traced the target tissue of the chorda tympani nerve to the anterior two-thirds of the tongue. The dependence of taste buds on nerve supply was experimentally shown by von Vintschgau and Hönigschmied (1877): 40 days after dissection of the glossopharyngeal nerve, the number of taste buds dramatically decreased. In similar experiments, Ranvier (1888) observed that taste bud sensory cells degenerate, and supporting cells pushed through the pore to the tongue surface. During this process, he observed *cellules migratrices* [phagocytic fibroblasts? (Suzuki et al., 1996)] loaded with fed particles, which were “probably responsible for removal of old material.” Soon it became evident that experiments based on vivisection were not

**Figure 29.15** Innervation of the human tongue and the taste bud-bearing epithelia (hatched regions), compiled from (Feneis, 1985) and (Sobotta, 1993). The cranial nerves VII (which includes the intermediate nerve with its branches, greater petrosal nerve and chorda tympani), IX and X contain sensory gustatory fibers (yellow). V, trigeminal nerve (blue) with its divisions  $V_1$ , ophthalmic,  $V_2$ , maxillary, and  $V_3$ , mandibular nerves. XII, hypoglossal nerve (red), is the motor nerve of the intrinsic tongue muscles. gG, geniculate ganglion; pG, pterygopalatine (sphenopalatine) ganglion; iG inferior ganglion of the glossopharyngeal (IX) and vagal (X) nerves, respectively; sG, submandibular ganglion with postganglionic autonomic nerve fibers of the chorda tympani to supply the submandibular and sublingual glands. (See plate section for color version.)

only painful for the animal (mostly dogs or cats), but also unreliable in their results (Alcock, 1836; Wagner, 1837). Nevertheless, the overall conclusions derived from these nineteenth century nerve dissection experiments (reviewed by Jägel, 1991; Parker, 1922) cannot deny their import for current knowledge of cranial nerve supply and taste sensitivity.

An elegant review of the background of peripheral taste pathways in humans was written by Lewis and Dandy (1930). They examined both the neurological and neuroanatomical literature on gustatory pathways. The sensory distribution of the facial nerve and its clinical importance was described by Hunt (1915). He disentangled the overlapping sensory fields of the facial nerve (including the chorda tympani) from the trigeminal nerve by documenting the distribution of herpes zoster inflammation. The herpetic eruptions outlined the sensory fields of the geniculate ganglion on the tongue, soft palate, and ear. Another basis for evaluating the involvement of the chorda tympani nerve with lingual taste buds came from patients who had undergone middle ear surgery (Borg et al., 1967; Bull, 1965). Contemporary reviews of human (Norgren, 1990; Prichard, 2011) and primate (Pritchard, 1991) taste pathways have incorporated observations from the second half of the twentieth century, particularly those derived from electrophysiological studies.

**1. Chorda tympani and greater petrosal nerve:** Distal to the intermediate nerve branch of the facial nerve, peripheral axons of some geniculate ganglion somata (the chorda tympani nerve) take a recurrent course within the facial canal in the petrosal part of the temporal bone, pass through the middle ear, and exit the skull via the petrotympanic fissure to join the lingual division of the trigeminal nerve, the lingual nerve.

Both intermedio-facial (gustatory) and trigeminal (somatosensory) fibers run in the lingual nerve and distribute to the fungiform papillae on the anterior two thirds of the tongue and may reach also the anterior portion of the foliate papillae. Taste buds on the soft palate are innervated by the greater petrosal branch of the intermedio-facial nerve, whose somata also lie within the geniculate ganglion (Harris, 1952; Miller and Spangler, 1982). Some chorda tympani fibers are reported to anastomose with the greater petrosal nerve via the otic ganglion (Pritchard, 1991; Schwartz and Weddell, 1938). Both the greater petrosal and chorda tympani nerves also carry parasympathetic fibers to their associated salivary glands: The greater petrosal nerve serves the palatine and the lacrimal glands, while the chorda tympani innervates the submandibular and sublingual glands via the submandibular ganglion.

**2. Glossopharyngeal nerve:** Axons of the glossopharyngeal nerve originate from ganglion cells mainly in the inferior (petrosal) glossopharyngeal ganglion. These peripheral axons supply both taste buds and general sensory innervation to the vallate and foliate papillae. Salivary glands (Ebner) are supplied by parasympathetic fibers via an intrinsic ganglion (Remak, 1852). Probably, the glossopharyngeal nerve also supplies taste buds in the pharynx. Bourgery and Jacob (1839) and Doty et al. (2009) observed that some CN IX fibers extend into the middle part of the tongue to overlap with innervation areas of the chorda tympani. However, it is unclear if they innervate taste buds.

**3. Vagus nerve:** Taste buds on the laryngeal surface of the epiglottis, larynx, and proximal portion of the esophagus are innervated by the superior laryngeal

- branch of the vagus nerve, which has the perikarya of its chemosensory neurons in the inferior (nodose) vagal ganglion.
4. *Trigeminal nerve:* The possible role of trigeminal nerve fibers in taste perception has been discussed for two millenia, and there is no end in sight. Via the lingual nerve, this nerve conveys somatosensory and viscerosensory information from the tongue to trigeminal brain stem nuclei. In fact, most of the nerve fibers entering the fungiform papillae are trigeminal, while a few fibers originate from the chorda tympani (25% in rat: Farbman and Hellekant, 1978).
- Trigeminal fibers may respond to sapid stimuli, as revealed by trigeminal transection experiments (Berridge and Fentress, 1985), electrophysiology (Harada and Smith, 1992), and trigeminal ganglion cell response (Liu and Simon, 1998). Taste receptors also occur in a variety of nongustatory cells proper, outside the oral cavity (Tizzano et al., 2011). Finally, taste qualities may be influenced by nonsapid stimuli, for example, temperature: approximately one-half of the nerve fibers involved in taste transduction respond to temperature (Cruz and Green, 2000). The interaction of both gustatory and somatosensory qualities may be as tight-knit as their anatomical proximity. Katz et al. (2000) suggest that gustation should be thought of as an integral part of a distributed, interacting multimodal system.
- In contrast to most other sensory systems, gustatory function is distributed among three different cranial nerves, which makes taste difficult to eliminate and, secondly, also difficult to distinguish from trigeminal perception (Prichard, 2011).
- The observation that taste buds degenerate after dissection of their sensory innervation and, subsequently, reappear after regeneration of their peripheral nerves has been a major focus of research in the peripheral taste system. Nineteenth- and early twentieth-century literature on taste bud degeneration, regeneration, and development was reviewed comprehensively by Parker (1922). Olmsted (1920) proposed that trophic maintenance of fish taste buds depended on the transmission of a putative trophic material from nerve to epithelium. Cross reinnervation of the glossopharyngeal nerve to fungiform taste buds (which are normally supplied by the chorda tympani) had no effect on the usual immunohistochemical properties of fungiform versus vallate taste buds (Smith et al., 1999). As a consequence, these authors believe that the protein expression in and subsequent function of taste buds depend on the epithelium from which the cells arise, and not the buds' specific nerve supply. Meanwhile, Nosrat and Olson (1995) and Nosrat et al. (2000) detected mRNA of brain-derived neurotrophic factor (BDNF) and neurotrophins in developing anterior tongue epithelium, before nerve fibers were observed. In BDNF-overexpressing mice, larger taste buds and more taste cells have been observed (Nosrat et al., 2012). This argues for the hypothesis that trophic factors act as target-derived chemoattractants for the early nerve fibers. These, in turn, initiate the formation of taste buds. BDNF-null mutant mice fail to develop taste buds (Oakley et al., 1998). Sensory ganglia involved in taste bud innervation (see above) are reduced by 40% in volume compared to about 20% of trigeminal ganglion under the same condition (Mistretta et al., 1999). Taste buds do not develop after injection of  $\beta$ -bungarotoxin into the amniotic fluid in fetal mice. This neurotoxin abolishes motor and sensory nerve development (Morris-Wiman et al., 1999).
- Although nerve fibers are required to maintain taste buds once the latter are formed and start to function (e.g., Hosley et al., 1987; Yee et al., 2005), nerves seem not to be necessary to initiate taste bud development. Initial taste bud development is nerve-independent, suggested by a series of studies in salamanders (Stone, 1940), axolotl (Barlow et al., 1996; Barlow and Northcutt, 1998a,b) and mouse (Mbiene and Roberts, 2003). Taste buds seem to develop from local epithelium and not from neurogenic ectoderm [axolotl: Barlow and Northcutt (1997), mouse: Stone et al. (1995)]. It may be that mechanisms of differentiation of the same receptor organ vary among vertebrate taxa (Barlow, 2003). Growth factors other than BDNF may contribute to the maintenance of gustatory papillae, for example, epidermal growth factor (EGF) supplied by salivary glands (Liu et al., 2008; Morris-Wiman et al., 2000). More detailed studies on developmental aspects of the peripheral gustatory system including whether taste buds may develop without the stimulation of nerves are described later in this book (Chapter 33).

## ACKNOWLEDGEMENTS

The authors are indebted to Dr. Inglis Miller, Jr. who wrote a previous version of this chapter in the first edition, and Mihnea Nicolescu, who provided the schematic drawings. Drs. Judith and Donald Ganchrow helped with critical reading of an earlier version of the manuscript.

# Chapter 30

---

## Chemical Modulators of Taste

JOHN A. DESIMONE, GRANT E. DUBOIS, and VIJAY LYALL

### 30.1 INTRODUCTION

In the consumer's lexicon, taste is a word that captures the sum total of perceptions following taking a substance into the mouth. Of course, this includes olfactory and tactile as well as gustatory sensations. A more limited definition of taste focuses on sensations emanating from the oral cavity which certainly would include sweet, bitter, salty, sour, and umami tastes, but also other sensations (e.g., astringent, cooling, hot, prickle, licorice-like, fatty, and mouthfeel). However, consensus among scientists limits taste to sweet, bitter, salty, sour, and umami and, accordingly, we limit our discussion to modulators of these tastes.

Now that the cellular basis of taste transduction has been described for each of the taste qualities, we have a structural foundation upon which to develop quality-specific taste modulators. Before transduction was understood, taste modulators were discovered largely by chance. Apart from being interesting curiosities they sometimes allowed some insight into taste mechanism. A good example is gymnemic acid, which blocks sweet taste in humans and closely related primates, but not in lower primates and other mammals (Hellekant et al., 1996). This suggested a mutation in the sweet taste receptor structure among species, long before this could be demonstrated in molecular terms. The epithelial sodium transport inhibitor, amiloride, led to a major paradigm shift in our thinking about the sodium taste receptor. The earlier view was that the sodium taste receptor was an equilibrium sodium-binding protein (Beidler, 1954). However, the lingual epithelium was later shown to actively transport sodium and that this sodium current could be blocked by ouabain and the sodium channel blocker amiloride (DeSimone et al., 1981; Stewart et al., 1997). When

amiloride was shown to block the chorda tympani taste response to NaCl in rats and other mammals, the cumulative data indicated that the sodium taste receptor was most likely the epithelial sodium channel, also found in lung and kidney (Stewart et al., 1997). Sodium taste reception is, therefore, a nonequilibrium process that results directly in a depolarizing sodium current that excites the release of the afferent neurotransmitter from receptor cells. Because of the high biochemical reactivity of hydrogen ions at the cellular level, it was perhaps not unexpected that at least for a time there might be a confusing plethora of proposed sour taste receptor mechanisms (DeSimone et al., 2001). Notwithstanding, human psychophysical studies have for more than a century shown that sourness does not in general correlate with stimulus pH, that is, sour taste receptors are not extracellular pH sensors (DeSimone et al., 2001). Consistent with the psychophysics, work over the last decade shows that sour taste receptors are rather intracellular pH sensors and that their responsiveness is especially sensitive to modulators of intracellular pH, as will be explained in detail below.

As we begin, it is essential that we reach consensus as to the meaning of "chemical modulator of taste." We define them to be chemical compounds which, at the level employed, are tasteless but which either enhance or inhibit one of the five tastes. Sweetness enhancers, bitterness inhibitors, saltiness enhancers, sourness inhibitors, and umami enhancers have obvious food and beverage applications. However, uses for sweetness inhibitors, bitterness enhancers, saltiness inhibitors, sourness enhancers, and umami inhibitors are less clear. Being as it may, applications for sweetness and saltiness inhibitors have been identified, whereas those for bitterness enhancers, sourness enhancers, and umami inhibitors remain to be identified. That being said, the future may lead to uses for such mod-

ulators and therefore we include discussion on enhancers and inhibitors for all of the five primary tastes, where such information is available.

## 30.2 MODULATORS OF SWEET TASTE

In a rational program targeted at sweet taste modulators, it is essential to understand the biochemical processes which mediate activation of the taste bud cells (tbc's) which signal sweet taste to the CNS. Enabled by the human genome sequence, tremendous progress was made in elucidation of the biochemistry and physiology of sweet taste as well as in understanding the Structure-Activity-Relationships (SAR) of sweeteners (DuBois et al., 2008a). To summarize, it is generally accepted that sweet taste is initiated by the single Class C heterodimeric G Protein-Coupled Receptor (GPCR) T1R2/T1R3, where the native agonists (e.g., sucrose, fructose, etc.) bind in large extracellular Venus Fly Trap (VFT) domains. Transduction of receptor activation is mediated by: (1) the G protein gustducin, (2) the enzyme phospholipase C $\beta_2$  (PLC $\beta_2$ ), (3) inositol triphosphate (IP<sub>3</sub>), (4) the ribosomal inositol triphosphate receptor (IP<sub>3</sub>R), (5) Ca<sup>2+</sup>, (6) a transient receptor potential ion channel TRPM<sub>5</sub>, as well as other factors. Sweet-sensitive tbc's are Type II tbc's characterized by apical microvillar projections which are the receptor loci. Efforts to identify synapses with afferent nerve fibers have been unsuccessful leading to the proposal (Huang et al., 2007) that excited sweet-sensitive tbc's secrete ATP through gap junction channels thus exciting Type III tbc's which subsequently communicate with afferent nerve fibers. However, as an experiment resulting in deletion of Type III cells (Huang et al., 2006) eliminated sour taste while not affecting sweet taste, the full details of the sweet-sensitive tbc signaling to afferent nerve fibers remain to be clarified.

As noted, all sweeteners activate T1R2/T1R3. However, to explain multiple observations not explained by this pathway, the Margolskee and Gilbertson laboratories provided evidence that carbohydrate (CHO) sweeteners have an additional activation mechanism involving glucose transporters and other glucose sensing proteins (Yee et al., 2011). However, these results are preliminary and much more remains to be done to validate this pathway.

Interest in modulators of sweet taste is primarily related to technologies which will enable improved replication of sucrose taste. In one approach to improved sucrose taste simulation, focus has been placed on enhancers for CHO sweeteners (e.g., sucrose, fructose and glucose) where the expectation is *retention of CHO sweetener taste*. Senomyx (San Diego, CA) was the first to develop a cell-based assay based on the human sweetener receptor (Li et al., 2002) and this assay enabled

high-throughput-screening (HTS) of large libraries of chemical compounds and discovery of the first sweetener enhancers, which really are more properly termed sweetener receptor Positive Allosteric Modulators (PAMs). Since then, other organizations have initiated PAM discovery programs including Chromocell of North Brunswick, NJ (Gravitz, 2012). Chromocell HTS technology is based on cells which naturally express the sweetener receptor, thereby more accurately recapitulating sweet-sensitive tbc physiology and improving assay fidelity for PAM discovery.

In a second approach to improved sucrose taste simulation, efforts have been focused on modulators of the negative taste attributes of high-potency (HP) sweeteners. Due to the non-sugar-like tastes of HP sweeteners like aspartame, saccharin, and stevioside (DuBois, 2008a), there is interest in modulation so as to enable more sugar-like tastes. HP sweeteners are often disadvantaged by: 1) low maximal sweetness (i.e., maximal response, R<sub>m</sub>), 2) bitter off taste, 3) sweetness which develops slowly and then lingers (i.e., non-sugar-like temporal profile), and 4) sweetness which causes desensitization of the sensory system. The discussion here is focused on modulation of the temporal profiles of HP sweeteners to enable more sugar-like tastes. At the present time, there is limited understanding of the biochemical rationale for low R<sub>m</sub> and preferential desensitization of the responses of HP sweeteners relative to CHO sweeteners. Therefore, these topics are not further discussed in this chapter.

Research has also been carried out to identify modulators which inhibit sweetness. Such ingredients may have application for reduction of the sweetness of food and beverage products which are too sweet due to the natural levels of CHO sweeteners present (e.g., lactase-treated milk) or because of a need for elevated levels of CHO sweeteners to provide some physical property to a food (e.g., crispness in crackers enabled by sucrose).

### 30.2.1 Positive Allosteric Modulators (PAMs) as Modulators of Sweet Taste

The principal challenge in sweetener research is accurate replication of sucrose taste. In principle, a very simple approach to this objective would be enhancement of the sweetness potency of sucrose and other CHO sweeteners. It is reasonable to expect that this could be accomplished by modulators acting at any step in the sweet-sensitive tbc excitation cascade. Many reports of modulators of sweet-sensitive tbc activity have appeared with the following being exemplary: (1) inhibitory activity of cholecystokinin and neuropeptide Y (Herness and Zhao, 2009), (2) inhibitory activity of leptin and enhancement activity of endocannabinoids (Niki et al., 2010),

(3) enhancement activity by TRPM<sub>5</sub> conductance potentiators (Bryant et al., 2008), and (4) enhancement activity by adenosine (Dando et al., 2012). However, these modulators are inactive in human sensory assays, presumably because they cannot readily access their molecular targets. And so, it appears that the only practical approach to enhancement of the activity of sweet-sensitive tbc's may be PAMs acting at extracellular sites on T1R2/T1R3.

The foregoing rationale provided justification for scientists at The Coca-Cola Company (TCCC) to initiate a PAM discovery program (DuBois, 2011). At the outset of this work, there were literature reports of CHO sweetener enhancers. However, none of the claims could be replicated. Nonetheless, in continuation of the program, 2, 4-dihydroxybenzoic acid (**1** in Figure 30.1) was evaluated, based on a report by Holland Sweetener Company (HSC) scientists of aspartame (APM) sweetness enhancement (Britton et al., 1999). HSC's interest in **1** was improvement of APM taste, but not enhancement. Thus it was found that formulation of 6% sucrose with **1** showed an unambiguous >1.3-fold enhancement and, importantly, *with retention of sugar taste*. This proof of concept for a sweetener receptor PAM was an early breakthrough which justified an intensive discovery program to follow. The CHO sweetener enhancement activity of **1** was strongest with sucrose, weaker with fructose and negligible with glucose, selectivity consistent with action as a PAM.

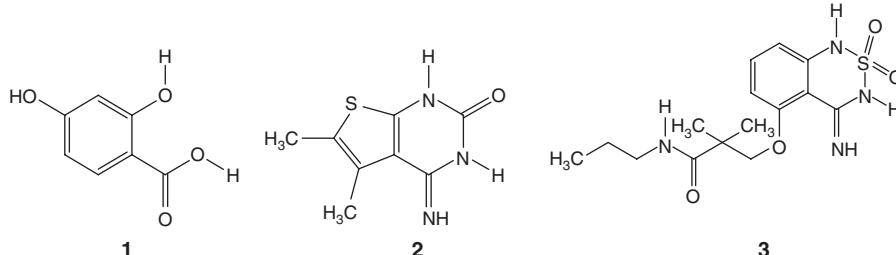

The Senomyx T1R2/T1R3 cell-based assay (Li et al., 2002) enabled a marked acceleration of sweetener receptor PAM discovery. T1R2/T1R3 is one of 12 Class C GPCRs and, beginning in the late 1990s, reports on discoveries of Class C GPCR PAMs as well as negative allosteric modulators (NAMs) began to appear, such that today PAMs and/or NAMs are known for all of them (Urweyler, 2011). Thus, in 2002, a PAM discovery program was initiated at Senomyx, in collaboration with TCCC. The program led to the sucralose-selective PAM **2** (Servant et al., 2010), the first high-potency/high-efficacy T1R2/T1R3 PAM. PAM **2** @ 9.7 mg/L enhances the sweetness of 100 mg/L sucralose to that of 600 mg/L sucralose (i.e., 6-fold). PAM **2** was quickly followed by sucrose-selective PAM **3** (Tachdjian et al., 2008). PAM **3** @ 8.8 mg/L enhances 6% sucrose sweetness to that of 10.6% sucrose (i.e., 1.8-fold) and importantly, *with retention of sugar-like taste*. Both PAMs

**2** and **3** now have regulatory approvals. In recent work (Zhang et al., 2010), evidence was presented that PAM **2** acts in the T1R2 VFT with concurrent binding to the receptor and sucralose. Analogous binding for PAM **3** and sucrose seems likely.

Subsequent to the pioneering work by Senomyx, other companies reported the discovery of sweetness enhancers as follows: 1) Cadbury Adams USA (Bingley et al., 2007), 2) Givaudan (Slack et al., 2007, Jia et al., 2008, Jia and Yang, 2009, Bouter et al., 2009, Wang and Daniher, 2009, Flamme et al., 2011, Flamme and Bom, 2011), 3) Nutri-nova (Krohn and Zinke, 2009a; 2009b), 4) Redpoint Bio Corporation (Salemme et al., 2010) and 5) Symrise (Ley et al., 2006; 2007; Krammer et al., 2007, Ley et al., 2008; Wessjohann, 2010). However, the enhancements reported are very modest and, in all cases, the enhancers are sweet themselves. Compounds exhibiting both agonist (e.g., sweetness) and PAM activities are termed “agoenhancers” (Schwartz and Holst, 2006) and so, since the claimed enhancements are small, it is not certain that they are truly enhancements.

It is noteworthy that many sweeteners are agoenhancers. However, in the sweetener literature, they are referred to as synergistic sweeteners. In effort to better understand “sweetness synergy,” Schiffman and coworkers carried out a systematic study on binary blends (Schiffman et al., 1995). Many synergistic pairs were identified and the sweeteners in these blends may be thought of as PAMs which are also agonists (i.e., sweeteners) and which are selective in their enhancement action. The structural similarities between PAMs **2** and **3** and well known sweeteners saccharin and acesulfame-K is striking. And thus it is logical to expect saccharin and/or acesulfame-K synergism with sucrose and sucralose. However, such synergy was not observed in the Schiffman study. It is interesting to note, however, that cyclamate is synergistic with 11 of the 14 sweeteners evaluated by Schiffman including sucrose, fructose, and glucose. And since agoenhancers are PAMs, cyclamate analogues may be a promising structural class of compounds for PAM discovery.

In summary, Senomyx has demonstrated tasteless T1R2/T1R3 PAMs (i.e., pure PAMs rather than agoenhancers) and it is possible that PAM ingredients could be a “breakthrough technology” (Servant et al., 2011).

**Figure 30.1** Human sweetener receptor Positive Allosteric Modulators.

Yet much remains unknown. Questions include the following: (1) Can PAMs with  $>/=20$ -fold enhancement effects be found as required to enable 0-calorie CHO ingredient labeling? (2) Can PAMs active with all CHO sweeteners be found? (3) Can natural product PAMs be found so as to permit all-natural ingredient labeling? (4) Can PAMs for natural HP sweeteners (e.g., rebaudioside A, mogroside V, etc.) be found and, if so, will they enable improved taste qualities for natural HP sweetener systems?

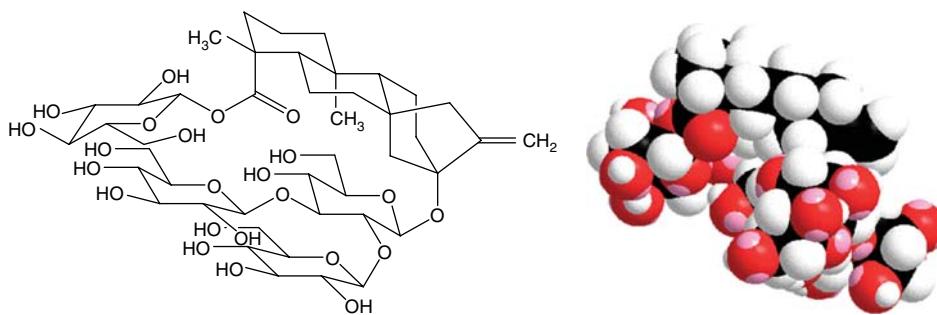

### 30.2.2 Osmolytes as Modulators of Sweet Taste

The singularly most challenging problem in replication of CHO sweetener taste with HP sweeteners is delivering on CHO sweetener temporal profile. HP sweeteners exhibit delays in sweetness onset and, especially, sweetness which lingers. Methods have been developed to quantify the temporal aspects of sweetener taste (DuBois and Lee, 1983).

In 2003, a program was initiated at TCCC for the development and commercialization of a natural product sweetener rebaudioside A (Figure 30.2) derived from the Paraguayan shrub *Stevia rebaudiana* (Bertoni) and often referred to as REBA (Prakash et al., 2008). A significant challenge in this program was modulation of the temporal profile of REBA so as to enable acceptable taste quality. This challenge was addressed by consideration of the most likely mechanistic rationale for REBA's slow sweetness onset and sweetness linger (DuBois, 2011). Clearly, given their higher potencies, HP sweeteners bind with higher affinity to the receptor than do CHO sweeteners. However, REBA's sweetness potency of ca. 200X sucrose is insufficient to explain a sweetness which persists for minutes. On consideration of the apparent equilibrium constant for REBA/receptor dissociation ( $K_d$ ) of 210  $\mu\text{M}$  (DuBois et al., 1991) and given that 1)  $K_d$  is the quotient of the rate constants for REBA/receptor dissociation ( $k_d$ ) and association ( $k_a$ ) and 2) rate constants for binding of small molecules to receptors reflect diffusion-controlled kinetics (i.e.,  $k_a \sim 10^{10} \text{ M}^{-1}\text{sec}^{-1}$ ), a  $k_d$  for REBA/receptor dissociation is estimated to be ca.  $2 \times 10^6 \text{ sec}^{-1}$ . Thus, if we

assume first order kinetics for REBA/receptor dissociation, at a time 60 sec after the time of maximal sweetness, the percentage of REBA still bound is  $\ll 1\%$ . Thus, it is clear that the potency of REBA cannot explain sweetness which lingers for many minutes. Michael Naim and colleagues (Hebrew University) proposed that sweetness linger may be a consequence of sweetener inhibition of G Protein Receptor Kinases (GRKs) involved in termination of sweetener receptor signaling (Zubare-Samuelov et al., 2005). However, this rationale does not explain slow sweetness onset, which always co-occurs with sweetness linger, and therefore is unlikely. Other explanations were considered as well. However, it was concluded that the most probable rationale for sweetness linger, which also accounts for slow sweetness onset, is that HP sweeteners, particularly large saponin-like molecules like REBA (Figure 30.2), engage in extensive non-specific binding to cell membrane sites throughout the oral cavity. If this is the case, it would be expected that much of the sweetener in a solution entering the mouth would bind weakly and rapidly to non-receptor sites and the concentration on the receptor would only reach its maximum after a delay. If this mechanistic rationale is operative, then, upon HP sweetener dissociation from the receptor, it would likely bind non-specifically to nearby non-receptor sites and thus may re-activate the receptor over and over, thus leading to lingering sweetness. This rationale for HP sweetener atypical temporal profiles was referred to as the Non-Specific Binding (NSB) hypothesis (DuBois, 2011).

If the NSB hypothesis is accurate, then the challenge in replication of the temporal profile of CHO sweeteners becomes one of formulation to attenuate non-specific binding. The tonicity of media is well understood to dramatically affect biological cells and, for this reason, they are normally incubated in isotonic buffered saline systems. If media tonicity is reduced, cells swell and may even lyse if sufficiently hypotonic. And conversely, if tonicity is increased to become hypertonic, cells shrink. Recognizing that hypertonic formulations of HP sweeteners may have such an effect on oral epithelia, it was considered that hypertonic formulation may be an effective approach for attenuation of HP sweetener non-specific binding, thereby

**Figure 30.2** Rebaudioside A illustrated in 3D structural representations. (See plate section for color version.)

accelerating sweetness onset and attenuating sweetness linger.

Support for the NSB hypothesis was found in observations of Maruzen Pharmaceutical Company (MPC) scientists (Crammer and Ikan, 1987). They reported that hypertonic NaCl enhanced the sweetness potency of a steviol glycoside (SG) sweetener composition by ca. 3-fold and of a SG/glycyrrhetic acid (GA) blend by 4- to 5-fold. NaCl and other salts have been reported to function as PAMs for a number of GPCRs (Christopoulos and Kennakin, 2002) and therefore this mechanism was considered as an explanation for the observed potency enhancements. However, no precedent exists for such a strong enhancement by salts (i.e., 3–5 fold) and so PAM action by NaCl was considered unlikely. SG and GA sweeteners normally exhibit notable delays in sweetness onsets and pronounced sweetness linger effects. However, in hypertonic NaCl, SG and GA temporal properties were observed to be similar to sucrose. In effort to explain the apparent enhancement effects, earlier findings on the sensory properties of SG sweeteners and GA were considered. Stevioside (STV) and REBA, both SG sweeteners, were determined to exhibit maximal sweetness responses of 9.9 and 10.0% SE, respectively, when evaluated in water (DuBois et al., 1991). And GA, under the same conditions was determined to exhibit a maximal response of 7.3% SE. Also, STV and GA in water were determined to require 22 and 69 seconds, respectively, for sweetness decay to a 2% sucrose equivalency (SE), while sucrose sweetness decay requires only 13 seconds (DuBois and Lee, 1983). However, as noted above, in hypertonic NaCl, SGs and GA show rapid sweetness onset and do not show sweetness linger. Thus, in hypertonic NaCl, the entire sweetness signals for SGs and GA are observed over a short window of time as is the case for sucrose, and this modulatory effect of NaCl leads to an increase in SG and GA  $R_m$ s, an observation interpreted as enhancement by the MPC scientists. In subsequent work on REBA temporal profile modulation (Prakash et al., 2007), it was demonstrated that NaCl was not unique in its effects on the temporal profiles of REBA and other HP sweeteners. It was demonstrated that osmolytes, in general, cause this effect. To illustrate, 500 mOsM NaCl, 500 mOsM KCl, and 500 mOsM erythritol were found to be equally effective in accelerating the sweetness onset of 500 mg/L REBA and in attenuating its sweetness linger.

Information presented above generally supports the NSB hypothesis as the mechanism for non-sugarlike temporal profiles of HP sweeteners. Direct support for the interactions of HP sweeteners with biological membranes was recently provided (Miyano et al., 2010) by a surface plasmon resonance study of CHO sweeteners and HP sweeteners (i.e., APM, STV, thaumatin, and single-chain monellin). The levels of interaction of these sweeteners

with model membranes correlate with observed levels of sweetness linger.

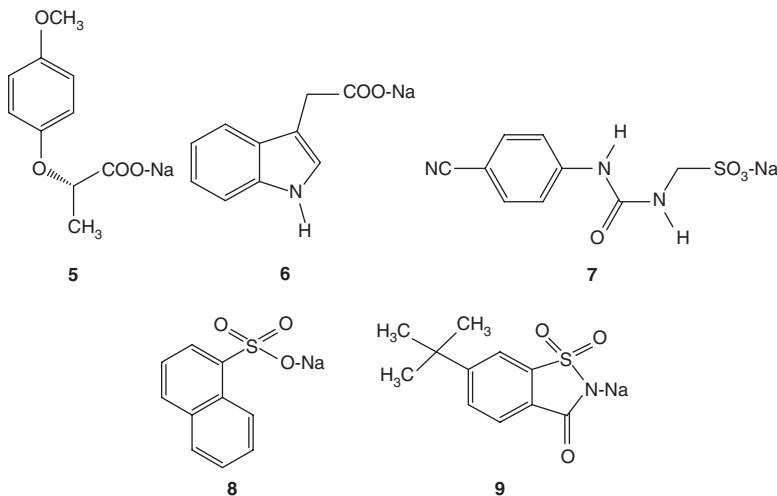

### 30.2.3 Antagonists as Modulators of Sweet Taste

In pharmacology, inhibitors historically have been very important for identification of receptor subtypes. Early sweetness inhibitors discovered were triterpenoid natural products including gymnemic acid, ziziphins, and hodulcin (Suttisri et al., 1995). None show sweetener selectivity and, generally, their inhibitory effects develop slowly and are long lasting. In the 1980s, Lindley of Tate and Lyle (Reading, England) initiated a focused program on sweetness inhibitors and identified multiple inhibitors (Lindley, 1991). One of these is phenoxyalkanoic acid salt **5** (Figure 30.3), now commonly known as lactisole. Interestingly, Lindley found that lactisole exhibited equivalent inhibitory effects for all sweeteners tested. At the time of this work, the general consensus was that multiple receptors mediate human sweetness. However, based on the absence of selectivity for lactisole, Lindley argued for a single receptor and now it appears that he was substantially correct. Later, in a cell-based assay, Senomyx scientists substantiated Lindley's conclusion based on sensory experiments and demonstrated lactisole to be a T1R2/T1R3 NAM (Jiang et al., 2005).

In experimentation with lactisole, DuBois and coworkers (D'Angelo et al., 1999) observed lactisole to exhibit a curious "sweet water aftertaste" (SWA). To be clear, water used to rinse the mouth after tasting lactisole @ 200 mg/L tastes strikingly sweet. Such a SWA effect had earlier been reported (Bartoshuk and Lee, 1972) as a taste observed on eating artichokes while drinking water. However, the biochemical mechanism for artichoke SWA has not been explained.

In the course of a sweetener discovery program at TCCC, on occasion new sweetener target compounds were found to be non-sweet, but, surprisingly, to exhibit SWA. And, based on the observation that the sweetness inhibitor lactisole exhibits SWA, other SWA compounds were evaluated for sweetness inhibition and, conversely, other known inhibitors were evaluated for SWA. Included in this study was lactisole (**5**) and indole acetic acid (**6**) which was also claimed a sweetness inhibitor by Lindley, the known phenylurea sweetness inhibitor **7** (Muller et al., 1992) and two non-sweet SWA compounds **8** and **9**. In this study, sweetness inhibitors **6** (@ 1000 mg/L) and **7** (@ 2000 mg/L) exhibited SWA. And both SWA compounds **8** (@ 5000 mg/L) and **9** (@ 500 mg/L) inhibited the sweetness of seven sweeteners tested.

In summary, the correlation between sweetness inhibition and SWA is clear. And, of course, this finding suggests a simplified approach to identification of novel

**Figure 30.3** Sweetness inhibitors which exhibit Sweet Water Aftertaste.

sweetness inhibitors. However, the question remains as to the mechanism of the SWA effect. A hypothesis was proposed by DuBois and coworkers (D'Angelo et al., 1999) based on three considerations: (1) biological receptors, independent of agonist presence, exist in both active ( $R_A$ ) and inactive ( $R_I$ ) states in rapid equilibrium (Monod et al., 1965), (2) most inhibitors (i.e., antagonists) are “inverse agonists,” compounds which bind to  $R_I$ , thereby inhibiting conformational change to  $R_A$ , and (3) some receptors are “constitutively active,” whereby, in the absence of agonist, they are substantially in the  $R_A$  state. Now, if the human sweetener receptor is constitutively active, then antagonists, acting as inverse agonists, will shift the equilibrium to  $R_I$ .

An adaptation of the cell to a reduced population of  $R_A$  may then prime the cell to signal following a water rinse causing a restoration of the  $R_A/R_I$  equilibrium with a concomitant increase in intracellular effector levels. Of course such signaling could only occur with a constitutively active receptor. Support for this hypothesis was provided by the Breslin group based on observation of SWA and sweetness inhibition for saccharin at high concentrations (Galindo-Cuspinera and Breslin, 2007).  $\text{Ca}^{2+}$  levels were demonstrated to drop in a T1R2/T1R3 cell system upon exposure to lactisole, thus demonstrating constitutive activity for T1R2/T1R3.

Many salts (e.g.,  $\text{NaCl}$ ,  $\text{KCl}$ ,  $\text{LiCl}$ ,  $\text{LiSO}_4$ , and  $\text{K}_2\text{SO}_4$ ), at or below their taste thresholds, exhibit weak sweet taste (Shallenberger, 1993) and, when formulated with CHO sweeteners, give small sweetness enhancements. Interestingly, however, Breslin and coworkers reported  $\text{ZnSO}_4$  to be an effective sweetness inhibitor (Keast et al., 2005).  $\text{ZnSO}_4$  @ 25 mM inhibited the sweetness of 10 sweeteners while not affecting the sweetness of sodium cyclamate, a selectivity effect not presently understood.

### 30.3 BITTER TASTE MODULATORS

Modulators of bitter taste are of interest for the elimination of the bitter off tastes of HP sweeteners (e.g., saccharin, REBA, etc.) as well as some foods (e.g., cruciferous vegetables), drugs and nutritional products. Early work on bitter taste inhibition has been reviewed elsewhere (Beauchamp, 1994; Roy, 1997). Here we summarize more recent progress.

As for other tastes, great progress has recently been made in elucidation of the biochemistry and physiology of bitter taste, as well as in understanding the breadth of bitterant SAR (DuBois et al., 2008a). To summarize, we now understand that bitter taste emanates from a subset of bitter-specific Type II tbc's expressing 25 Class A GPCRs known as T2Rs, thought to be dimeric. Demonstrating the potential complexity of bitterant receptors, Meyerhof and coworkers provided evidence that T2Rs may hetero- as well as homo-dimerize such that the total possible number of receptors is 325 (Kuhn et al., 2010). As with sweet taste, T2R receptors, upon activation, transduce their signals through gustducin,  $\text{PLC}\beta_2$ ,  $\text{IP}_3$ ,  $\text{IP}_3\text{R}$ ,  $\text{Ca}^{2+}$ ,  $\text{TRPM}_5$ , etc. en route to activation of afferent nerve fibers and communication to the CNS via labeled lines. As for sweet taste, it is unclear if activated bitterant-sensitive tbc's communicate directly with afferent nerve fibers or if Type III tbc's are intermediates (Huang et al., 2007). In any case, since bitter taste modulators must work on the same timescale as the bitterants themselves, research is focused on compounds which act at the receptor. In bitter taste research, substantial effort has been expended on T2R deorphanization. Exemplary of such work are the findings the groups of: (1) Meyerhof: (a) T2R16 – bitter glucopyranosides (e.g., salicin) and T2R10<sub>c</sub> – strychnine (Bufo et al., 2002), (b) T2R46 – sesquiterpenoid lactones, labdane diterpenoids, strychnine and denatonium salts (Brockhoff et al., 2007),

and (c) T2R50 – terpenoids andrographolide and amarogentin (Behrens et al., 2009), (2) Gruppen: T2R14 and T2R39 – soy isoflavones and other isoflavanoids (Roland et al., 2011), (3) Pronin: T2R44 – denatonium chloride and 6-nitrosaccharin and T2R61 – 6-nitrosaccharin (Pronin et al., 2004) and (4) Meyerhof and Hofmann: T2R4 and T2R14 – steviol glycoside (SG) sweeteners (Hellfritsch et al., 2012). The finding that SG sweeteners with bitter off taste activate >1 T2R is noteworthy, as activation of multiple T2Rs by individual bitterants is likely to be commonplace. Further, illustrating the complexity of the bitterant receptor situation, recently evidence was provided that the nicotinic acetylcholine receptor also activates bitterant-sensitive tbes (Oliveira-Maia et al., 2009).

In summary, the number of receptors mediating the activities of bitterants is likely to be large. Nonetheless, enabled by a basic understanding of these receptors, rational cell-based HTS discovery programs for bitterant inhibitors are possible. Examples of progress on this approach are provided below. Also summarized are alternative approaches to bitterness inhibition where the mechanistic details are not understood or which may operate without receptor involvement.

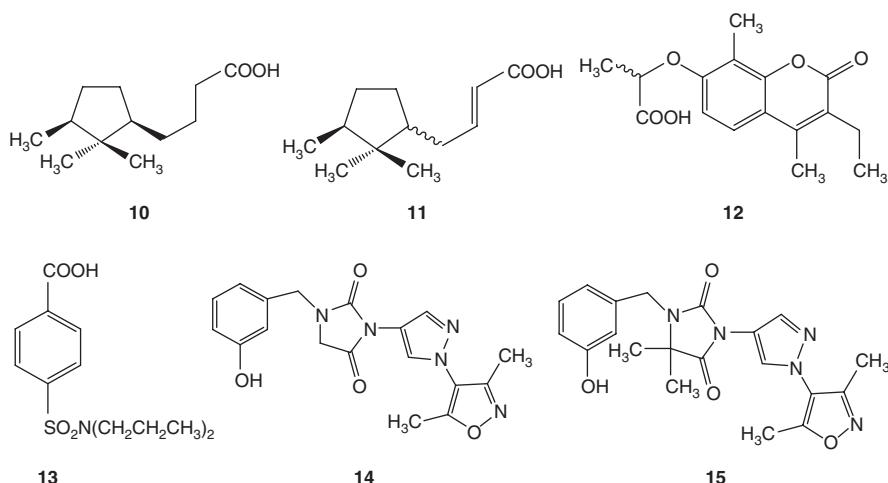

### 30.3.1 T2R Antagonists

Saccharin was the first HP sweetener to be commercially developed, although usage was limited due to bitter “off” taste. Recently, advantaged by knowledge of T2Rs responsive to saccharin, Givaudan scientists conducted a cell-based HTS program and identified carboxylic acid **10** (Figure 30.4) as a saccharin bitterness antagonist (Slack et al., 2010). Disappointingly, however, while **10** is very effective in the single T2R cell-based assay, it is not as effective in sensory panel testing. It was interesting to find that **10** also inhibits the bitterness of REBA (Slack and Evans-Pennimpede, 2009). Other interesting reports include that related compound **11** inhibits (Brune et al.,

2008) sucralose bitterness and that coumarin **12** inhibits the bitterness of REBA as well as of aspartame and sucralose (Ungureanu and Van Omeren, 2010). And finally, gout drug probenecid (**13**) was found effective in antagonism of multiple bitterant receptors including T2R16, T2R31, T2R38, and T2R43, thus enabling inhibition of the bitter tastes of salicin, saccharin, phenylthiocarbamide (PTC)/6-propyl-2-thiouracil (PROP) and aloin, respectively (Greene et al., 2011). In general, loci of action for antagonists on their receptors are unknown. However, studies on probenecid suggest allosteric action. Senomyx scientists have also carried out cell-based discovery programs on specific T2Rs and their work has led to the two bitterness inhibitors **14** and **15**, both now with regulatory approvals for use in foods and beverages (Li et al., 2011). They are claimed effective in inhibition of the bitter off taste of REBA as well as bitterants in coffee, cocoa, soy protein, and whey protein.

It is important to reflect on the possible rationale for the poor effectiveness of saccharin bitterness antagonist **10** in sensory panel assays while very effective in a cell-based assay. The most plausible rationale may be that, *in vivo*, bitterant-sensitive tbc activation may be mediated by a complex array of receptors, while *in vitro*, the response to a single homodimeric GPCR is observed. Thus, while discovery of potent antagonists for individual T2Rs may be routine, it seems probable that the discovery of antagonists that are fully effective in human taste will remain a challenge.

Today work is in progress to find bitterness antagonists for natural HP sweeteners (e.g., steviol glycosides, mogrol glycosides, etc.). However, while searching for broad-activity antagonists may appear rational, the practical utility of such antagonists may be limited. REBA and many HP sweeteners exhibit low  $R_m$ s and the major application for HP sweeteners is in beverages where high sweetness intensity is required. And since REBA exhibits an  $R_m$  of 10.0% SE (DuBois et al., 1991), it may be

**Figure 30.4** Inhibitors of the bitter off tastes of HP sweeteners: Saccharin (**10** and **13**), Aspartame (**12**), Sucralose (**11** and **12**) and Rebaudioside A (**10**, **12**, **14** and **15**).

impractical to formulate a beverage with REBA as the sole sweetener. Even if a 9.0% SE level of sweetness is adequate, it can be calculated that 1800 mg/L would be required, while the maximal allowable level for beverages (US) is 600 mg/L. A practical solution to this challenge with a low  $R_m$  sweetener like REBA is blending with a second sweetener. Thus, if in a binary blend, REBA is used to provide a 5% SE level of sweetness intensity, only 200 mg/L is required, where bitter off taste is negligible.

### 30.3.2 No-Known-Mechanism Inhibitors as Modulators of Bitter Taste

A very old approach to bitterness inhibition is based on a phenomenon known as *mixture suppression* (Lawless and Heymann, 1998). Thus compositions with bitter off taste are often formulated with sweeteners with the result that they taste less bitter. The mechanism of this effect is not known and much debate has centered on the question as to whether the effect occurs at the periphery (i.e., the taste bud) or in the CNS. Most scientists believe that both peripheral and central processes are operative.

Some salts attenuate bitterness. Thus NaCl reduces caffeine bitterness (Pangborn, 1960) and also quinine bitterness (Bartoshuk, 1975; Frijters and Schifferstein, 1994). Later, LiCl as well as NaCl were shown effective in suppression of urea bitterness, but KCl was not (Breslin and Beauchamp, 1995). Interestingly, the bitterness suppressive effect for sodium salts was found independent of saltiness since the less salty sodium acetate and sodium gluconate are equally potent in urea bitterness suppression. In continuing work (Keast et al., 2004), it was demonstrated that the sodium salt effect on bitterant taste suppression is not universal, not all bitterants being affected. In these studies, it was clearly demonstrated that sodium salts are effective at concentrations below their salty taste thresholds, and therefore, it is clear that their effect on bitter taste perception is not mixture suppression. The mechanism mediating bitterness suppression by sodium salts remains to be determined.

Zinc salts are also effective in inhibition of bitter taste (Keast, 2004). However, a problem in their use is that they also inhibit the sweetness of most sweeteners, thus limiting application to non-sweet products. However, a formulation of a zinc salt with sodium cyclamate is a possible solution to this problem, since cyclamate sweeteners are unaffected by zinc salts (Keast and Breslin, 2005). The mechanism for zinc salt inhibition of bitter taste is not known at this time.

Phosphatidic acid (PA) and PA/protein complexes (e.g.,  $\beta$ -lactoglobulin) are active in inhibition of the bitter tastes of many compounds including quinine, caffeine, propranolol, promethazine, denatonium salts, etc. (Katsuragi and Kurihara, 1995). The mechanism is thought

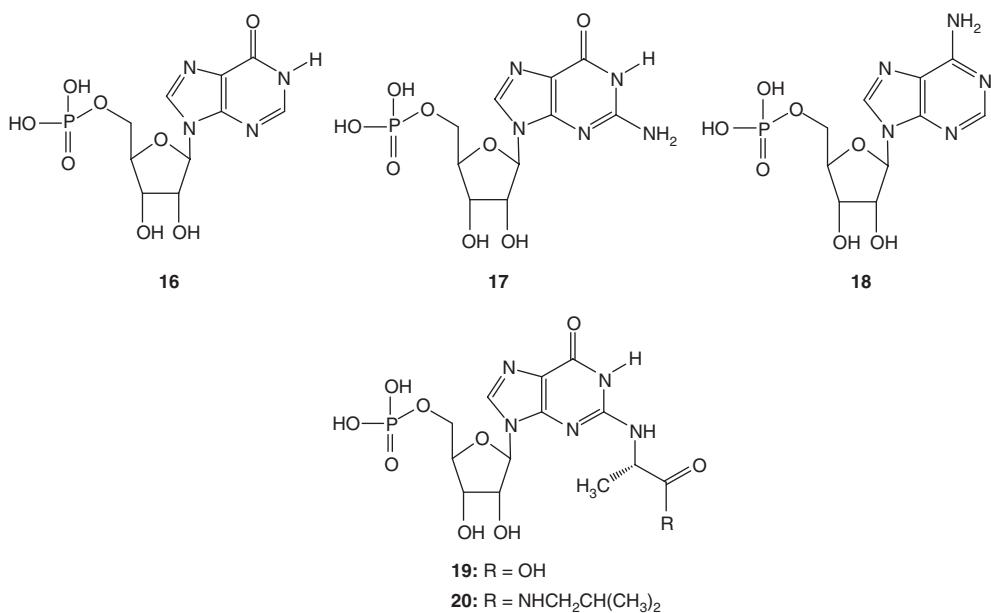

to be via sorption of bitterants into PA lipid vesicles rendering bitterants unavailable to bitterant receptors. Application of this approach to HP sweeteners (e.g., saccharin, REBA, etc.), however, is impractical since sweetness would also be suppressed.

## 30.4 MODULATORS OF UMAMI TASTE

In humans, umami taste is essentially the taste of glutamic acid salts, where monosodium glutamate (MSG) is the most common umami stimulus. Umami is a Japanese word meaning “delicious taste” and, in English, the word “savory” best describes the sensation. Interest in umami taste modulators is focused on two types of compounds: (1) MSG enhancers and (2) MSG enhancers which are also umami agonists. As is the case for the other taste modalities, great progress has been made over the last decade in elucidation of the biochemistry and physiology of umami taste, as well as in understanding the SAR of umami tastants (DuBois et al., 2008a). To summarize current knowledge, we now understand that umami taste emanates from a subset of umami-specific Type II tbcS expressing the heterodimeric Class C GPCR T1R1/T1R3. It is generally accepted that T1R1/T1R3 binds glutamate, its native agonist, in the hinge region of the extracellular VFT domain of T1R1. T1R1/T1R3, upon activation, transduces its signal through the same effectors as involved in sweet and bitter taste (i.e., gustducin, PLC $\beta$ <sub>2</sub>, IP<sub>3</sub>, IP<sub>3</sub>R, Ca<sup>2+</sup>, TRPM<sub>5</sub>, etc.) en route to activation of afferent nerve fibers which communicate to the CNS via a labeled line process. As for sweet and bitter tastes, it is unclear at the present time if activated umami-sensitive tbcS communicate directly with afferent nerve fibers or if Type III tbcS are intermediate (Huang et al., 2007). Clearly umami taste modulator research could be focused at many points in the cellular activation cascade. However, since they must work on the same timescale as MSG, research on umami receptor PAMs and PAM/agonists has been focused on compounds acting at the receptor.

### 30.4.1 Pure PAMs as Modulators of the Umami Receptor

The purine nucleotides inosine monophosphate (IMP (**16**)), guanosine monophosphate (GMP (**17**)), and adenosine monophosphate (AMP (**18**)), as well as many structural analogues, have been reported to exhibit umami taste, as has been reviewed (Yamaguchi, 1979). In addition to exhibiting umami tastes themselves, these compounds are claimed to be strongly synergistic with MSG, with relative enhancement potencies of 1.0, 2.3, and 0.18, respectively. However, *in vitro* studies on the rat (Nelson et al., 2002)

**Figure 30.5** Pure PAMs as modulators of the human umami receptor.

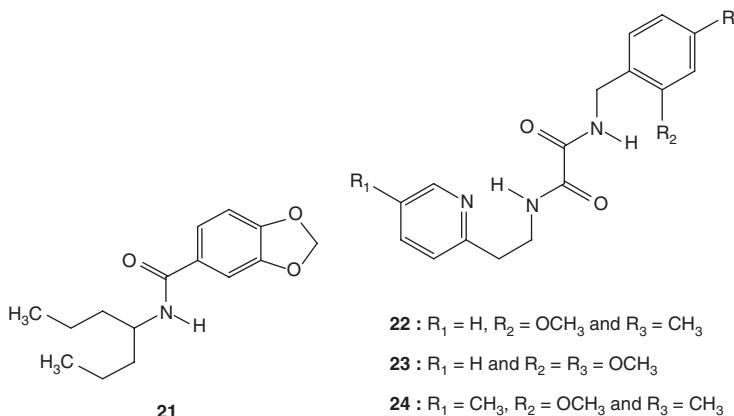

and human receptors (Li et al., 2002), showed that these nucleotides are inactive if evaluated in the absence of glutamate or other amino acids with umami taste. Normally, in the *in vitro* receptor assays carried out in heterologous cell systems, the extracellular fluid contains low levels of amino acids. And, under these conditions, purine nucleotides were observed to exhibit activity. However, to ensure that the activity observed was due to the purine nucleotides rather than an enhancement effect of endogenous amino acids, the cell preparations were washed with saline immediately before assay. Under these conditions, the purine nucleotides give no responses, while MSG responds in the normal manner. In summary, purine nucleotides **16–18** are not umami receptor agonists but are umami receptor PAMs for MSG. Supporting this conclusion is that, while 0.1 mM IMP exhibits a weak umami taste, no increase in umami taste intensity is observed for 1.0 and 10.0 mM solutions (DuBois and San Miguel, 2005). It appears that 0.1 mM IMP is sufficient to maximally enhance the umami taste of endogenous glutamate in saliva and thus increased IMP levels are without effect. It is noteworthy that IMP, GMP, and AMP exhibit quite variable efficacies as PAMs, as consistent with a receptor-mediated effect. Studies involving chimeric receptors, site-directed mutagenesis and molecular modeling aimed at elucidation of the mechanism for purine nucleotide enhancement of glutamate activity at the umami receptor have been reported (Zhang et al., 2008). And these studies suggest that purine nucleotides bind within the T1R1 VFT domain concurrently with the receptor and the glutamate agonist. Apparently, purine nucleotides are unable to affect closure of the VFT domain

by themselves, but, in the presence of glutamate, are able to increase the stability of the closed VFT domain conformation in comparison to the situation in the absence of the nucleotide.

In recent work in the laboratories of Meyerhof and Hofmann, a series of 25 structural analogues of GMP were prepared by reaction of GMP with dihydroxyacetone and glyceraldehyde under Maillard Reaction type conditions (Festrings et al., 2011). Of the 25 compounds prepared, 12 were found to be more efficacious as MSG-enhancing PAMs than GMP itself. Exemplary of the GMP analogues studied are carboxyalkyl derivative **19** and carboxamidoalkyl derivative **20**, where in a T1R1/T1R3 cell-based assay, the shifts in the MSG C/R function observed were 2.9- and 3.2-fold larger, respectively, than that of GMP.

### 30.4.2 Agoenhancers as Modulators of the Umami Receptor

Concurrent with the discovery of the human sweetener receptor, the human umami receptor was discovered by Senomyx scientists (Li et al., 2002) thus enabling a marked acceleration of umami receptor agonist and PAM discovery. This program led to the discoveries of many MSG enhancers including compounds **21–24** shown in Figure 30.6 (Tachdjian et al., 2012), which now have regulatory approvals. Benzodioxole **21** was reported to exhibit an EC<sub>50</sub> of 200 nM in a T1R1/T1R3 cell-based assay and, when employed at 30 nM in the same assay, caused a 6.92 shift in the MSG C/R function. Oxalamides **22**, **23**, and

**Figure 30.6** Agoenhancer modulators of the human umami receptor.

**24** were reported to exhibit EC<sub>50</sub>s of 40, 90 and 30 nM, respectively. And **23** @ 300 nM, caused a 6.51 shift in the MSG C/R function. In a sensory panel assay, benzodioxole **21** @ 3  $\mu\text{M}$  was reported to provide an enhancement of 12 mM MSG taste equivalent to that enabled by 100  $\mu\text{M}$  IMP. And oxalamides **23** @ 1  $\mu\text{M}$  and **24** @ 0.3  $\mu\text{M}$  were reported to provide enhancements of 12 mM MSG taste equivalent to that enabled by 100  $\mu\text{M}$  IMP. Also, in sensory panel assays (Shigemura et al., 2012), oxalamides **23** at 1  $\mu\text{M}$  and **24** at 0.3  $\mu\text{M}$  were reported to be equal in umami taste intensity to 12 mM MSG.

### 30.4.3 Antagonists as Modulators of the Umami Receptor

It is not clear that there is a practical utility for a umami taste antagonist. Nonetheless, it is noteworthy to point out that lactisole, a known antagonist for sweet taste that binds in the TMD region of T1R3, is also an antagonist for umami taste (Xu et al., 2004). Based on studies in a T1R1/T1R3 cell-based assay and a human sensory study on MSG taste thresholds, lactisole was demonstrated to be a umami antagonist. Lactisole antagonist activity for MSG was also demonstrated at suprathreshold levels (Galindo-Cuspinera and Breslin, 2006).

### 30.4.4 Glycoconjugated Peptides as Modulators of the Umami Receptor

During the aging and/or cooking process, a reaction called the “Maillard reaction” occurs between reducing carbohydrate and amino acids. Maillard peptides (1000–5000 Da) generated during the aging of soy-pesto and soy-sauce affected not only basic taste qualities but also enhanced “Kokumi,” a sensation of mouthfulness and continuity. Naturally occurring Maillard peptides (1000–5000 Da) were purified from Korean soy sauce matured for four years. Alternately, Maillard peptides were synthesized by

conjugating a peptide fraction (1000–5000 Da) purified from soy protein hydrolysate with galacturonic acid, glucosamine, xylose, fructose, or glucose. In an *in vivo* assay using chorda tympani (CT) taste nerve response in rats, wildtype (WT) mice, and TRPV1 knockout (KO) mice, Maillard peptides were found to modulate salty taste and umami taste. At low concentrations (0.05 to 1%) Maillard peptides conjugated with galacturonic acid, glucosamine, and xylose, modulated the benzamil (Bz)-insensitive NaCl CT responses in a biphasic manner (Katsumata et al., 2008; see below). However, at concentrations above those which modulate the neural responses to salt taste, Maillard peptides conjugated with xylose (at 2.5%) enhanced the CT response to mono sodium glutamate (MSG). In these studies the CT response to MSG was monitored in the presence of Bz (a blocker of the epithelial Na<sup>+</sup> channel; ENaC) and SB-366791 (a blocker of TRPV1/TRPV1t non-specific cation channel) to eliminate the contribution of Na<sup>+</sup> to the CT response. As expected, in these studies IMP enhanced the CT response to glutamate, however, in the presence of IMP+Maillard peptides conjugated with xylose, the magnitude of the CT response to glutamate was less than additive relative to the CT response to IMP alone or Maillard peptides conjugated with xylose. In contrast, Maillard peptides conjugated with galacturonic acid or glucosamine did not modulate the CT response to glutamate (Katsumata et al., 2008). These results suggest that IMP and Maillard peptides conjugated with xylose produce their effects on the CT response to glutamate by acting on the umami receptor. In human sensory studies naturally occurring Maillard peptides have recently been shown to enhance umami taste (Rhyu et al., unpublished observations).

### 30.4.5 NGCC as a Modulator of the Umami Receptor

Surprisingly, N-geranyl cyclopropylcarboxamide (NGCC), a compound synthesized by International Flavors and

Fragrances, also has similar effects on salty and umami taste as Maillard peptides. At low concentration range (1–10  $\mu\text{M}$ ) it modulates NaCl+Bz CT responses in rats and WT mice in a biphasic manner (see below). Above 20  $\mu\text{M}$  NGCC enhanced the CT response to glutamate (Dewis et al., 2013). In human sensory evaluation, NGCC enhanced the saltiness of 80 mM NaCl at 5 and 10  $\mu\text{M}$  and enhanced the umami taste perception of chicken broth containing 60 mM Na<sup>+</sup>. However, in the CT studies and human sensory studies several structurally related compounds N-cyclopropyl E2, Z6-nonadienamide, N-geranyl isobutanamide, N-geranyl 2-methylbutanamide, and allyl N-geranyl carbamate did not mimic the effects observed with NGCC (Dewis et al., 2013). These studies raise the possibility that the umami receptor can interact with a very diverse and broad range of compounds and peptides.

## 30.5 MODULATORS OF SOUR TASTE

### 30.5.1 Taste Cell Subset in Sour Transduction

Sour taste reception is evoked by both organic and mineral acids and is mediated by a subset of taste receptor cells that contain characteristic transient receptor potential polycystic (TRPP) marker proteins, PKD2L1 and PKD1L3 (DuBois et al., 2008). PKD2L1 is found in Type III taste cells in both the fungiform papillae of the anterior tongue and the circumvallate (CV) papillae of the posterior tongue while PKD1L3 is confined to CV taste cells (Ishimaru et al., 2006; Huang et al., 2006). Type III cells make conventional synapses with afferent taste nerve fibers, so encoding for sour taste probably involves this cell type exclusively (Vandenbeuch and Kinnamon, 2009). Eliminating the subset of taste cells containing PKD2L1 in mice eliminates neural responses specifically to sour stimuli (Huang et al., 2006). Accordingly, it was hypothesized that PKD2L1 and PKD1L3 might be sour taste receptors. However, in mice lacking PKD2L1 expression, CT responses to acids from the anterior tongue were only partially inhibited while PKD1L3 suppression had no effect (Horio et al., 2011). Single and double knock-out mice gave glossopharyngeal nerve responses to acids from the posterior tongue that were not different from wild type mice (Horio et al., 2011). Overall these results indicate that PKD2L1 and PKD1L3 are reliable markers of sour-sensitive taste cells, PKD2L1 may have some role in sour transduction in fungiform taste cells, but neither PKD2L1 nor PKD1L3 plays a role in sour transduction in CV taste cells. Sour ageusia human subjects lack transcripts for PKD2L1 and PKD1L3 in their fungiform papillae cDNA suggesting that the taste cells expressing these proteins are also sour taste transducing cells in humans (Huque et al., 2009).

### 30.5.2 Stimulus Flow Rate Modulates Phasic and Tonic Sour Taste Responses

A CO<sub>2</sub>/HCO<sub>3</sub><sup>-</sup> buffer at pH 7.4 is a potent sour taste stimulus, as determined by its CT response in rats, in spite of its alkaline pH (Lyall et al., 2001). This itself is proof that stimulus extracellular pH is not directly related to sourness, a conclusion supported by diverse physiological and psychophysical studies for over a century (DeSimone et al., 2001; DeSimone and Lyall, 2006). When applied at a flow rate of 1 ml/s the response consists of a rapid phasic increase in neural activity followed by a slower decrease in response that asymptotically approaches a steady-state, the so-called tonic response level. This phasic-tonic character and its relation to stimulus flow rate have been previously noted for other taste qualities (Pfaffmann, 1955; Smith and Bealer, 1975; Lyall et al., 2001; Lyall et al., 2002a). At the slower flow rate of 1 ml/min the phasic response is notably absent (Lyall et al., 2001). Rather the initial response is a decaying exponential rise that nonetheless attains the same tonic steady state (DeSimone and Heck, 1980). The results suggest the phasic and tonic parts of the response occur by independent processes, perhaps in separate receptor cell types and mediated by different transduction mechanisms (Lyall et al., 2006; McCaughey, 2007).

### 30.5.3 Calcium Modulates the Tonic Response to Acids but not Phasic

Acidification of a subset of isolated taste cells is accompanied by an increase in intracellular Ca<sup>2+</sup> (Liu and Simon, 2001; Richter et al., 2003). The role of Ca<sup>2+</sup> was found to be confined to the tonic phase of the response (Lyall et al., 2006). Only the tonic part of the CT response in rat to HCl (Lyall et al., 2006), to a CO<sub>2</sub>/HCO<sub>3</sub><sup>-</sup> buffer (pH 7.4) and acetic acid (DeSimone et al., 2012) was blocked after treatment of rat tongue with BAPTA-AM, precursor to the Ca<sup>2+</sup> chelator, BAPTA. The tonic response to each acid could be restored by adding additional intracellular Ca<sup>2+</sup> (using the Ca<sup>2+</sup> ionophore, ionomycin) to exceed the Ca<sup>2+</sup>-buffer capacity of the sequestered BAPTA (DeSimone et al., 2012). These results suggest that an increase in intracellular Ca<sup>2+</sup> is necessary for transduction during the tonic response to all acids and that the phasic response occurs by a Ca<sup>2+</sup>-independent mechanism.

### 30.5.4 Cell Shrinkage Modulates the Phasic Response to Acids

Intracellular acidification causes rapid taste cell shrinkage independently of stimulus osmolarity and involves the conversion of taste cell cytoskeleton F-actin to G-actin which

is driven by a decrease in intracellular pH ( $\text{pH}_i$ ) (Lyall et al., 2006). This then activates flufenamic acid-sensitive shrinkage-activated nonselective cation channels in the basolateral membrane of the taste cells that permit a  $\text{Na}^+$  current to depolarize the cells yielding the phasic response (Lyall et al., 2006).

### **30.5.5 Mannitol and Cytochalasin B Modulate Cell Shrinkage/Phasic Response**

$\text{pH}_i$ -decrease-induced cell shrinkage can be modulated by preshrinking the cells by presenting the acid stimulus in a hypertonic medium (e.g., 0.5 M mannitol) or by disrupting the F-actin-G-actin equilibrium by pre-treating the tongue with cytochalasin B (Lyall et al., 2006). Following cytochalasin B pre-treatment stimulating the tongue with  $\text{CO}_2$  in hypertonic mannitol, the phasic response was virtually eliminated, while the tonic response was unaffected. Mannitol suppression of the phasic response was completely reversible. The suppressive effect of cytochalasin B could be reversed by subsequent treatment of the tongue with phalloidin (Lyall et al., 2006). Phalloidin stabilizes F-actin and, therefore, opposes the action of cytochalasin B leading to recovery of the phasic response. These results suggest that the phasic and tonic responses are pharmacologically separable and arise from distinct transduction mechanisms that very likely occur in separate receptor cell types (McCaughay, 2007).

### **30.5.6 Tonic Response Modulated by Cell NHE1: A Balance Between Acid Entry and Exit**

The sour tonic response level is proportional to the time-invariant decrease in  $\text{pH}_i$  achieved when the rate of acid equivalents entering the taste cells across their apical membranes is just balanced by acid efflux across their basolateral membranes. The manner in which acids enter the sour taste cells differs for weak and strong acids (see next section), but the mechanism by which taste cells remove acid from their cytosol is the same for all types of acid stimulation.

Protons are removed from the sour-sensing cells by the sodium-hydrogen exchanger isoform 1 (NHE1) (Lyall et al., 2004a; Vinnikova et al., 2004). Measurement of taste cell  $\text{pH}_i$  changes in isolated rat polarized fungiform taste buds shows that NHE1 activity increases with increasing intracellular  $\text{Ca}^{2+}$  (Lyall et al., 2004a). Thus increasing intracellular  $\text{Ca}^{2+}$  has two effects: it sustains the tonic response and also stimulates NHE1 to remove  $\text{H}^+$  ions from the cytosol. The final intracellular  $\text{Ca}^{2+}$  concentration achieved is, therefore, critical in determining the final tonic response level or the sour adaptation level. For each of three

acids: HCl,  $\text{CO}_2$ , and acetic acid treatment of rat tongue with ionomycin, a  $\text{Ca}^{2+}$  ionophore, allowed increased  $\text{Ca}^{2+}$  entry which in each case significantly suppressed the tonic response (Lyall et al., 2004a). That this suppression arises from  $\text{Ca}^{2+}$ -stimulated increased  $\text{H}^+$  efflux through basolateral membrane NHE1 was demonstrated by treating the tongue with zoniporide, a specific inhibitor of NHE1 activity (Lyall et al., 2004a). In each case the response was fully restored. These results suggest that irrespective of the acid, it is the *decrease in intracellular pH* that is the proximate driver of the sour CT response, and that the steady state level of intracellular pH is, in turn, determined by the balance of acid influx across sour taste cell apical membranes and acid efflux through  $\text{Ca}^{2+}$ -regulated NHE1 across taste cell basolateral membranes. Increasing proton influx across the apical membranes of taste cells using the  $\text{K}^+-\text{H}^+$  ion exchanger, nigericin shifted the pH threshold of observing a CT response by 2 pH-units in the alkaline direction, reinforcing the idea that a decrease in intracellular pH of sour-sensing cells is the proximate signal for sour taste transduction (Sturz et al., 2011).

### **30.5.7 NADPH Oxidase-and cAMP-linked Membrane Proton Channels Mediate Sour Transduction of Strong Acids**

Strong acids (e.g., HCl) are fully dissociated, so protons must be able to cross the apical membranes of taste cells through ion channels or other ion transporters. Recent evidence indicates that at least two types of proton channel mediate  $\text{H}^+$  entry into taste cells. One of these is an NADPH oxidase-dependent proton channel and another is a channel regulated by cAMP (DeSimone et al., 2011). An apical membrane proton conductance unique to PKD2L1-expressing taste cells has been demonstrated (Chang et al., 2010). That one or more proton channels actually do mediate strong acid sour transduction was confirmed by monitoring CT nerve responses. First, the response to HCl can be completely blocked by  $\text{Zn}^{2+}$ , a specific blocker of proton conductance, (DeCoursey, 2003; DeSimone et al., 2011) but not the response to the nearly undissociated acetic acid (DeSimone et al., 2011). Second, the response to HCl is voltage sensitive, and that sensitivity is also blocked by  $\text{Zn}^{2+}$  (DeSimone et al., 2011). The rat CT response to HCl (but not weak acids) is enhanced by the NADPH oxidase activators  $\text{H}_2\text{O}_2$ , PMA, and nitrazepam (DeSimone et al., 2011). Knock-out mice lacking the  $\text{gp}^{91\text{phox}}$  subunit of NADPH oxidase had CT responses to HCl that were diminished by 64% relative to wild type mice and were unaffected by  $\text{H}_2\text{O}_2$  (DeSimone et al., 2011). However, the remaining response was still inhibited by  $\text{Zn}^{2+}$  and significantly enhanced by treating

the KO mouse tongue with a membrane permeable cAMP analogue (DeSimone et al., 2011).

### 30.5.8 Modulation of CT Response by Zn<sup>2+</sup>: Distinguishing Weak and Strong Acid Transduction Mechanisms

The CT response to HCl can be blocked completely by Zn<sup>2+</sup> indicating that all of transduction depends on proton channels (DeSimone et al., 2011). None of the response to acetic acid or CO<sub>2</sub> is blocked by Zn<sup>2+</sup>, suggesting that proton channels play no role in transduction of acids that are primarily presented as lipid permeable neutral molecules (DeSimone et al., 2011). Phosphoric acid is an acid that has both strong and weak acid properties. At 20 mM, phosphoric acid at pH 2.3 is about 60% dissociated, that is, 60% of the acid behaves as a strong acid and 40% as a weak acid. Consistent with this about 65% of the response to 20 mM phosphoric acid was blocked by Zn<sup>2+</sup> (DeSimone et al., 2011). Therefore, phosphoric acid is both a strong and weak acid stimulus, a fact that suggests that its sour taste quality may vary strongly over a narrow pH range as transduction for it engages strong as well as weak acid mechanisms.

### 30.5.9 Carbonic Anhydrase (CA) Mediates CO<sub>2</sub> Sour Taste Transduction

Carbon dioxide mobilization is essential in regulating respiration and acid–base balance and not surprisingly various isoforms of carbonic anhydrase are found in cells throughout the body, which catalyze the conversion of CO<sub>2</sub> to bicarbonate or the reverse. Carbon dioxide rapidly diffuses across lipid bilayers, so the acid that stimulates sour taste receptors (carbonic acid), is formed inside the cells by carbonic anhydrase catalyzed hydration of CO<sub>2</sub>. This will result in a decrease in intracellular pH (Lyall et al., 2001) provided the bicarbonate, which is also formed, can be transported out of the cell. Consistent with this, CT responses in rat were inhibited when the rat tongue was treated with a membrane permeable carbonic anhydrase inhibitor (Lyall et al., 2001). The CT response to CO<sub>2</sub> was shown to be voltage-sensitive (Lyall et al., 2001) and both the CT response to CO<sub>2</sub> and its voltage sensitivity could be blocked by the bicarbonate transport inhibitor, 4,4'-diisothiocyanostilbene-2,2'-disulfonic acid (DIDS) (unpublished observation). This indicates that bicarbonate is removed by an electrogenic transporter in the taste cell apical membrane. Membrane bicarbonate transporters often form a metabalon by linking to both intracellular and extracellular forms of carbonic anhydrase (Sterling et al., 2002). This appears to be the case for taste cells which

have the extracellular carbonic anhydrase-IV (CAIV) in addition to intracellular forms of CA (Chandrashekhar et al., 2009).

It has been suggested that CAIV by itself acts as a CO<sub>2</sub> taste receptor by catalyzing the formation of H<sup>+</sup> in the apical extracellular solution and detecting it by an unspecified mechanism (Chandrashekhar et al., 2009). However, were that the mechanism CAIV knockout mice would not give a CT response to CO<sub>2</sub>. They give a reduced response, but only after treating the mice with a membrane permeable carbonic anhydrase inhibitor is the response completely inhibited. This supports the metabalon concept of CO<sub>2</sub> detection where the functional unit that is responsible for lowering intracellular pH by CO<sub>2</sub> is a bicarbonate transporter linking CAIV with an intracellular CA. CO<sub>2</sub> responses result from an intracellular pH decrease regulated by NHE1 just like other acids (Lyall et al., 2004a). Were H<sup>+</sup> formation and detection occurring in the apical extracellular space, NHE1 regulation would not be expected. Finally, responses to a buffer system in which CO<sub>2</sub>, HCO<sub>3</sub><sup>-</sup>, and H<sup>+</sup> are in chemical equilibrium are routinely recorded (Lyall et al., 2004a). A response is observed because CO<sub>2</sub> rapidly enters the taste cell interior where CO<sub>2</sub>, HCO<sub>3</sub><sup>-</sup>, and H<sup>+</sup> are not in equilibrium. This is the necessary condition that enables intracellular CA to accelerate the hydration of CO<sub>2</sub>. If CAIV were to make contact with and act exclusively on the stimulus solution as hypothesized (Chandrashekhar et al., 2009), then CAIV action cannot, by itself, account for the observed response to CO<sub>2</sub> buffers in equilibrium. Catalysts of any sort do not drive reactions when the component species are in chemical equilibrium. Thus the mechanism of Chandrashekhar et al. has the serious problem of violating the second law of thermodynamics. CAIV is important in CO<sub>2</sub> taste transduction, but it must function in concert with HCO<sub>3</sub><sup>-</sup> transport out of the taste cells and intracellular CA action.

## 30.6 MODULATORS OF SALT TASTE

Maintaining proper Na<sup>+</sup> balance is a survival challenge for many terrestrial mammals especially herbivores. The discovery of edible salts in the environment by Na<sup>+</sup> seeking mammals is made possible by salt taste receptors including one that is Na<sup>+</sup> specific. For humans salt taste is generally appetitive and only in recent times has dietary salt been available in large quantities. For these reasons people in developed countries often ingest far more salt than is required to maintain a normal Na<sup>+</sup> balance (Weinberger, 1996). In the USA the clinical and public health recommendations by the Institute of Medicine of the National Academies in 2010 are that Na<sup>+</sup> intake be no more than 2,300 mg/day for persons of two or more years of age.

Because of a lack in food flavor low  $\text{Na}^+$  diets are difficult to maintain and, therefore, do not work to lower  $\text{Na}^+$  intake over an extended period of time. For that reason the identification of the salt taste transduction mechanisms leading to possible discovery of natural and synthetic agonists of salt taste, could result in ways of making low  $\text{Na}^+$  diets more palatable by maintaining an acceptable sensation of salty at reduced dietary  $\text{Na}^+$  levels (Wenner, 2008).

In mammals at least two salt taste receptors have been characterized so far: one that is  $\text{Na}^+$  specific, and a second that does not discriminate among  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{NH}_4^+$ , and  $\text{Ca}^{2+}$ . The  $\text{Na}^+$ -specific receptor in fungiform Type I taste cells is the amiloride- and benzamil(Bz)-sensitive epithelial  $\text{Na}^+$  channel (ENaC) and is the predominant salt taste transducer in rats, many mice species and hamsters (DeSimone and Lyall, 2008; Chandrashekar et al., 2010). The non-specific salt taste receptor is amiloride- and Bz-insensitive, and is the predominant transducer of salt taste in some mammalian species, including humans (Ossebaard and Smith, 1995). The best evidence to date suggests that it is a constitutively active, non-selective cation channel that shares many similarities with TRPV1 (TRPV1t) (Lyall et al., 2004b). However, additional amiloride-insensitive salt taste receptors may be present in taste receptive fields apart from the anterior tongue (Treesukosol et al., 2007). Thus, modulators of ENaC and the putative TRPV1t in taste cells are, therefore, potential targets for modifying the taste of  $\text{Na}^+$ .

### 30.6.1 Modulators of ENaC-Dependent Salt Taste

**30.6.1.1 Osmolarity.** Rat chorda tympani (CT) responses to  $\text{NaCl}$  are reversibly enhanced in mixtures containing  $\text{NaCl}$  + hypertonic mannitol or cellobiose. Both the  $\text{NaCl}$  response and the subsequent enhancement in the presence of hypertonic  $\text{NaCl}$  stimulating solutions are blocked by amiloride (Lyall et al., 1999). This effect is most likely due to a sustained decrease in taste cell volume in hypertonic mannitol or cellobiose and the shrinkage-induced activation of ENaC.

**30.6.1.2 Intracellular pH.** Similar to other tissues, in taste cells ENaC is regulated by changes in intracellular pH ( $\text{pH}_i$ ). A decrease in taste cell pH inhibited, and an increase cell pH increased the Bz-sensitive  $\text{NaCl}$  CT response. Diethylpyrocarbonate and  $\text{Zn}^{2+}$ , modification reagents for histidine residues in proteins, attenuated the  $\text{pH}_i$ -induced inhibition of the Bz-sensitive  $\text{NaCl}$  CT responses (Lyall et al., 2002b).

**30.6.1.3 Intracellular Calcium.** In taste cells ENaC is regulated by changes in intracellular  $\text{Ca}^{2+}$

( $[\text{Ca}^{2+}]_i$ ). A decrease in taste cell  $[\text{Ca}^{2+}]_i$  enhanced and an increase  $[\text{Ca}^{2+}]_i$  inhibited the Bz-sensitive  $\text{NaCl}$  CT response. Since changes in  $\text{pH}_i$  show an inverse relationship with  $[\text{Ca}^{2+}]_i$  in a subset of taste cells, an increase in  $\text{pH}_i$  and the related decrease in  $[\text{Ca}^{2+}]_i$  may produce additive effects in increasing the Bz-sensitive  $\text{NaCl}$  CT response (Lyall et al., 2003).

**30.6.1.4 3'-5'-cyclic Adenosine Monophosphate (cAMP).** Increasing cAMP in taste cells directly by the topical lingual application of membrane permeable form of cAMP (8-(4-chlorophenylthio)-adenosine 3', 5'-cyclic monophosphate) enhanced the Bz-sensitive  $\text{NaCl}$  CT response (Lyall et al., 2011). Arginine vasopressin and cAMP also enhance currents through amiloride-sensitive ENaC in isolated hamster taste cells (Gilbertson et al., 1993). These results suggest that in taste cells ENaC and the amiloride-sensitive  $\text{NaCl}$  CT responses are regulated by the same hormonal intracellular signaling mechanisms found in other tight epithelia.

**30.6.1.5  $\text{Na}^+$ -Self Inhibition.** In taste cells topical lingual application of  $\text{Zn}^{2+}$  enhanced the Bz-sensitive  $\text{NaCl}$  CT response at low  $\text{NaCl}$  concentrations (DeSimone and Lyall, 2008).  $\text{Zn}^{2+}$  most likely enhances  $\text{NaCl}$  CT response by interfering with the  $\text{Na}^+$ -self inhibition of the ENaC in taste cells (Gilbertson and Zhang, 1998). Ouabain, a blocker of the  $\text{Na}^+-\text{K}^+$ -ATPase, inhibited the  $\text{NaCl}$  CT response (Lyall et al., unpublished observations). This suggests that the  $\text{Na}^+$ -self inhibition of the ENaC in taste cells is most likely involved in adaptation of the  $\text{NaCl}$  CT response.

**30.6.1.6 Channel Activating Proteases and Small Molecule Activators.** Treating the lingual surface with trypsin for 20 min enhanced the CT response to  $\text{NaCl}$ , suggesting that similar to other tissues, in taste cells ENaC activity is regulated by proteases (DeSimone and Lyall, 2008). A small molecule activator, N-(2-hydroxyethyl)-4-methyl-2-((4-methyl-1H-indol-3-yl)thio)pentanamide, that activates human ENaC (Lu et al. 2008) enhanced the rat Bz-sensitive  $\text{NaCl}$  CT response (Mummalaneni et al., 2014). This suggests that ENaC modulators can be useful in modulating salt taste in humans.

**30.6.1.7 Temperature.** Increasing the temperature from  $23^\circ\text{C}$  to  $30^\circ\text{C}$  enhanced the Bz-sensitive  $\text{NaCl}$  CT response. However, progressively increasing the temperature from  $30^\circ\text{C}$  to  $36.8^\circ\text{C}$  and above inhibited the Bz-sensitive  $\text{NaCl}$  CT response in a temperature-dependent manner (DeSimone and Lyall, 2008). This suggests that at temperatures above  $37^\circ\text{C}$  ENaC does not contribute significantly to salt taste perception.

### 30.6.2 Modulators of Putative TRPV1t-dependent Salt Taste

#### 30.6.2.1 TRPV1 Agonists and Antagonists.

The Bz-insensitive NaCl CT response is modulated by several agonists that also modulated TRPV1. To date all of the agonists tested have one property in common, that is, they modulate the Bz-insensitive NaCl CT response in a biphasic manner. At low concentrations they enhance and at high concentrations they inhibit the Bz-insensitive NaCl CT response. These agonists include resiniferatoxin, capsaicin, cetylpuridinium chloride, nicotine, ethanol, N-geranylcylopropylcarboximide, and both synthetic and naturally occurring glycoconjugated peptides (Katsumata et al., 2008). Both the constitutive Bz-insensitive NaCl CT response and its modulation by the above agonists are inhibited by TRPV1 blockers, capsazepine, and N-(3-methoxyphenyl)-4-chlorocinnamid and by high concentration of the above agonists (Lyall et al., 2004b). In contrast to the wildtype mice, the TRPV1 knockout mice (KO) demonstrate no constitutive Bz-insensitive NaCl CT response and the response remains at the rinse baseline level in the presence of the above agonists. Unlike TRPV1, the constitutive Bz-insensitive NaCl CT response is observed at room temperature, in the absence of an agonist, is pH-insensitive and is modulated by cetylpuridinium chloride, which is most likely not a TRPV1 agonist. This suggests that the Bz-insensitive NaCl CT response may be dependent upon a putative variant of TRPV1, TRPV1t (Lyall et al., 2004b). Although, the Bz-insensitive constitutive NaCl CT response is pH-independent, the relationship between pH and the agonist-induced increase in the neural response is bell shaped, with the maximum increase in the response being observed around pH 6.1.

Although in behavioral studies TRPV1 KO mice did not show significant differences in response to NaCl+amiloride relative to the wildtype mice (Treesukosol et al., 2007), both glycoconjugated peptides (Katsumata et al., 2008) and N-geranylcylopropylcarboximide (Dewis et al., 2013) modulate human salt taste perception. In alcohol-preferring (P) rats the Bz-insensitive NaCl CT response is spontaneously upregulated and further enhancing its magnitude by glycoconjugated peptide decreased consumption of 150 mM NaCl+Bz and NaCl preference relative to the control alcohol non-preferring (NP) rats (Coleman et al., 2011).

#### 30.6.2.2 Intracellular Calcium.

Similar to the ENaC-dependent NaCl CT response, the Bz-insensitive NaCl response is also modulated by changes in taste cell  $[Ca^{2+}]_i$ . A decrease in  $[Ca^{2+}]_i$  enhanced the constitutive Bz-insensitive NaCl CT response and shifted the relationship between the agonist concentration and the magnitude of the CT response upwards relative to control. Under

these conditions, no inhibition of the Bz-insensitive NaCl CT response was observed at high agonist concentrations. In contrast, increasing taste cell  $[Ca^{2+}]_i$  did not alter the constitutive Bz-insensitive NaCl CT response but attenuated the magnitude of the neural response at all agonist concentrations (Lyall et al., 2009). Altering the phosphorylation-dephosphorylation state of the putative TRPV1t in taste cells produced similar changes in the Bz-insensitive NaCl CT response in the absence and presence of resiniferatoxin. This suggests that changes in  $[Ca^{2+}]_i$  modulate the Bz-insensitive NaCl CT responses partly by altering the phosphorylation-dephosphorylation state of the putative TRPV1t channel (Lyall et al., 2009).

#### 30.6.2.3 Phosphatidylinositol 4, 5-bisphosphate (PIP<sub>2</sub>).

Increasing cell membrane PIP<sub>2</sub> levels by topical lingual application of U73122 (a non-specific blocker of phospholipase C) or direct application of DiC8-PIP<sub>2</sub> (a synthetic PIP<sub>2</sub>) not only inhibited the constitutive Bz-insensitive NaCl CT response but also attenuated the agonist-induced enhancement of the neural response. In contrast, decreasing cell membrane PIP<sub>2</sub> levels by the topical application of phenylarsine oxide (a blocker of PI<sub>3</sub> kinase) enhanced both the constitutive Bz-insensitive NaCl CT response and the agonist-induced enhancement in the neural response (Lyall et al., 2010). Under these conditions no inhibition of the neural response was observed at high agonist concentrations.

#### 30.6.2.4 Temperature.

Increasing the temperature of the NaCl stimulating solutions progressively from 36°C to 43°C, enhanced the Bz-insensitive NaCl CT response in a dose-dependent manner. However, above 43°C the magnitude of the neural response was attenuated relative to 43°C (Lyall et al., 2004b; DeSimone and Lyall, 2008). In mixtures containing NaCl+Bz and varying resiniferatoxin concentrations, the relationship between temperature and magnitude of the neural response was higher and shifted to lower temperatures. This suggests that both temperature and resiniferatoxin produce additive effects on the Bz-insensitive NaCl CT response.

In summary, many intracellular signaling effectors and agonists of ENaC and putative TRPV1t channel in the anterior taste receptive field that modulate the Bz-sensitive and Bz-insensitive neural responses are potential targets for developing safe and effective salt taste enhancers that can help reduce salt intake in humans.

## 30.7 CONCLUSIONS

In conclusion, molecular biochemical methods have revolutionized the chemosensory sciences providing answers

to long standing questions regarding the transduction mechanisms of the five basic qualities. These techniques, supplemented by electrophysiology and pharmacology, will play an important role in the further investigation of sensory properties such as taste adaptation and taste modulation. Subtle, but important, integrative effects such as the modulation of the time necessary to extinguish a primary taste response by properties of the rinse solution, such as ionic strength, can now be understood as a coupling of physical and primary biochemical events at the taste bud level. It is through such integrative effects that primary tastes may be modulated in the taste periphery, combining to create temporal effects that influence overall flavor perception.

## ABBREVIATIONS

AMP	adenosine monophosphate
APM	aspartame
Bz	benzamil
CHO	carbohydrate
CT	chorda tympani
GPCR	G Protein-Coupled Receptor
DIDS	4,4'diisothiocyanostilbene-2,2'-disulfonic acid
ENaC	epithelial Na <sup>+</sup> channel
CAIV	extracellular carbonic anhydrase-IV
GA	glycyrrhizic acid
GRKs	G Protein Receptor Kinases
GMP	guanosine monophosphate
HTS	high-throughput-screening
HP	high-potency
IMP	inosine monophosphate
IP3	inositol trisphosphate
IP3R	inositol trisphosphate receptor
pHi	intracellular pH
Rm	maximal response
MSG	monosodium glutamate
NAMs	negative allosteric modulators
NGCC	N-geranyl cyclopropylcarboxamide
NSB	non-specific binding
REBA	Rebaudioside A
PTC	phenylthiocarbamide
PA	Phosphatidic acid
PIP2	Phosphatidylinositol 4, 5-bisphosphate
PROP	6-propyl-2-thiouracil
PAMs	Positive Allosteric Modulators
NHE1	sodium-hydrogen exchanger isoform 1
SG	steviol glycoside
STV	Stevioside
SAR	Structure-Activity-Relationships

SWA	sweet water aftertaste
tbc	taste bud cells
TRPP	transient receptor potential polycystic marker proteins
VFT	Venus Fly Trap

## The Molecular Basis of Gustatory Transduction

STEVEN D. MUNGER and WOLFGANG MEYERHOF

### 31.1 INTRODUCTION

The initial stage of taste perception is the detection and transduction of taste stimuli within the oral cavity. These stimuli are generally nonvolatile and are components of foods. They engage specific detection mechanisms present in taste cells of the gustatory epithelium to trigger cellular changes that result in neural signals being sent to the brain. Over the last two decades, key components of the taste transduction apparatus have been identified, including many of the receptors, ion channels, and intracellular signaling molecules that couple stimulus detection to an electrochemical response (Yarmolinsky et al., 2009). In this chapter, we will discuss a number of the important findings that have illuminated the molecular basis of gustatory transduction in mammals as well as the implication of these findings for understanding how we make sense of what we choose to ingest or reject.

Taste stimuli have long been grouped according to the perceptual qualities they elicit in humans. The existence of sweet, bitter, sour, and salty tastes has been universally accepted for years. More recently, umami taste (the savory taste of glutamate) has gained broad acceptance as a fifth taste quality (Beauchamp, 2009). Fat, calcium, starch, and even water have been suggested to elicit distinct taste perceptions, but each remains controversial to different degrees (Bachmanov and Beauchamp, 2007). Prior to the identification of many of the molecular components of taste transduction mechanisms, a clear understanding of the strategies used by mammals to detect and encode different types of taste stimuli remained elusive.

Organizational principles of taste processing in the gustatory epithelium are now being defined, at least in part as a result of our growing understanding of the molecular basis of taste transduction (Yarmolinsky et al., 2009). Although they will be discussed in greater detail below, these principles include: (1) stimuli that elicit the same perceptual quality are detected by the same receptor or by a family of closely related receptors; (2) taste receptors that mediate different taste qualities do so because they are segregated into distinct taste cell subpopulations that are dedicated (“tuned”) to a single taste quality. This latter characteristic of the taste system was most clearly demonstrated in mice engineered to express a specific human bitter receptor, called T2R16, in either of two populations of taste cells (Mueller et al., 2005): one that normally express sweet taste receptors, and another that normally express bitter taste receptors. Wild-type mice are indifferent to the cognate agonists of T2R16,  $\beta$ -glucopyranosides, although humans find these compounds to be extremely bitter (Bufo et al., 2002). However, mice in which T2R16 was expressed in bitter taste cells acquired strong avoidance of  $\beta$ -glucopyranosides, whereas mice in which T2R16 was expressed in sweet taste cells found this normally innocuous stimulus to be highly appetitive (Mueller et al., 2005). Thus, while the receptor type dictates the stimulus selectivity of a particular taste cell, it is the cell itself (presumably because of its particular connections to the nervous system) that dictates the *meaning* of the stimulus (i.e., sweet, bitter, umami, salty, or sour). Data such as these also illustrate that the rapid advances in molecular biology, genetics, and genomics has not only allowed

researchers to identify the molecular components of the taste transduction apparatus, but has revealed basic principles of taste coding in the periphery that can help us to understand why both sugars and artificial sweeteners taste sweet, why we have trouble discriminating most bitter stimuli, and even why umami should be considered a distinct taste quality.

## 31.2 TASTE RECEPTORS AND TRANSDUCTION MECHANISMS

The molecular mechanisms employed by mammals to detect and transduce taste stimuli vary with the taste quality they elicit. Sweet, bitter, and umami stimuli bind to different G protein-coupled receptors (GPCRs; each expressed in different subpopulations of taste cells) (see Table 31.1), but engage similar intracellular signaling cascades (Bachmanov and Beauchamp, 2007; Yarmolinsky et al., 2009). These GPCR-mediated transduction mechanisms will be discussed later in this section. Salty and sour stimuli, by contrast, seem to require ion channels as their primary means of detection (Bachmanov and Beauchamp, 2007; Yarmolinsky et al., 2009).

### 31.2.1 Ion Channels as Taste Receptors

**31.2.1.1 Salt Taste.** Sodium chloride is the prototypical salt stimulus, although many other salts have a salty taste (e.g., sodium gluconate, KCl, LiCl) (DeSimone and Lyall, 2006). NaCl is appetitive to mammals at concentrations below  $\sim$ 150 mM, but becomes aversive at higher concentrations (Duncan, 1962). This complex response likely reflects the fact that while sodium is an important nutrient that we must obtain from the environment, the ingestion of high concentrations of sodium and other salts (such as in seawater) can lead to severe dehydration, kidney damage and death. The concentration-dependent differences in the hedonic quality of sodium salts as well as the chemically diverse array of salty-tasting compounds suggest multiple mechanisms for the detection of salty stimuli. This indeed appears to be the case.

**EPITHELIAL SODIUM CHANNELS (ENaCs) AND SODIUM TASTE** The recognition that mammalian taste responses to NaCl were sensitive to the diuretic amiloride offered a pharmacological clue to the identity of the sodium salt sensor (DeSimone et al., 1981; Schiffman et al., 1983; Heck et al., 1984; Brand et al., 1985). Amiloride was known to inhibit sodium transport across membranes, and was later found to act on a broadly expressed type of  $\text{Na}^+$ -selective channel known as the epithelial sodium channel (ENaC; a.k.a., sodium channel non-neuronal 1,

Scnn1) (Canessa et al., 1993, 1994). The ENaCs are multimeric channel complexes typically composed of  $\alpha$ ,  $\beta$ , and  $\gamma$  subunits (although the  $\alpha$  subunit is replaced by a related  $\delta$  subunit in some human tissues); all three subunits are required for full channel function (Kashlan and Kleyman, 2011). But while the physiological properties of sodium taste, including the sensitivity to amiloride, are consistent with a role for ENaCs, the evidence was not definitive. For example, amiloride has effects on molecular targets other than ENaCs including acid-sensing ion channels (ASICs) and  $\text{Na}^+ \text{-H}^+$ -exchangers. Furthermore, ENaCs are found in many tissues (Kashlan and Kleyman, 2011), begging the question of whether the expression of ENaC subunits in taste buds is indicative of a specialized taste role. A more direct test of the role of ENaCs in sodium taste would be to delete one of the subunits in mice and assess the impact on taste function. However, because ENaC gene deletions result in embryonic lethality, such assessments awaited a conditional knockout strategy that could largely restrict the deletion to taste buds. This was recently achieved by deleting the *Scnn1a* gene (which encodes ENaC $\alpha$ ) in cells expressing a marker for mature taste cells, cytokeratin 19. Mice lacking ENaC $\alpha$  in taste cells exhibited no amiloride-sensitive sodium taste responses in behavioral assays or in chorda tympani nerve recordings (Chandrashekhar et al., 2010). Remarkably, these mice retained an amiloride-insensitive NaCl response as well as normal responses to other salts and to sweet, umami, bitter, and sour stimuli (Chandrashekhar et al., 2010). Furthermore, NaCl-sensitive, ENaC $\alpha$ -expressing taste cells comprise a distinct subpopulation of taste bud cells, indicating that they are dedicated sodium sensors (Chandrashekhar et al., 2010). Although it has taken nearly 30 years and a multitude of approaches, a primary role for ENaCs in the detection and transduction of sodium salts is now firmly established.

**MEDIATORS OF AVERSIVE SALT TASTE** Both the taste of non-sodium salts and the aversive taste of high concentrations of sodium salts appear to rely on one or more ENaC-independent mechanisms. ENaCs are highly selective for  $\text{Na}^+$  and  $\text{Li}^+$ , but not  $\text{K}^+$ . The ENaC blocker amiloride inhibits chorda tympani responses and raises the detection threshold for NaCl but not KCl (Heck et al., 1984; Spector et al., 1996; Geran et al., 1999; Geran and Spector, 2000; Eylam and Spector, 2003). Furthermore, mice lacking a functional ENaC channel in taste cells retain behavioral and chorda tympani nerve responses to NaCl (albeit only for higher concentrations) and KCl (Chandrashekhar et al., 2010). The exact molecular identity of the ENaC-independent salt taste mechanism(s) is unknown. One candidate, a splice variant of the capsaicin-sensitive transient receptor potential V1 (TRPV1) ion channel, has been suggested based on the observation that this channel can be amplified from taste

**Table 31.1** Symbols for human and mouse bitter taste receptor genes approved by Hugo Gene Nomenclature Committee and International Committee on Standardized Genetic Nomenclature for Mice, along with any previous aliases (adopted from Behrens and Meyerhof, 2011).

tissue and amiloride-insensitive salt taste electrophysiological responses are reduced or eliminated in TRPV1 knockout mice (Lyall et al., 2004; Treesukosol et al., 2007). However, these same mice show normal behavioral responses to NaCl and KCl in the presence or absence of amiloride (Ruiz et al., 2006; Treesukosol et al., 2007), casting doubt on the necessity of the TRPV1 channel for amiloride-insensitive salt taste responses. More recent studies suggest that both non-sodium salts and high concentrations of sodium salts activate sour and bitter-sensitive taste cells in an amiloride-independent manner (Oka et al., 2013). Even so, the molecular basis of aversive salt taste transduction remains unknown.

**31.2.1.2 Sour Taste.** The information conveyed by sourness is not clear, but may indicate spoilage or a lack of ripeness. In any case, sour is predominantly an aversive taste. Most sour-tasting stimuli are acids. However, the proximate stimulus for sourness remains controversial. One model holds that a proton conductance contributes directly to cellular depolarization of sour-sensing taste cells. Support for this model includes the identification of a proton conductance specifically expressed in sour-sensing taste cells that can lead to cellular depolarization and the generation of action potentials (Chang et al., 2010). By contrast, other studies favor a role for intracellular acidification of

signaling proteins in sour-sensing taste cells (Lyall et al., 2001; Huang et al., 2008). The observation that weak acids (e.g., acetic acid) are perceived as more sour than strong acids (e.g., HCl) at the same concentration (Taylor, 1928) suggests that sourness is not strictly dependent on  $H^+$  concentration. In fact, both mechanisms may contribute to sour taste: strong acids (which are fully dissociated in solution) may depolarize sour-sensing taste cells via the conductance of extracellular protons, while weak acids may diffuse through taste cell membranes before acidifying proteins that influence cellular physiology.

Although a number of candidates for sour taste sensors have been suggested, the molecular basis of sour taste remains unclear (Bachmanov and Beauchamp, 2007). One of the most intriguing candidates has been a TRP-family channel composed of the subunits polycystic kidney disease 2L1 (PKD2L1) and PKD1L3 (Huang et al., 2006; Ishimaru et al., 2006; LopezJimenez et al., 2006). The PKD2L1 subunit is certainly expressed in most, if not all, sour-sensitive cells, as genetic ablation of the PKD2L1-expressing taste cell population in mice disrupts sour taste behavioral and electrophysiological responses (Huang et al., 2006). However, while PKD2L1 is a marker of sour taste cells, it appears unlikely that this channel is the sour taste sensor itself. For example, while PKD2L1 requires coexpression with PKD1L3 to confer acid sensitivity in heterologous cells (Ishimaru et al., 2006), PKD1L3 is not expressed in PKD2L1-expressing fungiform or palatal taste buds (Huang et al., 2006; Ishii et al., 2009). Furthermore, electrophysiological studies in heterologous cells indicate that the PKD2L1-PKD1L3 channel is activated by the removal, not the application, of acids (Inada et al., 2008). Finally, sour taste responses are unaffected by deletion of the *Pkd1l3* gene and only partially reduced in mice lacking the *Pkd2l1* gene (Nelson et al., 2010; Horio et al., 2011).

While the search continues for the primary detector of sour stimuli, a specialized mechanism appears to mediate the sour taste of  $CO_2$  (Lyall et al., 2001). Sour-sensitive cells express the membrane-associated, extracellular carbonic anhydrase, Car4.  $CO_2$ -dependent activation of sour taste cells (identified by their expression of PKD2L1) requires Car4 (Chandrashekhar et al., 2009), which likely mediates sour taste by catalyzing the conversion of  $CO_2$  and water to bicarbonate and  $H^+$ , thus increasing the local proton concentration.

### 31.2.2 G Protein-Coupled Taste Receptors

**31.2.2.1 Sweet and Umami Taste.** The primary value of food is the nutrients it provides. The gustatory system plays a critical role in sampling the nutrient content of foods before we ingest them. As described above,

amiloride-sensitive salt taste is critical for assessing the sodium content of foods. Similarly, sweet and umami taste are essential for the detection of certain carbohydrates and amino acids. Sweet-tasting stimuli include a number of mono- and disaccharides (e.g., glucose, fructose, galactose, sucrose, maltose, lactose) commonly found in many fruits, vegetables, and dairy products. Certain amino acids, including d-phenylalanine and glycine, also have a sweet taste. For humans, umami stimuli include l-glutamate, and the 5'-ribonucleotides inosine monophosphate and guanosine monophosphate. These substances are commonly found in fish, meat, fermented foods (e.g., cheeses) and certain fruits and vegetables (e.g., tomatoes, mushrooms). Although sweet and umami stimuli exhibit great chemical diversity, it is now established that these two taste qualities both rely on Class C GPCRs for recognition by the gustatory system.

**TYPE 1 TASTE RECEPTORS (T1RS)** Driven by the nutritional value of sugars and the structural diversity of the various sweet tasting substances—including mono- and disaccharides, amino acids, peptides, proteins, plant secondary metabolites as well as various types of synthetic substances—there have been numerous attempts to identify and characterize the receptors responsible for sweet taste. Based on structure activity relationships, Shallenberger and Acree developed the acid-hydrogen-base model in which appropriately spaced hydrogen donor and acceptor were thought to form the receptors' active site (Shallenberger and Acree, 1967). Although refined several times, the model failed to explain sweetness of large molecules or of molecules with flexible structures, leading to the assumption that different types of sweet receptors exist. This assumption was reinforced by structure-activity investigations, human psychophysical experiments and nerve recordings using various sweeteners (Faurion, 1987). Only recently, sophisticated molecular biological studies and mining of genome databases allowed for the identification of the sweet taste receptor as well as the structurally and functionally related umami receptor.

Vertebrate genomes contain a small family of genes (*TAS1Rs* in humans, *Tas1rs* in rodents) that encode three GPCRs known as type 1 taste receptors (T1Rs): T1R1, T1R2, and T1R3 (Hoon et al., 1999; Vigues et al., 2009; Yarmolinsky et al., 2009). The *Tas1R3* gene is expressed in a subset of taste bud cells in all three types of gustatory papillae as well as in the palate (Kitagawa et al., 2001; Max et al., 2001; Montmayeur et al., 2001; Nelson et al., 2001; Sainz et al., 2001). Rodent T1R3-expressing cells often coexpress either T1R1 (in fungiform and palatal taste buds) or T1R2 (in foliate, vallate, and palatal taste buds), suggesting that T1Rs, like some other class C GPCRs, function as heterodimers. Indeed, heterologous expression studies indicate that T1R3 must be coexpressed with either

T1R1 or T1R2 to produce a fully functional umami or sweet receptor, respectively (Nelson et al., 2001, 2002; Li et al., 2002). Thus, sweet and umami receptors contain one common subunit (T1R3) and one specific subunit (T1R1 or T1R2). Both the sweet and umami receptors are activated by quite high agonist concentrations (>10 mM) as compared to typical GPCRs, with their dose-response function matching the nutritionally relevant concentration range of carbohydrate and amino acid stimuli. This relatively low efficacy is consistent with the proposed roles of these receptors as nutrient detectors that prevent animals from wasting time on foods with insufficient caloric or nutritional content.

**The sweet taste receptor** The sweet taste receptor, T1R2–T1R3, responds in functional receptor assays to mono- and disaccharides but also to all other sweet tasting compounds tested (Vigues et al., 2009; Behrens and Meyerhof, 2011). The role of T1R2 and/or T1R3 in sensing sweeteners is strongly supported by various independent lines of evidence (Chandrashekhar et al., 2006; Vigues et al., 2009). First, T1R3 corresponds to *Sac*, a locus in the mouse genome that determines differences in sweet taste sensitivity across strains of mice (Bachmanov et al., 2001). Second, a “non-taster” strain of mouse has been rescued to respond with exquisite sensitivity to sweet substances by transgenic expression of the “taster” T1R3 variant (Nelson et al., 2001). Third, knockout mice with eliminated *Tas1r2* and/or *Tas1r3* genes show largely diminished or abolished gustatory responses to a number of tested sweet stimuli (Damak et al., 2003; Zhao et al., 2003). Fourth, differences in T1R2–T1R3 agonist profiles across species establish interspecies sweet taste differences (Li et al., 2002; Xu et al., 2004). This is impressively demonstrated in cats, which are obligatory carnivores. Cats do not sense sweet stimuli and do not make a functional sweet taste receptor due to pseudogenization of the *Tas1r2* gene (Li et al., 2005). A similar correlation of defective *Tas1r* genes with diet is seen in other carnivores including the giant panda, vampire bat, otter, and sea lion (Zhao et al., 2010; Jiang et al., 2012). Moreover, the chicken genome lacks *Tas1r2* while frogs possess no *Tas1r* genes at all, thus predicting that these species will have vastly different responses to sweeteners and amino acids as compared with humans and rodents (Shi and Zhang, 2009). Depending on species, bony fish do have 1–4 functional *Tas1r* genes. In cell-based receptor assays, both fish T1R1–T1R3 and fish T1R2–T1R3 responded to amino acids but not sugars (Oike et al., 2007), suggesting that ancestral T1Rs were tuned to detect amino acids and evolution only later brought about T1R2-type receptors for sugars. Intriguingly, human and rodent T1R2–T1R3 is sensitive to the amino acids glycine and l-alanine, highlighting its evolutionary origin (Behrens et al., 2011). In addition, interspecific sequence

differences in functional *TAS1R* genes are associated with both differences in the agonist profiles of the sweet receptors and phenotypic variation in sweet taste perception. For example, sweet proteins and aspartame, both of which taste sweet to humans but to which rodents are “taste-blind,” are effective agonists for human but not rodent T1R2–T1R3 receptors (Li et al., 2002).

Although T1Rs have not been crystallized and diffracted, combinations of various experimental strategies have provided some insights into their structure-function relationship. These approaches include computational structure prediction and ligand-docking methods, analysis of mutated receptor subunits in heterologous expression systems, and biochemical/biophysical characterization of recombinant amino-terminal domains (Li, 2009; Vigues et al., 2009; Behrens et al., 2011; Servant et al., 2011). As typical class C GPCRs, T1Rs possess a heptahelical transmembrane domain that is connected by a cysteine-rich domain (CRD) to a large amino-terminal venus flytrap domain (VFTD). This VFTD consists of two lobes separated by a hinge region. The transmembrane domain, CRD and VFTD are each able form ligand binding sites. Orthosteric binding of agonists can occur in the VFTD of all T1R protomers, thereby switching the VFTD from inactive ‘open’ to active ‘closed’ configurations. Biophysical measurements of the purified recombinant VFTDs indicates that sucrose, saccharose, and glucose bind to the VFTD of both the T1R2 and T1R3 protomers (Nie et al., 2005). By contrast, analyses of chimeric receptors indicates that the amino acid derivatives aspartame and neotame bind only to T1R2 (Xu et al., 2004), while neoculin, a pH-sensitive, sweet-tasting protein, interacts primarily with the VFTD of T1R3 (Koizumi et al., 2007).

The T1R2–T1R3 receptor is also a target of allosteric agonists and modulators. The sweet tasting proteins monellin and brazzein interact with the CRD of T1R3 (Jiang et al., 2004), while the sweet agonists neohesperidin dihydrochalcone and cyclamate and the sweet taste inhibitor lactisole bind to an overlapping set of amino acids that form an allosteric binding pocket in the TMD of T1R3. This latter site of agonist/inhibitor binding is consistent with the observations that cyclamate and lactisole modulate the activity of both T1R1–T1R3 and T1R1–T1R3 (Xu et al., 2004). Finally, researchers have recently synthesized several small molecule positive allosteric modulators that bind, in an agonist-specific fashion, close to orthosteric sugar binding site in the VFTD of T1R2 (Servant et al., 2010; Zhang et al., 2010a,b). The presence of these modulators synergistically enhances activity of the sweet receptor dimers (Servant et al., 2011).

**The umami taste receptor** The T1R1–T1R3 receptor shares a number of functional properties with human and rodent umami/amino acid taste, making it the top candidate

to mediate this taste quality. In heterologous expression assays, the human variant of T1R1–T1R3 is narrowly tuned to l-glutamate; by contrast, several l-amino acids stimulate the rodent receptor (Li et al., 2002; Nelson et al., 2002). The activity of the glutamate-bound T1R1–T1R3 is further enhanced by the simultaneous presence of the 5'-ribonucleotides IMP, AMP or GMP (Li et al., 2002; Nelson et al., 2002; Li, 2009). The importance of T1R1–T1R3 for umami taste is further supported by the observation that mice in which the *Tas1r1* and/or *Tas1r3* genes have been deleted show little to no response to umami stimuli (the extent to which umami responses are lost in *Tas1r* knockouts continues to be the subject of debate; see below). Analogous to the orthosteric binding site for sugars on the sweet taste receptor, glutamate binds to the hinge region of the VFTD in T1R1. This binding induces the ‘closed’ configuration and subsequent receptor activation. The VFTD of T1R1 also contains the allosteric binding site for 5'ribonucleotides: IMP binds within the VFTD, adjacent to the binding site for glutamate, where it acts to stabilize the closed conformation (Zhang et al., 2008).

While a dominant role for T1R1–T1R3 in umami taste is undisputed, other receptors have been suggested to contribute (Chaudhari et al., 2009; Yasumatsu et al., 2009). For example, while one group of studies finds that umami taste responses are completely abolished in T1R3 knockout mice (Zhao et al., 2003), others find residual taste responses to glutamate (Yasumatsu et al., 2012). These residual glutamate responses are unresponsive to ribonucleotide synergism and predominantly associated with taste nerves innervating the posterior tongue. Leading candidates for T1R-independent umami taste receptors include isoforms of the metabotropic glutamate receptors (mGluRs), which, like T1Rs, are Class C GPCRs. Evidence supporting a role for mGluRs in umami taste includes the expression of two isoforms, mGluR1 and mGluR4, in taste cells and the ability of mGluR-active pharmacological agents on glutamate-induced taste responses. The fact that umami stimuli are weakly appetitive in mice has probably contributed to the difficulty in clearly defining the full repertoire of glutamate-responsive receptors involved in the detection of umami tastants. This continues to be an area of active investigation.

**31.2.2.2 Bitter Taste.** Bitterness is believed to indicate the presence of potential toxins in food. In fact, numerous toxins elicit a bitter taste (Meyerhof, 2005). Strong bitter taste is highly aversive and causes food rejection. Compared with sweet and umami taste stimuli, which only elicit taste responses in the millimolar range, bitter stimuli are perceived over a broad range reaching from millimolar to upper nanomolar concentrations (Meyerhof et al., 2010). This high sensitivity means that food

contaminated with very low concentrations of some bitter compounds, including the highly toxic strychnine and aristolochic acid, will be rejected. By contrast, food containing less potent bitter substances that are less toxic or nontoxic, such as glycosides, can still be consumed. In this way, vital calories can be consumed even though the foods in which they are found may be tolerably spoiled with harmful substances. Despite their potential toxicity, humans and other animals adapt to bitter compounds and tolerate or even prefer some bitterness in their diets (Drewnowski, 2001). Thus, adaptation can be considered another way to enable organisms to ingest calories despite the presence of acceptable amounts of harmful substances or of repulsive but otherwise harmless compounds. Bitter compounds are often of plant origin but are also produced during food processing or from animal sources (Drewnowski, 2001). Bitter substances are numerous and ubiquitous and of amazing structural diversity, observations that led to the early proposal that multiple receptors mediate bitter detection (Belitz and Wieser, 1985; DuBois et al., 2008). This proposal was supported by psychophysical experiments showing cross-adaptation for some bitter compounds but not for others (McBurney et al., 1972). Cross-adapting bitter substances were thought to activate the same receptor, whereas the absence of cross-adaptation suggested that the test substances used different bitter receptors. The observation that some genetic loci determine bitter sensitivity to specific bitter compounds in mice was also in agreement with the existence of several bitter receptors (Lush and Holland, 1988). Finally, this assumption was fully supported by molecular biology approaches involving data base mining, mouse genetics, expression analysis and demonstration of receptor function *in vitro* that identified a family of GPCRs expressed in taste cells and responsive to bitter stimuli (Adler et al., 2000; Chandrashekhar et al., 2000; Matsunami et al., 2000).

**TYPE 2 TASTE RECEPTORS (T2RS)** Bitter taste receptors are encoded by a small GPCR gene family called type 2 taste receptors (*TAS2Rs* in human or *Tas2rs* in rodents, encoding the T2Rs). The *TAS2R/Tas2r* nomenclatures are confusing because these receptors have been cloned independently and simultaneously in several laboratories and have been subjected to nomenclature changes several times (Behrens and Meyerhof, 2011). Humans possess 25, and mice 35, functional bitter taste receptor genes, which are present in clusters at only a few chromosomal loci. Segregating pseudogenes and copy number variations create interindividual variability in the number of *TAS2R* genes per human genome (Kim et al., 2005; Pronin et al., 2007; Roudnitzky et al., 2011); similar events may have occurred in other species. Moreover, numerous single nucleotide polymorphisms in the *TAS2R* genes predict considerable functional diversity for the encoded receptors,

thus accounting for population differences in bitterness perception. The clearest example of such differences is provided by the *TAS2R38* gene, which encodes two major receptor variants: a fully functional one, T2R38-PAV (with proline, alanine and valine at amino acid positions 49, 262 and 296, respectively), and a non-functional variant, T2R38-AVI (with alanine, valine and isoleucine at those positions). PAV carriers are sensitive to the bitter tasting compounds phenylthiocarbamide, propylthiouracil and similar thiourea compounds, whereas homozygotes for the AVI variant display virtually no perception of these bitter chemicals (Kim et al., 2003b; Bufe et al., 2005). Similar observations have also been made for the genes encoding T2R9, T2R16, T2R31, and T2R43, suggesting that genetically determined differences in bitter taste perception are widespread (Soranzo et al., 2005; Pronin et al., 2007; Dotson et al., 2008; Roudnitzky et al., 2011). These genetic differences in T2Rs may shape preferences for foods and beverages or affect other phenotypical properties including alcohol consumption, glucose homeostasis, colorectal cancer, longevity, eating behaviors, or even responsiveness to bitter-tasting pharmaceuticals (Hinrichs et al., 2006; Dotson et al., 2008, 2009, 2012; Carrai et al., 2011; Clark et al., 2012).

While T2Rs are GPCRs, they differ considerably in sequence from, and lack the signatures of, other GPCR subfamilies (Meyerhof et al., 2011). T2Rs are quite small (only 290–330 amino acids), but are encoded by genes containing a single open reading frame. They are characterized by very short amino-termini and are glycosylated at a highly conserved asparagine-linked glycosylation site in the extracellular loop 2 (GPCRs are more typically glycosylated within the amino terminus). Glycosylation of T2Rs is required for proper folding and maturation. T2Rs generally require the addition of amino terminal plasma membrane targeting sequences or coexpression with various auxiliary proteins to facilitate their functional expression in heterologous cells (Chandrashekhar et al., 2000; Bufe et al., 2002; Behrens et al., 2006; Ilegems et al., 2010). This suggests that such factors are active in native taste receptor cells and required for proper T2R expression.

Expression studies in heterologous cells have revealed key functional properties of T2Rs. Humans possess at least three very broadly tuned T2Rs, each sensitive to about one-third, and together recognizing ~50%, of ~100 tested bitter substances (Meyerhof et al., 2010). The cognate agonists for these receptors exhibit amazing structural diversity, making it impossible to identify common structural features required for T2R activation. Eight T2Rs exhibit intermediately broad and moderately overlapping agonist spectra (Meyerhof et al., 2010). Again, no common structural motifs responsible for receptor activation have been identified. By contrast, seven T2Rs are narrowly tuned to a very few (1–3) compounds. However, two T2Rs

do show predictable ligand selectivity: T2R38 responds to with a  $-N=C=S$  moiety, while T2R16 responds to  $\beta$ -glucopyranosides (Bufo et al., 2002; Bufo et al., 2005; Meyerhof et al., 2010). Together, these response properties explain how countless and structurally diverse bitter tasting chemicals can be recognized.

Despite their generally broad tuning, T2Rs do respond quite specifically to their cognate agonists. For example T2R16 is sensitive to  $\beta$ -gluco- and mannosides, whereas  $\alpha$ -glucopyranosides and galactosides fail to activate this receptor (Bufo et al., 2002). Similarly, whereas many sesquiterpene lactones activate T2R46, others do not even though they differ only slightly in structure from the agonists (Brockhoff et al., 2007). These properties likely account for pronounced differences in bitterness between structurally similar chemicals, such as between the bitter tasting phenyl- $\beta$ -D-glucopyranoside and the non-bitter phenyl- $\beta$ -D-galactopyranoside.

Each T2R recognizes its cognate compounds with different potencies and efficacies (Meyerhof et al., 2010). Potency and efficacy ranking can be moderate to extreme. For example, various glucopyranosides differ only about 20-fold in potency and little in efficacy for T2R16 activation. By contrast, aristolochic acid ( $EC_{50} \approx 80$  nM) and acesulfame K ( $EC_{50} \approx 10$  mM) demonstrate a  $\sim 10^6$ -fold difference in potency and a substantial difference in efficacy at T2R43, making the former a full agonist and the latter only a weak partial agonist. Finally, potencies for of a single agonist can vary across receptors. Denatonium benzoate, for example, activates T2R47, T2R10, and T2R46 with  $EC_{50}$  values of 0.27, 120, and 240  $\mu$ M, respectively. Thus, a given receptor could make a major contribution to the bitterness of one compound and only a minor contribution to the bitterness of another.

Genes encoding T2Rs are found in numerous species (Shi and Zhang, 2009). Surprisingly, gene numbers vary largely across species, ranging from only three in chicken to 49 in clawed frog. This broad range in *TAS2R* number could reflect differences in the poisonous load of food or the efficacy of detoxification mechanisms across species. In other words, some species might require only restricted protection against food intoxication and thus relatively few bitter taste receptors. Alternatively, T2Rs in species with few genes could all be broadly tuned to numerous substances whereas those in species with many genes could include more narrowly tuned receptors. In this latter case, different species could have comparable bitter perception despite having different numbers of *TAS2R* genes. Finally, it must be considered that, although the numbers of genes are known, the numbers of functional receptors remains unclear. Human T2Rs can oligomerize (Kuhn et al., 2010), suggesting that the 25 *TAS2R* gene products could result in 325 different heterodimeric receptors (or even more if higher oligomeric structures are adopted). However,

the functional significance of the oligomers has not been determined.

Bitter taste inhibitors are now being reported. Based on sensory experiments in humans, bitter taste masking substances have been identified (Ley, 2008). Certainly, such compounds could optimize the taste of some foods and beverages. However, the T2Rs targeted by these substances have never been identified. The first T2R-specific antagonist, 4-(2,2,3-trimethylcyclopentyl) butanoic acid, or GIV3727, was isolated by screening a synthetic compound library for molecules suppressing saccharin-activation of T2R31 in a cell-based assay (Slack et al., 2010). This molecule acts in the micromolar range as a competitive antagonist. The observation that GIV3727 prevents the activation of T2R31 by all of its agonists reinforces the notion that T2Rs possess only a single agonist binding pocket. GIV3727 also blocks the activation of five other T2Rs by their cognate agonists. The drug probenecid, which is used in certain cell assays, has also been implicated as an inhibitor of certain T2Rs, including T2R16 and T2R38 (Greene et al., 2011). Interestingly, several natural compounds from edible plants also have been identified as T2R antagonists with properties similar to those of GIV3727 (Brockhoff et al., 2011). As animals and humans usually have numerous compounds present in the mouth during chewing, it is likely that T2R antagonists are often present. Thus, the normal presence of bitter blocking agents could regularly impact the bitterness of foods. Moreover, the presence of bitter blockers in food likely shaped the molecular evolution T2Rs. The existence of multiple T2Rs with partially overlapping ligand spectra ensures protection against a complete block of bitter perception and potentially fatal outcomes (Brockhoff et al., 2011).

The amazing responsiveness of some T2Rs to many structurally diverse compounds has prompted a number of studies addressing the question of how T2Rs accommodate their agonists. Traditional receptor binding studies are problematic because of low predicted affinities and relatively poor expression in heterologous cells. Instead, studies have relied on computational structure prediction and agonist docking and on functional expression of wild type and mutated receptors. One such study focused on the closely related receptors T2R31, T2R43, and T2R46, which, despite high sequence similarities, demonstrate unique agonist spectra (Brockhoff et al., 2010). It was reasoned that amino acids that differ in the receptors could mediate interactions with the respective cognate ligands. Indeed, such residues have been identified in T2R46 by mutation and functional expression. Transfer of these few amino acid residues that impaired agonist responsiveness of T2R46 to the same positions in T2R43 or T2R31 switched the agonist spectra of the recipient receptors to that of the donor receptor, providing strong evidence for

the existence of a single binding pocket for all agonists. Essentially the same conclusions were drawn from similar studies on T2R16 and T2R38 (Biarnes et al., 2010; Sakurai et al., 2010). Computational studies predict that the T2R binding pockets are formed by residues within the transmembrane helices, even though differences are apparent regarding the specific transmembrane (TM) regions that contribute. Whereas residues of TM III and TM VI form the binding site of T2R38, residues of TM III, TM V, and TM VI are responsible in T2R16 and residues of TM II, TM III, TM V, and TM VII assemble the binding pocket in T2R46. Not only do the TMs that form the binding pockets differ across receptors but the amino acid residues that interact with agonists vary. Only a single residue, N<sup>3,36</sup>, appears to be involved in agonist interaction in all three of these T2Rs. In marked contrast to these studies, another mutational study on T2R31 and T2R43 found evidence for agonist specific interactions of amino acid residues in the extracellular loop I (Pronin et al., 2004). At present this apparent disparity cannot be resolved but could be due to differences in experimental techniques or agonists. Alternatively, extracellular loop residues could regulate the access of some agonists to the binding pocket or, when mutated, result in overall conformational changes that impact agonist-dependent activation.

Whereas the variable residues in the upper, extracellularly-directed parts of the TM bundle appear to interact with ligands, conserved residues in the lower, intracellularly-directed regions have been suggested to participate in T2R activation. Experimental support for this idea has been obtained in studies of T2R1 and T2R4, results from which suggested a network of interhelical hydrogen bonds that stabilize the receptors in the inactive conformation (Singh et al., 2010; Pydi et al., 2012). Disruption of this network through mutation or agonist binding would thus be part of a receptor activation mechanism.

### **31.2.2.3 Other GPCRs Expressed in Taste Cells.**

Other GPCRs, including GPR40, GPR120 and the calcium-sensing receptor (CaSR), have been described in the gustatory system (San Gabriel et al., 2009; Cartoni et al., 2010; Galindo et al., 2011). GPR40 and GPR120 are sensitive to stimulation with medium and long-chain fatty acids and have been implicated to mediate a chemosensory component of fat detection and in preference for fatty acids (Cartoni et al., 2010; Galindo et al., 2011). Indeed, GPR40 knockout mice and GPR120 knockout mice show diminished preferences for linoleic acid and oleic acid and attenuated nerve responses to several fatty acids. The CaSR is not only activated by calcium ions but also by amino acids, glutathione and so-called kokumi peptides (Ohsu et al., 2009; Maruyama et al., 2012). Kokumi, also referred to as mouthfeel or richness, appears to be a sensation

that enhances the classical sweet, salty and umami taste perception. Although under debate and requiring further research, these receptors may play modulatory roles in gustation rather than mediating separate taste qualities.

### 31.3 TRANSDUCTION OF SWEET, UMAMI AND BITTER TASTE STIMULI

Although they are segregated in different subsets of taste cells, sweet, umami and bitter taste receptors employ very similar signal transduction pathways (Zhang et al., 2003). Agonist activation of both T1Rs and T2Rs leads to stimulation of heterotrimeric G proteins, activation of effector enzymes, release of  $\text{Ca}^{2+}$  from intracellular stores, gating of ion channels in the plasma membrane, cellular depolarization and neurotransmitter release.

#### 31.3.1 G Proteins

Several G protein  $\alpha$ -subunits have been implicated in mammalian taste transduction. The most compelling evidence supports a role for the  $\text{G}\alpha_{i/o}$  family protein  $\alpha$ -gustducin in bitter, sweet and umami taste. Alpha-gustducin is closely related to  $\alpha$ -transducin, the G protein subunit that is essential for phototransduction in the vertebrate retina. Originally isolated from bovine taste epithelia (McLaughlin, 1992),  $\alpha$ -gustducin is expressed in almost all T2R-expressing taste cells (Adler et al., 2000) and in a subset of T1R-expressing cells. It is clear that  $\alpha$ -gustducin plays a critical role in bitter taste transduction: T2Rs functionally couple to  $\alpha$ -gustducin (Chandrashekhar et al., 2000) and  $\alpha$ -gustducin knockout mice have vastly diminished bitter responses (Wong et al., 1996). Residual bitter taste responses in these mice may be due to the ability of other G protein  $\alpha$ -subunits to partially compensate for  $\alpha$ -gustducin. In particular,  $\alpha$ -transducin, which is also expressed in taste cells, may contribute to bitter taste responses (He et al., 2002; Ozeck et al., 2004).

Alpha-gustducin knockout mice are also compromised in their sweet and umami responses (Glendinning et al., 2005), albeit to a lesser extent than for bitter responses. These differences, and the observation that sweet taste is less affected than umami taste in  $\alpha$ -gustducin knockouts, may reflect a more variable and regionally restricted coexpression with T1Rs (Kim et al., 2003a). Other G proteins likely also play important roles in these appetitive responses. One candidate is  $\text{G}\alpha_{14}$ , which is coexpressed with T1R3 on the posterior tongue (Shindo et al., 2008; Tizzano et al., 2008). However, verification of a role for  $\text{G}\alpha_{14}$  in sweet and umami responses must await studies in mice lacking this subunit.

Specific G protein  $\beta$  and  $\gamma$  subunits have also been implicated in taste transduction. Specifically, both  $\beta 3/\gamma 13$

or  $\beta 1/\gamma 13$  complexes have been identified in taste cells and implicated in taste transduction (Huang et al., 1999). As will be discussed below, it is these  $\beta/\gamma$  subunits that act to stimulate effector enzyme activity that is critical to taste transduction.

#### 31.3.2 Enzymes and Second Messengers

Sweet, bitter and umami stimuli are transduced via a phosphoinositide-dependent signaling cascade (Yarmolinsky et al., 2009). Upon activation of T1R and T2R receptors by taste ligands, the associated heterotrimeric G proteins will dissociate and the  $\beta/\gamma$  subunits can act to stimulate the plasma membrane-associated enzyme phospholipase C  $\beta 2$  (PLC $\beta 2$ ) (Rossler et al., 1998; Huang et al., 1999). PLC $\beta 2$  can then cleave the membrane phospholipid phosphatidylinositol 4,5-bisphosphate (PIP<sub>2</sub>) into two second messengers: diacylglycerol and inositol 1,4,5-trisphosphate (IP<sub>3</sub>). The actions of diacylglycerol in taste cells are not clear. However, IP<sub>3</sub> is thought to open type III IP<sub>3</sub> receptors (IP<sub>3</sub>R3) on the endoplasmic reticulum (Clapp et al., 2001), thus releasing  $\text{Ca}^{2+}$  from intracellular stores and elevating cytoplasmic  $\text{Ca}^{2+}$  concentrations (Akabas et al., 1988; Hwang et al., 1990). The obligatory role of PLC $\beta 2$ -mediated signaling in sweet, bitter and umami taste was confirmed by studies in PLC $\beta 2$  knockout mice (Zhang et al., 2005). In the absence of PLC $\beta 2$ , mice do not behaviorally differentiate sweeteners, amino acids or bitter tastants from water, nor do they exhibit electrophysiological responses in chorda tympani nerve recordings. However, overexpression of PLC $\beta 2$  under the control of a T2R gene promoter can rescue bitter, but not sweet or umami, responses.

Even so, sequence similarities between  $\alpha$ -gustducin and  $\alpha$ -transducin had suggested that taste stimuli might also influence cyclic nucleotide signaling in taste cells (McLaughlin et al., 1992). Indeed, biochemical measurements of membrane preparations obtained from taste tissues indicated that both sweet and bitter stimuli regulate cAMP levels *in vitro* (Yan et al. 2001; Striem et al., 1989). However, the functional relevance of this second messenger remains unclear. An intriguing possibility is that cAMP modulates the PLC $\beta 2$ -mediated transduction cascade, perhaps by regulating protein kinase A-dependent phosphorylation of IP<sub>3</sub>R3 or PLC $\beta 2$  (Chaudhari and Kinnamon, 2008).

#### 31.3.3 Effector Channels

The IP<sub>3</sub>-mediated elevation of intracellular  $\text{Ca}^{2+}$  is not sufficient to elicit neurotransmitter release. Rather, this  $\text{Ca}^{2+}$  response must be coupled to membrane depolarization. In taste cells, this occurs through the  $\text{Ca}^{2+}$ -gating of

the transient receptor potential channel isoform TRPM5, which is expressed in sweet, bitter and umami-sensitive taste cells (Perez et al., 2002; Zhang et al., 2003). This channel is selective for monovalent cations and activated by micromolar concentrations of intracellular  $\text{Ca}^{2+}$  (Hofmann et al., 2003; Liu and Liman, 2003). Separate analyses from two different lines of TRPM5 knockout mice have arrived at slightly different conclusions about the role of TRPM5 in sweet, bitter and umami taste transduction. One group found that taste electrophysiological responses (recordings from the chorda tympani and glossopharyngeal nerves) and behavioral responses to sugars, amino acids and bitter tastants were completely abolished in mice lacking TRPM5 (Zhang et al., 2003), indicating that TRPM5 is required for sweet, bitter and umami taste transduction. By contrast, others have reported that while TRPM5 deletion causes significant functional impairment, some taste responses (primarily at the level of nerve activity) remain (Damak et al., 2006). Simultaneous experiments in both mouse lines are needed to resolve these discrepancies. Even so, it is clear that TRPM5 is required for normal taste responses to sweet, bitter and umami stimuli.

### 31.4 NEUROTRANSMITTERS AND NEUROPEPTIDES

While taste receptor cells are excitable, they are not neurons and do not send afferent projections to the central nervous system. Rather, these taste cells must communicate with cranial nerve fibers innervating the taste bud, and it is these nerves that will carry taste information from the taste bud to the gustatory areas of the brainstem. Unfortunately, the neurochemical mechanisms of intercellular communication within the taste bud are anything but simple (Yarmolinsky et al., 2009; Chaudhari and Roper, 2010). First, there are at least two different types of synaptic communication between taste cells and afferent nerve fibers. One cell population (largely comprised of sour-sensitive cells) exhibits typical presynaptic endings containing synaptic vesicles, while a second population (the sweet, bitter and umami-sensitive cells) does not contain obvious presynaptic modifications. Second, there is extensive evidence for paracrine signaling between cells within individual taste buds. Finally, taste buds express a large number of classical, non-classical and peptide neurotransmitters. Because of this neurochemical complexity, making sense of neurotransmission in the taste bud has been a challenge.

A major breakthrough came with the identification of adenosine triphosphate (ATP) as a major neurotransmitter in taste buds. Based on the observation that the purinergic receptors P2X<sub>2</sub> and P2X<sub>3</sub> are localized to taste nerves in rat (Bo et al., 1999), taste responses were assessed in P2X<sub>2</sub>/P2X<sub>3</sub> double knockout mice (Finger et al., 2005).

Chorda tympani and glossopharyngeal nerve responses to stimuli of all taste qualities were completely abolished in these mice. However, behavioral responses were not as clear: while sweet, umami and salty stimuli were ineffective, sour and some bitter (i.e., quinine hydrochloride) showed residual responses. Subsequent studies demonstrated that mice use additional orosensory systems to recognize acids and quinine HCl: these stimuli also activate the superior laryngeal nerve in the P2X<sub>2</sub>/P2X<sub>3</sub> knockout mice (Ohkuri et al., 2012). ATP release is not vesicular, but rather occurs through hemichannels in response to an elevation of intracellular  $\text{Ca}^{2+}$  and membrane depolarization (Huang and Roper, 2010). Several membrane channels have been implicated at the ATP release channel in taste cells. The leading candidate is the voltage-sensitive ion channel calcium modulated homeostasis 1 (CALHM1); deletion of this channel in mice results in the loss of sweet, bitter and umami taste (Taruno et al., 2013). However, there is also experimental support for both connexin and pannexin hemichannels in these functions (Huang et al., 2007; Romanov et al., 2007; Huang and Roper, 2010; Romanov et al., 2012). The mechanistic details of purinergic neurotransmission in the taste bud are yet to be fully understood.

Although ATP plays the primary role in the communicating taste information from taste cells to afferent nerves, both it and other small molecule neurotransmitters are found in taste buds and have been implicated in intercellular signaling. For example, serotonin, norepinephrine and  $\gamma$ -aminobutyric acid (GABA) are released by sour-sensitive cells (Obata et al., 1997; Huang et al., 2008a,b, 2009, 2011; Cao et al., 2009; Dvoryanchikov et al., 2011). Acetylcholine, on the other hand, is released from cells that respond to sweet, bitter or umami stimuli (Ogura, 2002; Dando and Roper, 2012). The primary targets of all of these neurotransmitters are taste cells themselves. Autocrine and/or paracrine signaling through these neurotransmitters (and perhaps others) provides the opportunity to modulate taste cell function and thus shape the output of the taste bud before signals are transmitted to afferent nerves.

Taste buds also express a large number of peptides that may serve as autocrine, paracrine or endocrine signals. These include glucagon (Elson et al., 2010), glucagon-like peptide-1 (GLP-1) (Shin et al., 2008), neuropeptide Y (NPY) (Zhao et al., 2005), vasoactive intestinal peptide (VIP) (Shen et al., 2005), cholecystokinin (CCK) (Shen et al., 2005) and ghrelin (Shin et al., 2010). When produced in the stomach or intestine, these peptides serve as satiety signals or regulators of metabolism. While the precise roles of these peptides in taste coding remain unclear, immunohistochemical and behavioral studies have contributed some intriguing insights. For example, GLP-1 and glucagon are produced in partially-overlapping subpopulations of taste cells that also express the sweet and umami receptor

subunit T1R3 (GLP-1 is also found in a subset of serotonergic taste cells), and genetic and/or pharmacological disruption of GLP-1 or glucagon signaling in mice results in reduced sweet taste responsiveness in behavioral assays (Shin et al., 2008; Elson et al., 2010). Cognate receptors for GLP-1 are found on cranial nerve fibers closely apposed to taste cells, while glucagon receptors are expressed on the same cells that produce the glucagon peptide (Shin et al., 2008; Elson et al., 2010). Thus, these peptides may function as local signals to modulate the processing of sweet taste signals within the taste bud and to communicate this information to afferent nerve fibers. However, it cannot be ruled out that peptides produced in the taste bud serve as endocrine signals, entering the bloodstream to act at distant sites. Similarly, the peptide receptors present in taste buds may be targeted by hormones released from the gut or other organs, thus allowing peripheral taste function to be regulated in the context of the body's nutritional needs or metabolic state. Indeed, both the anorectic peptide hormone leptin, which is produced by fat cells, and the appetite-stimulating endocannabinoids, can act on their cognate receptors expressed on taste cells to reciprocally modulate sweet taste responses (Niki et al., 2010).

### 31.5 TASTE TRANSDUCTION MOLECULES OUTSIDE THE TASTE SYSTEM

Although  $\alpha$ -gustducin, TRPM5, T1Rs and T2Rs were discovered in the taste system, it took little time to find that these molecules are not taste specific. Indeed, there is growing evidence for the expression of "taste transduction" molecules throughout the gastrointestinal (GI) and respiratory systems (and perhaps other tissues, as well). The first extraoral cells found to express  $\alpha$ -gustducin were brush cells of the stomach and intestine (Hofer et al., 1996). Subsequently, evidence of  $\alpha$ -gustducin expression (at the message and/or protein level) was found in populations of gut enteroendocrine cells, pancreatic islets, solitary chemoreceptors of the nasal cavity and upper airways, ciliated respiratory epithelia and airway smooth muscle (Behrens and Meyerhof, 2011). Similarly, T1R1, T1R2 and/or T1R3, as well as numerous T2Rs, are reported expressed in many of these same cell types (Behrens and Meyerhof, 2011). TRPM5 expression has particularly been described in brush cells of the GI tract and solitary chemosensory cells of the respiratory epithelium (Bezencon et al., 2008).

In most cases, direct evidence supporting an extragustatory function of these proteins is circumstantial at best. Exceptions include enteroendocrine L cells, pancreatic  $\beta$  cells, and solitary chemosensory cells, where experimental support for the roles of T1Rs,  $\alpha$ -gustducin and/or

TRPM5 is more robust. The use of knockout mice lacking  $\alpha$ -gustducin, T1R2 or T1R3 have shown that both this G protein and the sweet taste receptor play critical roles in coupling the detection of luminal glucose (and other sweet-tasting compounds) to the secretion of the incretin hormone glucagon-like peptide-1 (GLP-1) (Jang et al., 2007; Geraedts et al., 2012), the regulation of glucose absorption (Margolskee et al., 2007), and the maintenance of glucose homeostasis (Jang et al., 2007; Geraedts et al., 2012). The sweet taste receptor is also implicated the modulation of insulin secretion from pancreatic  $\beta$  cells: T1R2 knockout mice are deficient in fructose-potentiation of glucose-stimulated insulin secretion (Kyriazis et al., 2012), while islets from T1R3 knockout mice display slowed kinetics of insulin granule fusion (Geraedts et al., 2012). Finally,  $\alpha$ -gustducin and TRPM5 knockout mice lack the acyl-homoserine lactone-induced respiratory changes seen in wildtype animals, presumably due to a functional loss in the solitary chemosensory cells of the respiratory epithelium that express these proteins (Tizzano et al., 2010).

### 31.6 SUMMARY/CONCLUSIONS/IMPLICATIONS

The great advances made over the last two decades in dissecting the molecular basis of taste transduction have already led to surprising insights into the way we detect and respond to tastes and nutrients. For example, the identification of the T1R and T2R families of taste receptors has allowed researchers to employ high throughput systems to screen thousands of natural and synthetic compounds for their ability to activate or inhibit receptor function. Indeed, candidate sweet taste enhancers and bitter taste blockers have already been identified based on their actions on taste receptors expressed in heterologous systems (Servant et al., 2010; Slack et al., 2010; Zhang et al., 2010). These compounds, or ones like them, could be important tools in combating obesity (by reducing the amount of sugar needed to achieve sweetness in processed foods) or increasing tolerance for pharmaceuticals (by blocking the bitter taste of many common drugs). The identification of taste receptors and taste transduction molecules has also provided researchers with important tools needed to begin to tease apart the neural strategies for stimulus, quality and hedonic coding by the peripheral and central gustatory system and to better assess the contribution of specific taste functions to ingestive behaviors and post-ingestive responses (Sclafani, 2006; Simon et al., 2006; Fernstrom et al., 2012). And of course, the observations that receptors and other transduction molecules first identified in the gustatory epithelium may also play significant physiological roles in other tissues could have a far-reaching impact on how we understand diverse physiological and

pathophysiological responses to diverse chemostimuli such as ingested nutrients, inhaled pathogens and the metabolites of symbiotic microorganisms found throughout the body (Yarmolinsky et al., 2009; Behrens and Meyerhof, 2011; Clark et al., 2012). In these ways, and many others, investigations into the molecular basis of taste transduction promises to stimulate important research for years to come.

---

## Central Taste Anatomy and Physiology of Rodents and Primates

THOMAS C. PRITCHARD and PATRICIA M. DI LORENZO

### 32.1 INTRODUCTION

Our understanding of the mammalian gustatory system, though incomplete, has grown tremendously over the last 15–20 years. Rodents and nonhuman primates have been among the many species that have served as animal models over this period, but it is interesting that they have played almost complementary roles in this common effort. Most of what is known about the hindbrain has been obtained from rodents; in the forebrain, primate research has prevailed, but the balance is rapidly shifting to rodents. Many reviews have been written about the anatomy and physiology of the rodent and primate gustatory systems; few have attempted to present this information in a side-by-side fashion. Juxtaposing the data from rodents and primates, level by level, from the periphery through frontal cortex, is revealing. For all of the differences between the two species, the similarities are more striking.

### 32.2 GUSTATORY NEURAL CODING: THE BASICS

A prerequisite to any discussion of gustatory neural coding is an understanding of how taste responses are measured. These methods are common to electrophysiological studies directed at single fibers of peripheral nerves as well as evoked activity in individual neurons in the central nervous system. The basic data provided by these analytical techniques forms the foundation for all theories of gustatory neural coding as well as our understanding of how the sense of taste supports ingestive behavior.

### 32.2.1 Response Intervals and Sensory Confounds

The chemical senses of gustation and olfaction analyze peripheral stimulation that usually lasts several seconds. Excitatory responses are most common, but the time course is quite variable. Some gustatory evoked responses are coincident with the application of the sapid stimulus; others stop before or after taste stimulation has ceased. Gustatory responses usually begin with a phasic burst of action potentials followed by a sustained period of activity that exceeds the cell's or fiber's average spontaneous rate. The fluctuating nature of taste responses makes the determination of the response interval – the time period during which the response is analyzed – a critical decision. Most investigators count the number of action potentials during a fixed time interval (~3–5 sec.), beginning at the moment of stimulus onset and including the period when the sapid stimulus bathes the tongue. After subtracting the cell's spontaneous rate from the response evoked by the tastant, the resultant net increase or decrease in activity reflects the response attributable solely to the taste stimulus. Because many if not most taste-responsive cells also respond to tactile or thermal stimuli (Ogawa et al., 1988; Halsell et al., 1993), a more conservative approach is to apply distilled water or artificial saliva to control for potential tactile or thermal stimulation. Subtracting the firing rate during the water (or saliva) presentation from the response evoked by sapid stimulus yields the net or corrected taste response. The decision to correct for spontaneous rate or water depends on the response characteristics of the neurons under investigation. When neurons respond to the topical flow of fluids, *per se*, it is problematic to use water or

saliva to correct for thermal and tactile sensitivity (Rosen et al., 2010a; McDonald et al., 2012; de Araujo et al., 2003a).

### 32.2.2 Temporal and Ensemble Coding

Calculating the average firing rate over the predetermined response interval assumes that the nervous system also averages neural activity across time. Use of the average response rate across time ignores the temporal fluctuations of action potentials that carry as much or more information than the average firing rate (brainstem: Chen et al., 2011; Di Lorenzo and Victor, 2003, 2007; Di Lorenzo et al., 2009a; Roussin et al., 2008, 2012; gustatory cortex (GC): Katz et al., 2001; Stapleton et al., 2006). The recognition that spike tempo can convey taste information has spawned a subspecialty of sensorineural analysis known as temporal coding. Sole reliance on spike count also precludes analysis of the potential contribution of synchronized or coordinated neural activity to the coding of taste. This is important. Katz et al. (2002) and Stapleton et al. (2007) have reported that taste quality information in the GC of rats is coded by neuron ensembles.

### 32.2.3 Stimulus Selection

Electrophysiologists design experiments knowing that they have only a limited time to test the chemical sensitivity of the neurons they isolate. When large stimulus arrays are used, it is unlikely that all of the chemicals can be tested before electrical isolation is lost. Use of a small stimulus set makes it likely that testing can be completed, but it limits the scope of the experiment. These completing issues make choice of the stimulus array a vitally important decision, one that will not only affect data interpretation, but also whether the goals of the experiment can be achieved.

Depending on the questions that are asked, some investigators have tested as few as four tastants, while others have examined more than a dozen. Investigators who opt for just a few stimuli always include representatives of the four “basic” taste qualities: salty (NaCl or N), sweet (sucrose/glucose or S/G), sour (HCl or H), and bitter (QHCl or Q). With increasing evidence that monosodium glutamate (MSG) represents a fifth primary taste quality (umami or savory; Yarmolinsky et al., 2009), many investigators now include MSG in their stimulus battery. Larger stimulus arrays may include amino acids (e.g., alanine, glycine), organic and inorganic salts, sugars, artificial sweeteners, and even chemicals such as oils and lipids whose status as gustatory stimuli is being actively debated (Gilbertson et al., 1998). Today, the search and even the meaning of what constitutes a primary taste quality is being

assisted by molecular biological tools that have provided detailed descriptions of taste receptors and the enzymatic cascades that transduce taste stimuli. Knowledge about the receptor proteins to which tastants bind in order for gustatory transduction to take place will inevitably expand and refine the criteria for defining primary taste qualities.

After the chemical array has been selected, the concentration of each stimulus must be chosen. Again, because of the limited time for testing, many electrophysiological studies have tested each chemical at only one concentration. The chosen concentration usually lies in the mid-range of the concentration-response function obtained from either a multi-neuron or multi-fiber recording; not surprisingly, individual neurons may vary considerably from the population average. The response demographics of individual neurons, as well as between-neuron analyses (e.g., breadth of tuning, interneuronal response correlations, multidimensional analyses), depend on the choice of tastants and their concentration(s). In short, stimulus choice has a profound influence on how we interpret the organization of the nervous system and its strategy for coding taste quality.

### 32.2.4 Quality Coding – Within or Across Neurons?

The collective taste literature over the last half century shows that the majority of gustatory neurons at every level of the neuraxis respond to exemplars of more than one taste quality. Despite sharing this common trait, the breadth of tuning across the four or five basic taste qualities, as well as the relative sensitivity to one taste quality over others, varies widely. This diversity is seen in the chorda tympani (CT) and glossopharyngeal (GP) nerves which convey gustatory information to the caudal brainstem. It is telling that the theories of taste coding based on peripheral nerve recordings have been applied without modification to taste responsive neurons in the central nervous system.

In early work on single axons of the CT nerve, it was shown that the taste stimulus which evokes the most vigorous response was a good predictor of the relative response magnitudes of the stimuli representing the other taste qualities (Frank, 1973). The heuristic value of the best stimulus analysis is reflected in the fact that it forms the basis for the labeled line theory, which is really a working hypothesis that axons and neurons convey qualitative taste information about only the most effective (or best) stimulus. Thus, NaCl-best cells encode saltiness, sucrose-best cells encode sweetness, and so on, while “sideband” responses to the second or third most effective stimuli are irrelevant and represent neural noise. A corollary to the labeled line theory is that each group of cells identified by their best stimulus represents a separate neuron type. This argument has been buttressed by observations that manipulations such as sodium

deprivation (Contreras, 1977; Contreras and Frank, 1979; Scott and Giza, 1990), conditioned taste aversion learning (Chang and Scott, 1984), taste adaptation (Di Lorenzo and Lemon, 2000; Smith et al., 1996), and sex hormones (Di Lorenzo and Monroe, 1989, 1990) affect one class of best stimulus neurons, but not others, in predictable ways. These studies demonstrated that the best stimulus classification system is relevant to taste-guided behavior, and by extension, give credence to the assertion that members of each best stimulus group are the neural messengers for their signature taste quality.

In contrast to the labeled line theory, investigators have proposed that the responses of the entire population to all stimuli, including the sideband responses, contribute to the neural code for taste quality (Erickson, 2008). Because the majority of taste-responsive cells respond to more than one stimulus, each tastant generates a unique pattern or envelope of spike activity across the neural population. This inclusive view of quality coding defines the across neuron (or fiber) pattern (ANP or AFP) theory of taste quality coding. The ANP theory (actually, another hypothesis) gathers support from studies showing that similar tasting stimuli evoke comparable (i.e., positively correlated) patterns of activity across the population of fibers (or neurons) under study (Doetsch and Erickson, 1970). More recent variants of the ANP theory propose that taste quality is coded by the pattern of responsiveness across a subset of cells (Lemon and Smith, 2006).

Recent studies have provided data that support a partial merging of the labeled line and the AFP/ANP theories. These studies blocked transduction of NaCl with the Na<sup>+</sup> channel blocker amiloride and then recorded the electrophysiological response evoked by topical application of NaCl to the tongue. Although some reports concluded that amiloride blockade only affects NaCl responses in NaCl-best neurons in the nucleus tractus solitarius (NTS) of the rat (Giza and Scott, 1991; Scott and Giza, 1990), more recent studies in the hamster concluded that amiloride affects NaCl responses in both NaCl-best and sucrose-best NTS neurons (Boughter and Smith, 1998; Smith et al., 1996). Smith et al. (2000) concluded that the code for NaCl is represented by the neural activity in both salt-best and sucrose-best neurons. Thus, the idea of neuron types is retained, but the pattern of activity across both sets of neurons (instead of the entire population) conveys the information. More recently, Lemon and Smith (2006) demonstrated that NTS cells could be classified as NaCl-, HCl-, or sucrose-sensitive based on their best responses across taste qualities. However, they also showed that the total spike count of the best stimulus neurons was an unreliable measure of taste identity unless these data were supplemented by information about the pattern of firing across cells.

Both the labeled line and ANP theories are based on the sum or average number of action potentials evoked by taste stimuli over a defined period; both ignore the information conveyed by the temporal pattern of neural activity. Of course, temporal coding can mean several things (see Hallock and Di Lorenzo, 2006, for a review). Spike count, for example, reflects an average firing rate across a response interval, so in the strictest sense of the word, it can be considered a global measure of the temporal characteristics of a response. It is more common, however, for temporal coding to be defined as the dynamic changes in firing during the response interval. The rate envelope, or “time course” of the response, reflects the phasic-tonic firing rate changes during a sustained response. The ratio of the phasic to tonic components of taste responses conveys information about taste quality and/or hedonics in several taste-related brain areas (Scott and Mark, 1987; Travers and Norgren, 1989; Verhagen et al., a).

Recently, it has been shown that spike timing in individual cells and the cooperative activity within neural ensembles contribute to quality coding in the brainstem and cerebral cortex. In a series of studies, the information conveyed by spike timing was compared to that carried by spike count for stimuli that varied in taste quality (Di Lorenzo and Victor, 2003; Roussin et al., 2008, 2012), flow rate (Di Lorenzo and Victor, 2007) or concentration (Chen et al., 2011) in the NTS. In about half of all neurons, spike timing was significantly more informative than spike count alone. Spike timing was also sufficient to enable individual neurons to discriminate the components of taste mixtures from one another (Di Lorenzo et al., 2009a). In the pontine parabrachial nucleus (PBN), spike timing was also more effective than spike count alone in conveying information about taste quality (Rosen et al., 2011). In the GC, ensemble coding, a process that depends heavily on the temporal activity of networked cells, contributes to taste quality coding (Katz et al., 2002; Stapleton et al. 2007).

To demonstrate that the temporal characteristics of neural responses contribute to sensory neural coding and behavior, Di Lorenzo and colleagues tested awake, behaving rats during lick-contingent patterned electrical pulse trains that mimic the responses of NTS neurons to the taste of sucrose (Di Lorenzo et al., 2003a; Di Lorenzo and Hecht, 2003) or quinine (Di Lorenzo et al., 2009b). In these experiments, conditioned aversions learned to the patterned “sucrose simulation” or the “quinine simulation” generalized specifically to real sucrose or quinine, respectively. Randomized electrical pulse trains with the same number of pulses and the same compliment of interpulse intervals were ineffective. These data provide strong direct evidence that the temporal pattern of brainstem activity conveys information about taste quality and underscore the functional significance of temporal coding.

### 32.3 ANATOMY AND PHYSIOLOGY OF THE GUSTATORY SYSTEM

#### 32.3.1 Taste Bud Innervation

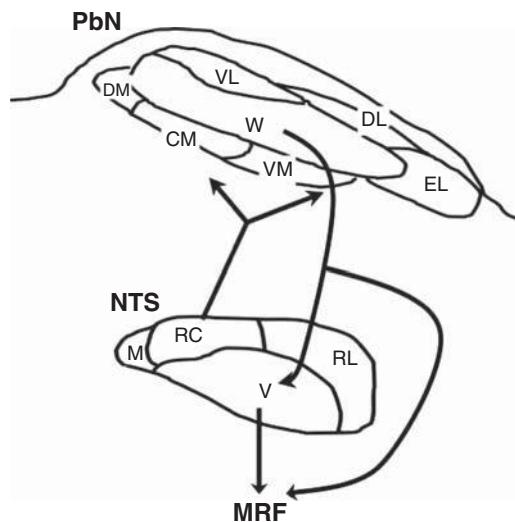

The most striking fact about the features of taste buds, their distribution throughout the oral cavity, and their peripheral innervation in rodents and primates, is their similarity. The facial, GP, and vagus nerves innervate taste buds located throughout the oral cavity (see Figure 32.1). The facial nerve contains two branches: the CT nerve and the greater superficial petrosal (GSP) nerve. Innervation of the taste buds on the rostral 2/3 of the tongue and the anterior two or three foliate papillae located along the lateral margin of the tongue is provided by the CT nerve (McManus et al., 2011; Taillibert et al., 1998). Taste buds in the nasoincisor duct of the rat and along part of the soft palate of rodents and primates are innervated by the GSP nerve (Hamilton and Norgren, 1984). Taste buds on the caudal 1/3 of the tongue, within the posterior two or three foliate papillae, and on the nasopharynx are innervated by the lingual branch of the GP nerve. The GP nerve and the superior laryngeal branch of the vagus nerve innervate taste buds located on the soft palate. Cell bodies of the facial, GP, and vagus nerves are located in the geniculate, petrosal, and nodose ganglia, respectively; the central processes of these nerves terminate in the NTS in a roughly topographical order, with considerable overlap (Hamilton and Norgren, 1984; Halsell et al., 1993; May and Hill, 2006; McPheeeters et al., 1990; Travers and Norgren, 1995).

#### 32.3.2 Caudal Brainstem

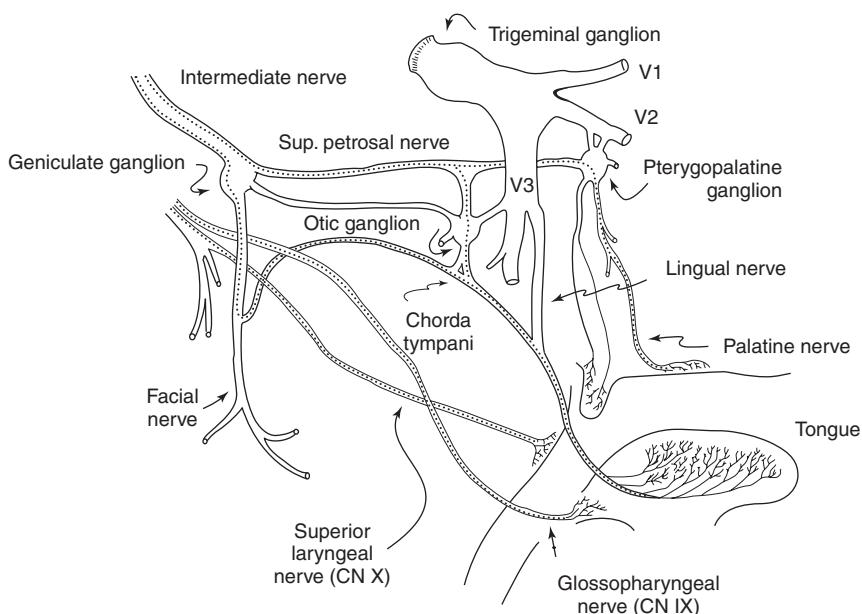

##### 32.3.2.1 Intrinsic Anatomy of the NTS.

**RODENT** Taste-responsive neurons are located in the rostral third of the NTS, which, based upon functional

and morphological criteria, consists of four distinct subnuclei: rostral central, rostral medial, rostral lateral, and rostral ventral (Halsell, et al. 1996; Whitehead, 1988; see Figure 32.2). In both rat and hamster, the rostral central subnucleus of the NTS receives most of its projections from the three nerves that innervate the taste buds in the oral cavity (Whitehead, 1988; Lundy and Norgren, 2013, 2014) and contains the majority of NTS taste neurons (Whitehead and Frank, 1983). Primary afferent glutamatergic neurons terminate within glomeruli located along the distal dendrites

**Figure 32.2** Subnuclear organization and reciprocal projections of the NTS (bottom) and PbN (top) in the rat. Abbreviations in PbN: VL = ventrolateral nucleus; DL = dorsolateral nucleus; EL = external lateral nucleus; DM = dorsomedial nucleus; W = waist area; CM = central medial nucleus.; VM = ventromedial nucleus; in NTS: M = medial nucleus; RC = rostrocentral nucleus; RL = rostralateral nucleus, V = ventral nucleus.

**Figure 32.1** Gustatory innervation of the oral cavity in primates. (Diagram adapted with permission from Oxford University Press).

and spines in the rostral central and rostral lateral NTS (Li and Smith, 1997; Wang and Bradley, 1995, 2010b; May and Hill, 2006; Whitehead, 1986; Whitehead and Frank, 1983). The rostral central subnucleus consists of neurons responsive to convergent taste and tactile stimulation; these are projection neurons that relay taste information centrally to the PBN (Halsell et al., 1993; Norgren and Pfaffmann, 1975). Cells in the NTS that project rostrally are separate from those with local brainstem projections (Halsell et al., 1993). This anatomical segregation of function has also been observed in the geniculate ganglion where different groups of cells project to areas of the NTS that are part of the ascending taste pathway related to sensory discrimination and homoeostatic functions, or elements of the local or descending circuits associated with orofacial reactivity (Zaidi et al., 2008). Neurons in the rostral ventral NTS project to the intermediate reticular formation and other brainstem areas involved with taste-related reflexes (Beckman and Whitehead, 1991; Travers, 1988).

Morphological studies of neurons in the rostral NTS have identified three general cell types: fusiform, stellate, and ovoid. The fusiform and stellate cells are the projection neurons of the rostral central NTS (Whitehead, 1993). Fusiform cells have at least two primary dendrites which can extend for several hundred micra in the mediolateral plane, perpendicular to the incoming fibers from the solitary tract (Whitehead, 1986; Whitehead and Frank, 1983). This arrangement maximizes synaptic opportunities with incoming taste fibers (Davis and Jang, 1986; Whitehead, 1986; Whitehead and Frank, 1983). There is conflicting evidence using 3-D reconstruction of neurobiotin-labeled cells, however, suggesting that the NTS actually contains very few bipolar neurons (Renahan et al., 1994). This group proposed a more intricate cell classification based on cluster analyses of six quantified morphological features. One of these features, cell size, can be associated with immunohistochemical characteristics. For example, large neurons show immunoreactivity to tyrosine hydroxylase (Davis, 1998), suggesting that these are dopaminergic cells. Small cells are believed to be GABAergic, inhibitory interneurons (Davis, 1993; Lasiter and Kachele, 1988b; Whitehead, 1986). Based upon vesicle distribution, high density (GABA-HD) and low density (GABA-LD) GABAergic terminals have been identified within the rostral NTS (Leonard et al., 1999; Whetherton et al., 1998). Proximal dendrites and soma contain both LD and HD variants of GABA terminals; only GABA-HD terminals are found at distal dendrites (Leonard et al., 1999). In general, GABAergic synapses are concentrated on the proximal dendrites and soma of NTS cells in the rostral central NTS; afferent glutamatergic input from peripheral nerves synapse on distal dendrites (Leonard et al., 1999; Whitehead, 1993).

Wang and Bradley (2010a), using a transgenic mouse strain where the expression of a green fluorescent protein

is under the control of a glutamic acid decarboxylase promoter (GAD67-GFP), identified a subset of inhibitory neurons that express somatostatin. Based upon their morphological and physiological characteristics, this subset of GABAergic neurons consists of two groups. The most common type of GAD67-GFP cells (73%) are small ovoid or fusiform that fire in phasic bursts; larger fusiform or multipolar GAD67-GFP cells fire tonically when depolarized (Wang and Bradley, 2010a). Because these GAD67-GFP neurons are concentrated in the ventral subdivision of the NTS, they have little direct interaction with cells in the CT or GP terminal fields; they may, however, influence taste-responsive cells through polysynaptic connections.

The widespread distribution of GABAergic terminals in the NTS underscores the importance of inhibitory circuits in medullary taste processing. Indeed, over half of the neurons in the rostral central and rostral lateral subdivisions of the NTS respond to exogenously applied GABA (Davis, 1993; Liu et al., 1993; Smith and Li, 1998, 2000). Although both GABA<sub>A</sub> and GABA<sub>B</sub> receptors are present in the NTS (Liu et al., 1993; Smith and Li, 1998), most (84%) NTS GABAergic cells are affected by the GABA<sub>A</sub> antagonist bicuculline; only 14% of GABA-responsive NTS neurons respond to baclofen, a GABA<sub>B</sub> agonist.

At the physiological level, inhibition provides a backdrop for incoming excitatory signals. In fact, Smith and Li (1998) have shown that NTS cells are tonically inhibited. Electrical stimulation of the solitary tract evokes both excitatory (mean 4.8 ms latency) and inhibitory (mean 8.8 ms latency) postsynaptic potentials (PSPs) in NTS cells *in vitro* (Grabauskas and Bradley, 1996; Bradley, 2007). Bradley (2007) has suggested that the time course of each of these PSPs indicates monosynaptic excitation followed by polysynaptic recurrent inhibition.

The idea that excitatory input to the NTS initiates an inhibitory process was supported by a series of experiments using electrical stimulation of the CT nerve. After Grabauskas and Bradley (1998, 1999) demonstrated that tetanic stimulation of NTS cells can potentiate inhibitory PSPs *in vitro*, Lemon and Di Lorenzo (2002) showed that tetanic stimulation of the CT nerve *in vivo* can suppress or enhance subsequent taste responses in NTS neurons. These effects are stimulus-specific, with NaCl responses most frequently affected; HCl responses are typically unaffected. However, the relationship of this effect to natural taste stimulation is unclear. To study this issue, Di Lorenzo et al. (2003b) used brief (100 ms) pulses of taste stimuli to provide a natural counterpart to tetanic electrical stimulation, followed at 1 or 5 s by the same or a different taste stimulus. Results showed that these “pre-pulses” of taste stimuli have a similar effect on taste responses in the NTS as tetanic stimulation of the CT nerve. That is, pre-pulses of some taste stimuli, like tetanic stimulation of the CT nerve, suppress or enhance the responses to subsequently presented taste stimuli in a stimulus-specific

manner. This effect is so pronounced that it changed the cell's most effective taste stimulus in 39% of the sample. Pre-pulses are effective when the pre-pulse/taste stimulus interval is 1 s, but not when the interval is increased to 5 s, suggesting that the pre-pulse potentiation effect dissipates over time.

Experiments using paired pulse stimulation have provided further insight into the function of NTS inhibition. For example, Grabauskas and Bradley (2003), using paired pulse electrical stimulation of the solitary tract *in vitro* in newborn rats, showed that the inhibitory postsynaptic current (IPSC) evoked by a conditioning pulse summates with the IPSC evoked by a subsequent test pulse when the pulses are <200 ms apart. In adult rats, field potential recordings from the NTS following paired-pulse CT stimulation showed that the response to the test pulse is suppressed by the conditioning pulse for about 2 s (Lemon and Di Lorenzo, 2002). Paired-pulse stimulation of the CT nerve attenuates the extracellular CT-stimulation evoked response of single NTS cells (Rosen and Di Lorenzo, 2009, 2012; Rosen et al., 2010b). These experiments described two types of paired-pulse attenuation: 1) a short latency (~20 ms) response that degrades quickly (~100 ms); and 2) a long latency (~50 ms) response that degrades slowly (~500 ms). During sapid stimulation of the tongue, the short latency, fast decay NTS neurons are generally more narrowly tuned to the four basic taste stimuli and exhibit larger responses than the other group of neurons that respond to paired-pulse stimulation with long latencies and a prolonged decay. These observations prompted Rosen et al. (2010b) to propose a model of NTS circuitry that incorporates a series of taste-stimulus specific cell assemblies in which the activation of one assembly inhibits others, perhaps through lateral inhibition. Research using simultaneous recordings from multiple NTS cells provides further support for this type of organization (Rosen and Di Lorenzo, 2012).

**PRIMATE** Although the general organization of the NTS in nonhuman primates is very similar to the pattern described above for rodents, less is known about the sub-nuclear organization and chemoarchitecture in primates. The most common parcellation of the primate NTS uses the solitary tract as a landmark that divides the nucleus into medial and lateral subdivisions (Beckstead and Norgren, 1979). Besides ease of use, dividing the NTS in this fashion creates a lateral, primarily gustatory, subdivision that dominates the rostral half of the nucleus and a medial, mostly viscerosensory, region in the caudal and commissural regions. Fibers of the facial nerve terminate almost exclusively in the lateral division, while vagal terminals dominate the medial division; axons of the GP nerve

terminate in both medial and lateral divisions (Beckstead and Norgren, 1979; Satoda et al., 1996; Rhon, 1968). Thus, the rostrocaudal terminal pattern of the CT, GP, and vagus nerves within the NTS of primates follows the same sequence as the rat, with the addendum that the lateral gustatory division of primates extends rostrally beyond the entry point of the facial nerve (Beckstead and Norgren, 1979; Rhon, 1968). The anatomical organization of primates, including humans, is described in more detail in Pritchard (2012).

### 32.3.2.2 Efferent Projections of the NTS.

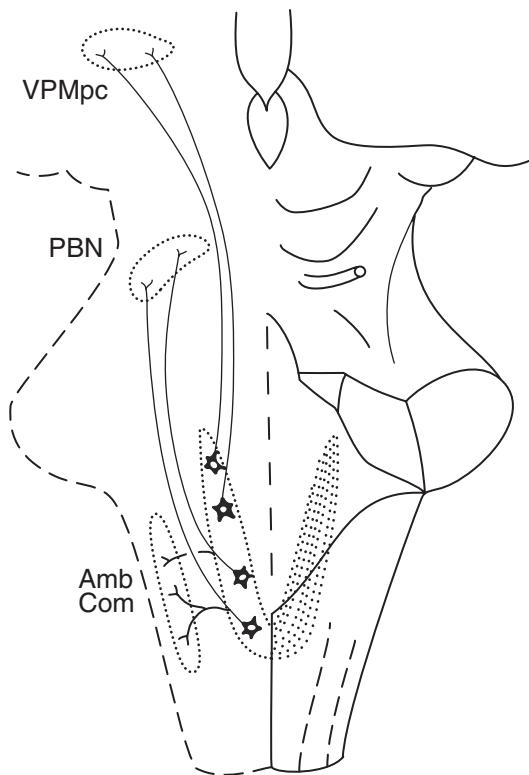

**RODENT** The efferent projections from the NTS are complex, involving multiple subnuclei which project to areas that control orofacial and ingestive behaviors, affect autonomic function, and contribute to neural coding of taste quality and intensity. This review focuses on the ascending projections that lead to the forebrain.

In the rat, about a third of the cells in the NTS have direct projections to the PBN (Monroe and Di Lorenzo, 1995; Ogawa et al., 1984; Ogawa et al., 1982); in the hamster, about 85% of NTS cells project to the PBN (Cho et al. (2002)). In addition to this species difference, NTS projects to the contralateral solitary nucleus in the hamster (Li et al., 2008), but not in the rat (Lundy and Norgren, 2014).

**PRIMATE** Axons of gustatory neurons in the rostral NTS enter the central tegmental tract, ascend ipsilaterally through the pons and midbrain, and finally terminate in the parvicellular division of the ventroposteromedial nucleus of the thalamus (VPMpc; Beckstead et al., 1980; see Figure 32.3). The gustatory portion of VPMpc occupies the medial aspect of the ventrobasal thalamus, immediately medial to the oral somatosensory representation. The projection from the NTS to VPMpc in nonhuman primates bypasses the PBN, which is an obligate relay in rodents for gustatory information ascending from the medulla to the thalamus (Loewy and Burton, 1978; Norgren, 1978; Norgren and Leonard, 1973). In primates, the PBN relays general visceral and nociceptive information from the caudal NTS (Beckstead et al., 1980) and the spinal cord (Westlund and Craig, 1996) to the forebrain. There is no evidence of a gustatory presence in the PBN of primates (Pritchard et al., 2000).

### 32.3.2.3 Subnuclear Organization of the PBN

**in the Rat.** Most of the neurons in the rostral central subnucleus of the NTS project to the “waist” region of the PBN, so named because this cellular area occupies the somewhat constricted part near the mid-section of the brachium conjunctivum (BC; see Figure 32.2). The

**Figure 32.3** Efferent projections of the NST to the caudal brainstem and thalamus of the monkey. Whereas, the caudal visceroreceptive NST projects to the PBN, the rostral gustatory NST bypasses the PBN and terminates in VPMpc. (Used with permission from John Wiley and Sons, Inc.).

waist region contains several PBN subnuclei, including the central medial and ventral lateral nuclei; other gustatory neurons are scattered among the fascicles of the BC itself (Davis, 1991; Lasiter and Kachele, 1988a; Norgren, 1978; Travers, 1988). Gustatory neurons in the waist region are classified as fusiform and multipolar (Davis, 1991; Lasiter and Kachele, 1988a); compared with cells in the NTS, they have more elaborate, but less expansive, dendritic arborizations (Davis, 1991).

#### 32.3.2.4 4 Neural Coding in the Caudal Brainstem.

**RODENT** Neural activity, both spontaneous and evoked, is generally sluggish in the gustatory system compared to other sensory systems. In the CT nerve of the rat, the spontaneous rate averages only 1.09 spikes/s (Pritchard and Scott, 1982), but it increases to 14.2 spikes/s in the NTS (Giza and Scott, 1996). Using the published reports of Erickson and Doetsch (1965) and Doetsch and Erickson (1970) on taste responses in the CT nerve and NTS, respectively, Scott and Erickson (1971) concluded that

NTS response magnitudes exceed those of the CT nerve by a factor of four.

Salt-and acid-best neurons account for approximately 60% and 30% of NTS taste neurons, respectively (Di Lorenzo and Monroe, 1997; Giza and Scott, 1991). Neither of these studies, nor Di Lorenzo and Monroe (1997), found any neurons that gave their largest response to QHCl. Despite this, all three studies reported that medullary taste neurons are broadly tuned with an average entropy of approximately 0.82.<sup>1</sup>

Gustatory response profiles of PBN neurons are similar to those in the NTS, although whether PBN responses are slightly smaller (Verhagen et al., 2003) or slightly larger (Di Lorenzo and Monroe, 1997; Di Lorenzo et al., 2009c) depends on the detail of analysis used to address this issue. When the responsiveness of PBN neurons is calculated separately for NTS relay and intrinsic neurons, the response magnitude of the former group is significantly higher (Di Lorenzo and Monroe, 1997; Monroe and Di Lorenzo 1995; Cho et al., 2002; Ogawa et al., 1984). Similarly, taste responses in PBN-thalamic relay neurons are larger than non-relay cells (Ogawa et al., 1987).

Data on the functional specialization of the waist area and external subnuclei of the PBN are conflicting. Based on results from *c-fos* studies, Yamamoto et al. (1994) proposed that the PBN waist area processes hedonically positive taste stimuli (NaCl, sucrose), while unpleasant gustatory stimuli (QHCl) are routed through the external lateral subnucleus. King et al. (2003), however, showed that intraoral infusions of QHCl produce *fos*-like immunoreactivity in both areas; Travers et al. (1999) reported the same results in decerebrate rats.

Just as in the NTS, the PBN of anesthetized rats is dominated by NaCl- and HCl-best neurons (Di Lorenzo and Monroe, 1997); in awake rats, NaCl-best neurons predominate (Nishijo and Norgren, 1997). Regardless of anesthetic state, PBN neurons are broadly responsive to the four basic taste stimuli ( $H = 0.58$  to  $0.87$ ; Halsell and Travers, 1997; Di Lorenzo and Monroe, 1997; Nishijo and Norgren, 1991, 1997). These similarities aside, PBN gustatory neurons in the awake rat have a higher spontaneous rate and greater sucrose sensitivity than their anesthetized counterparts (Nishijo and Norgren, 1990, 1997). Both effects could be related to relief from anesthetic depre-

<sup>1</sup>The entropy coefficient ( $H$ ) reflects the breadth-of-tuning of a neuron, that is, the degree to which an individual neuron responds to each of the four prototypical taste stimuli: NaCl, sucrose, HCl, and QHCl (Smith and Travers, 1979). The entropy equation is:  $H = -k \sum p_i \log p_i$  Where  $H$  = breadth of tuning;  $k$  = the scaling constant;  $p_i$  = the proportional response to each of the four stimuli;  $i = 1-4$  stimuli. When  $k$ , the scaling constant, is set to 1.661, the entropy coefficient will equal 1.0 when the cell's response to all four stimuli is identical.

sion, either locally or in forebrain areas that modulate PBN taste activity (Lundy and Norgren, 2014). An alternate explanation for the prevalence of sucrose responsiveness is that a wider area of the oral cavity, including the taste buds around the nasoincisor duct, is stimulated when the awake rats drink the sapid stimuli. Taste buds located around the nasoincisor duct are preferentially sensitive to sucrose (Travers et al., 1986) and are seldom effectively stimulated when sapid stimuli are delivered by the investigator.

Data from simultaneous recordings of NTS and PBN cells in the anesthetized rat reveal that PBN cells with a given response profile, for example, NaCl-best or sucrose-best, receive direct projections from NTS neurons that have a variety of response profiles, and sometimes different best stimuli (Di Lorenzo and Monroe, 1997). However, NTS-PBN cell pairs that have the same best stimulus communicate more effectively than those with dissimilar best stimuli (Di Lorenzo and Monroe, 1997). That is, action potentials of NTS neurons are more likely to be followed by a spike in a PBN neuron if these functionally connected neurons share a best stimulus.

**PRIMATE** Recording from the NTS in nonhuman primates is such a daunting task that few investigators have attempted it. The NTS is a long, narrow target, buried deep in the posterior cranial fossa and protected dorsally by the fibrous tentorium. When acute rodent preparations are used, some investigators remove the overlying cerebellum and resect the tentorium; this option is not available to primate researchers who, for a variety of reasons, employ recording systems that permit repeated (chronic) experiments on the same animal. The primary advantage to using chronic recording techniques is that the monkeys can be tested while awake, which enables the animals to actively engage the investigator and the sapid stimuli.

For these reasons, only two papers have described the neural coding properties of taste neurons in the primate NTS. Scott et al. (1986a) reported that taste neurons in the NTS have concentration-response functions and threshold sensitivity that match human psychophysical data (Collings, 1974). Gustatory neurons in the NTS are broadly tuned ( $H = 0.87$ ) and respond more often to glucose (40%) and NaCl (35%) than to QHCl (17%) or HCl (8%).

In the second report, Yaxley et al. (1985) reported that allowing a monkey to drink glucose to the point of satiety does not affect the glucose-evoked response by individual NTS taste neurons. This paradigm, and the significance of these negative data, will be described in more detail in the section on the orbitofrontal cortex (OFC) where the responses of taste neurons are modulated by internal factors such as satiety.

### 32.3.2.5 Projections of the PBN in the Rat.

**DESCENDING PROJECTIONS** Neurons in the waist area of the PBN send a reciprocal projection to the ventral subnucleus of the NTS (see Figure 32.2), which in turn, projects to the adjacent medullary reticular formation (MRF), another recipient of direct projections from the PBN. The MRF contains premotor circuits that contribute to taste-evoked orofacial reflexes (Halsell et al., 1996; Karimnamazi and Travers, 1998; Travers and Norgren, 1983). The external lateral and external medial subnuclei of the PBN also receive taste-related input from the NTS, but they project to the MRF rather than the solitary nucleus (Herbert et al., 1990; Halsell and Travers, 1997; Karimnamazi et al., 2002; Yamamoto et al., 1994).

**ASCENDING PROJECTIONS** Axons of gustatory neurons in the PBN join the central tegmental tract and terminate bilaterally in VPMpc (Bester et al., 1999; Karimnamazi and Travers, 1998; Krout and Loewy, 2000; Norgren, 1974). Electrophysiological experiments have confirmed that VPMpc gustatory receptive fields are located bilaterally on the tongue as well as on the hard and soft palates (Nomura and Ogawa, 1985; Ogawa and Nomura, 1988). Other PBN efferents terminate in the GC (Saper, 1982), lateral hypothalamus (LH: Bester et al., 1997), the central nucleus of the amygdala (CNA: Bernard et al., 1993; Karimnamazi and Travers, 1998), substantia innominata (Karimnamazi and Travers, 1998) and the bed nucleus of the stria terminalis (BNST: Alden et al., 1994). See Lundy and Norgren (2014) for a review of the central taste pathways of the rat.

**32.3.2.6 Centrifugal Modulation of Gustatory Responses in the Brainstem.** Top down modulation is a feature of every sensory system, including gustation. In rodents, projections originating in the GC terminate in VPMpc (Norgren and Grill, 1976; Shi and Cassell, 1998; Wolf, 1968), the CNA (Norgren and Grill, 1976; Shi and Cassell, 1998), the PBN (Lasiter et al., 1982; Norgren and Grill, 1976; Wolf, 1968), and the NTS (Norgren and Grill, 1976; Whitehead et al., 2000). The CNA, in turn, projects to the NTS (Whitehead et al., 2000) and the PBN (Kang and Lundy, 2009; Tokita et al., 2009). The PBN and NTS also receive direct projections from the LH (Bereiter et al., 1980; Hosoya and Matsushita, 1981; Whitehead et al., 2000), and the BNST (Kang and Lundy 2009; Tokita et al., 2009). In hamster, projections from the contralateral NTS have also been reported (Whitehead et al., 2000); electrical stimulation of these fibers modulates taste responses in the NTS (Li et al., 2008).

Although the anatomy of centrifugal input to taste-related structures has been well described, less is known about the physiology of these projections and their

functional significance. Both inhibitory and facilitatory responses have been recorded in VPMpc following electrical stimulation of the GC (Ganchrow and Erickson, 1972; Yamamoto et al., 1980). Both long and short duration effects were noted: long duration (~60 ms) responses that are either inhibitory or excitatory and short duration (~10 ms) responses which are strictly inhibitory (Yamamoto et al., 1980). Subsequent research in the somatosensory system suggests that these effects might be mediated by a disynaptic cortico-reticular pathway (Lam and Sherman, 2011; see also Guillery et al. 1998). Yamamoto et al. (1984) also studied the effects of GC electrical stimulation on CNA neurons. In that study, 13 of 16 CNA neurons were facilitated and/or inhibited by GC stimulation with a mean latency of 16 ms. Such a long latency suggests that the GC feedback to the CNA is mediated by a polysynaptic pathway. Similarly, evidence for a polysynaptic influence of the GC on the LH was reported by Kita and Oomura (1981), who observed excitation followed by inhibition, or inhibition alone.

There is considerable evidence that descending projections from the forebrain affect taste-evoked activity in the brainstem. For example, Di Lorenzo and Monroe (1995) showed that infusion of procaine, a short acting local anesthetic, into either side of the GC in rats decreases the number of basic taste stimuli that evoke responses in the NTS. The largest effects of GC inactivation are seen in the NTS intrinsic neurons, that is, the neurons that do not project to the PBN. Di Lorenzo and Monroe (1995) showed that ipsilateral GC inactivation preferentially affects NTS responses to sucrose and saccharin, both sweet tastes, while contralateral infusions enhance differences between palatable and unpalatable taste stimuli. Smith and Li (2000) reported that chemical or electrical stimulation of the GC produces excitation and inhibition in separate groups of cells in the NTS of hamster. The excitatory effects are distributed across all best stimulus types, but the inhibition targets NTS neurons that are more responsive to NaCl. Electrical stimulation of the contralateral GC is more effective than stimulation of the ipsilateral side; this relationship is reversed in the rat (Di Lorenzo and Monroe, 1995).

Taste responses in the NTS are also modulated by input from the BNST, the CNA, and the LH (reviewed in Lundy, 2008). In hamster, inhibitory influences originate predominantly in the BNST; excitatory effects most often originate in the LH and the CNA; these data have been reviewed by Smith et al. (2005a). Stimulation of the BNST, which inhibits 36% of NTS cells, mostly targets citric acid-best neurons (Smith et al., 2005b). Cho et al. (2002) reported that both ipsilateral and contralateral LH stimulation affects taste-responsive NTS cells, although contralateral stimulation is more effective. Ipsilateral stimulation can have either an excitatory or inhibitory effect on NTS cells, but contralateral LH stimulation

is always excitatory. In general, stimulation of the LH during rapid stimulation of the tongue more than doubles the magnitude of NTS taste responses. Li et al., (2002) report that only a third of NTS neurons are affected by CNA stimulation; this influence targets NTS cells that are only weakly taste-responsive. Subthreshold stimulation of the CNA, however, enhances taste responses in NTS neurons that receive CNA input (Li et al., 2002). Cho et al. (2003) reported that 24% of NTS cells are affected by stimulation of both the LH and the CNA; in rat, however, the influence of the CNA on NTS taste responses is more widespread, with more than half of NTS neurons affected (Kang and Lundy, 2010). Collectively, these studies show that descending forebrain projections, by differentially targeting best stimulus cell types, influence taste-evoked activity in the NTS in complex ways.

In both rat (Lundy and Norgren, 2001; 2014) and hamster (Li et al., 2005; Li and Cho, 2006), the PBN receives substantial centrifugal projections from the GC, the BNST, the LH, and the CNA (reviewed in Lundy, 2008). Interestingly, for each of these forebrain sites, the centrifugal projections to the PBN and NTS originate from different groups of neurons (Kang and Lundy, 2009). In hamster, nearly all PBN cells project to the CNA and/or the LH, but only a third receive reciprocal projections from these nuclei (Li et al., 2005). Similarly, in rat, about a third of taste-responsive PBN cells receive descending projections from the GC (Di Lorenzo and Monroe, 1992). Electrical stimulation of the LH and CNA of the hamster inhibits or facilitates PBN taste-evoked responses (Li et al., 2005). Inhibition narrows tuning of NaCl-best cells and broadens tuning of citric acid-best neurons (Lundy and Norgren, 2001). Electrical stimulation of the GC and CNA inhibits responses in approximately two-thirds of PBN taste neurons; about half of the PBN taste cells are either inhibited or facilitated by LH stimulation (Lundy and Norgren, 2014). Overall, centrifugal input sharpens PBN response profiles.

To summarize, descending projections to the PBN and NTS is both complex and varied, often depending on the best stimulus classification of the target neuron (Lundy, 2008). By changing the across neuron pattern of activity, descending projections often accentuate differences between taste qualities. The ability of centrifugal input to modulate taste-response profiles and, at times, the best stimulus classification of individual neurons, strongly suggests that neural coding of taste quality is a network dependent, fluid process and not a stable, immutable characteristic of individual neurons.

### 32.3.3 Neural Coding in the Forebrain

The thalamic sensory nuclei have, historically, been considered passive relays to the cerebral cortex. This is certainly true for the gustatory thalamus which has received much less attention than either the gustatory peripheral nerves, the NTS, or the PBN. Even though this view is changing, the role of the thalamus in perception is still not well-understood (see Saalmann and Kastner, 2009; Sherman, 2007; Bruno, 2011). Aside from this issue, from a strictly technical standpoint, the greatest challenge to studies on neural coding in the forebrain is the impact of general anesthesia. General anesthetics depress and distort neural activity throughout the visual, auditory, and somatosensory systems (Land et al., 2012; Detsch et al. 1999; Chapin and Lin, 1984), but the effect is particularly pronounced in the gustatory forebrain (Scott and Erickson, 1971). Even ketamine, which is generally considered to have a lesser impact on neural activity than barbiturates, virtually eliminates spontaneous and evoked taste responses in the thalamus of macaques (Pritchard, unpublished observations, 1987). The challenge presented by general anesthesia is best summed up by Scott and Erickson (1971) who after reporting that thalamic gustatory neurons were “quite unresponsive,” switched to the paralytic gallamine triethiodide (Flaxedil). These recordings in paralyzed rats were better, but still sluggish. After the use of paralyzing agents for invasive procedures fell into disfavor in the research community, there was little incentive to study taste coding in the forebrain of mammals. Finally, chronic recording techniques, which had been used in primate sensory and motor research for years, began to see widespread use in gustatory research (e.g., Pritchard et al., 1989; Scott et al., 1986a).

### 32.3.4 Thalamus

#### 32.3.4.1 Anatomy.

**RODENT** In the rat, axons originating in the PBN terminate in VPMpc, the medial small-celled extension of the oral somatosensory relay, VPM. Cell-size changes so gradually along the mediolateral dimension of the ventrobasal thalamus that the VPMpc/VPM boundary cannot be identified solely on the basis of neuron morphology. Electrophysiological studies have shown that the taste area is bounded laterally by lingual, thermosensitive neurons, which lie medial to oral tactile neurons, but determination of the boundaries between these areas awaits a study that combines anatomical reconstruction with detailed electrophysiological mapping of the region with taste, thermal, and tactile stimuli. Size estimates of the taste-responsive region of VPMpc in the mediolateral dimension approach 2.0 mm, but a more realistic width would be 0.5–1.0 mm (Lundy and Norgren, 2014).

**PRIMATE** In primates, gustatory projections to VPMpc originate in the rostral NTS (Beckstead et al., 1980). Just as in rodents, the boundaries between the gustatory, thermal, and tactile regions of the ventrobasal thalamus are, at best, rough estimates, but based on electrophysiological recordings, the taste area is almost cube-shaped, measuring at least 0.75 mm on each side (Pritchard et al. 1989).<sup>2</sup>

**32.3.4.2 Physiology.** In both rat (Verhagen et al., 2003) and monkey (Benjamin, 1963; Pritchard et al., 1989), several different sensory modalities are represented within the limited confines of VPMpc. In the anesthetized rat, VPMpc gustatory neurons (9%) co-mingle with cells that respond to thermal (8%) or tactile (6%) stimulation. Multimodal neurons (41%) are common and 36% of the neurons in the thalamic taste area have no identifiable adequate stimulus. In awake, behaving macaques, gustatory neurons account for 36% of the population, with another 11% responsive to tactile stimulation (Pritchard et al., 1989). Thermosensitive neurons are scarce (<1%) and unresponsive neurons (18%) still account for a significant fraction of the population. Similar to the observations in the rat, about half of the thalamic taste neurons also respond to either thermal or tactile stimulation. In 35% of VPMpc neurons, spontaneous activity is inhibited immediately prior to fluid delivery. These neurons, which may provide the link between taste perception and ingestive behavior, are unlikely to be responsive in anesthetized animals.

**RODENT** The spontaneous rate of taste neurons in the thalamus is slower than in either the CT, the NTS, or the PBN (Verhagen et al., 2003, 2005). It is widely believed that anesthetics and paralytics suppress neural activity more in the forebrain than in the hindbrain, but it is uncertain to what degree the low spontaneous activity in the thalamus reflects inherent properties of these neurons, or is a byproduct of drug restraint. In the thalamus, spontaneous activity in paralyzed and anesthetized rats ranges from 3–6 spikes/s (Scott and Yalowitz, 1978; Nomura and Ogawa, 1985; Ogawa and Nomura, 1988; Verhagen et al., 2003, 2005). In awake monkeys, the spontaneous rate of thalamic taste neurons is 9.4 spikes/s, which is significantly higher than in the NTS (1.2 spikes/s; Scott et al., 1986a).

Verhagen et al. (2003) reported that gustatory stimuli activate 42% of the neurons in the thalamus of rats anesthetized with a urethane-chloralose mixture. Only 9% of the sample respond exclusively to sapid stimulation of the oral cavity; the remaining 33% respond to thermal stimulation. Interestingly, only 6% of the sample responds to tactile stimulation and only one of these was a gustatory

<sup>2</sup>This estimate is based upon sapid stimulation limited to the anterior tip of the tongue.

neuron. Nomura and Ogawa (1985), using paralyzed and artificially ventilated rats, reported that 88% of a small sample ( $N = 16$ ) of thalamic taste neurons respond to “strong mechanical stimulation, that is pinching with non-serrated forceps.” In most cases, the tactile and taste receptive fields did not overlap. Most gustatory neurons respond to bilateral stimulation of the tongue (43%), with the receptive fields of the remaining 57% restricted to either the ipsilateral (28.5%) or contralateral (2.5%) side (Nomura and Ogawa (1985; see Ogawa and Nomura, 1988).

Based upon the entropy statistic, thalamic gustatory neurons are broadly sensitive ( $H = 0.79$ ), but chemosensitivity is not evenly distributed across the four prototypical taste stimuli (Verhagen et al., 2003). Approximately half (51%) of the gustatory cells in the thalamus respond best to 0.1 M NaCl, with 0.01 M HCl evoking the largest responses in only a quarter (26%) of the sample; sensitivity to 0.5 M sucrose (16%) and 0.01 M QHCl (7%) was low. This is strikingly similar to the pattern observed in the NTS (Giza and Scott, 1991; Giza et al., 1991).

**PRIMATE** Pritchard et al. (1989) reported that the gustatory receptive fields in the VPMpc of macaques are located on the ipsilateral side of the tongue, thereby confirming the anatomical observations of Beckstead et al. (1980) and Pritchard et al. (2000). A subsequent electrophysiological report by Lenz et al. (1997) also shows that taste localizes to the ipsilateral side of the tongue of human neurosurgical patients. The laterality of the ascending gustatory pathway is an important issue because of its clinical implications, yet because the data from human stroke patients are so contradictory, this question remains unsettled (Pritchard, 2012).

Gustatory-evoked responses are typically more sluggish in VPMpc than in the NTS of anesthetized rats (Scott and Erickson, 1971; Scott and Yalowitz, 1978), but when this issue is examined in awake, behaving monkeys, rates are higher in the thalamus (Pritchard et al., 1989) than in the medulla (Scott et al., 1986a). Despite having a moderate spontaneous rate of 9.4 spikes/s, inhibition is uncommon (9.1% of all responses). Approximately 60% of all taste neurons in VPMpc respond to 1.0 M sucrose, with 1.0 M NaCl a distant second (26%); approximately 7% of the taste-responsive neurons respond best to either 0.01 M HCl or 0.001 M QHCl. This pattern contrasts sharply with the thalamic data collected from the rodent thalamus, which is dominated by salt- and acid-best neurons (see above), but these differences are confounded by both species and anesthesia issues. When anesthesia effects are eliminated through the use of awake, behaving primates, a valid comparison can be made between medullary and thalamic taste neurons. Unlike the thalamus where sucrose-best neurons dominate, 1.0M NaCl is more effective than 1.0M glucose (43% vs 31%) in the NTS. Thalamic taste cells

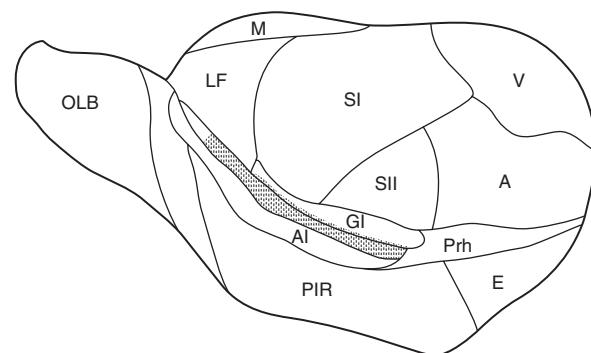

are broadly tuned in both the NTS ( $H = 0.87$ ) and VPMpc ( $H = 0.73$ ), but given the nonlinearity of the entropy statistic (see Pritchard et al., (1989), medullary neurons are considerably more broadly tuned those in the thalamus.

### 32.3.5 Primary Taste Cortex

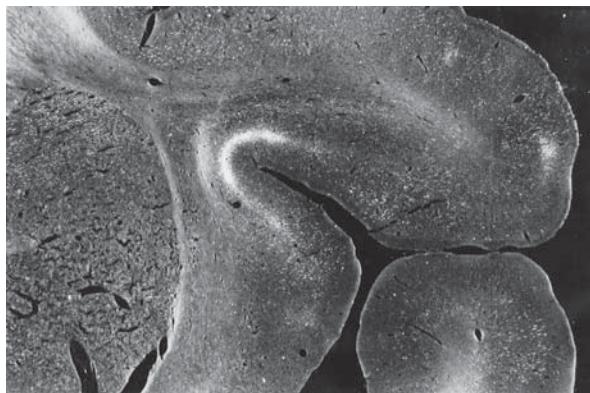

#### 32.3.5.1 Anatomy.

**RODENT** In rats, fourth-order gustatory neurons in VPMpc project to a narrow band of cortex dorsal to the rhinal fissure that overlies the claustrum (Kosar et al., 1986b; Norgren and Wolf, 1975; see Figure 32.4). This area contains so few granule cells that it has been described as “agranular” by some investigators (e.g., Kosar et al., 1986a) and “dysgranular” by others (e.g., Cechetto and Saper, 1987). The gustatory strip lies ventrally to a dysgranular band of thermosensitive neurons, which is ventral to a larger granular cortical zone that contains the lingual representation of primary and secondary somatosensory cortices (Kosar et al., 1986a; Guldin and Markowitsch, 1983; Shi and Cassell, 1998). The CT field is rostral to the GP field, which partially overlaps regions containing visceroreceptive and nociceptive neurons (Hanamori et al., 1997, 1998a, b). As described above, neurons in GC project to each of the subcortical taste relays including VPMpc, the PBN, the NTS, and affiliated gustatory nuclei, including the LH and the CNA (Kang and Lundy, 2009; Di Lorenzo and Monroe, 1995; Lundy and Norgren, 2014; Yamamoto et al., 1980).

**PRIMATE** In primates, taste neurons in VPMpc project to a small crescent of granular neocortex that straddles the inner operculum and dorsal insula (Benjamin and Burton, 1968; Benjamin et al., 1968; Pritchard et al., 1986; see

**Figure 32.4** Diagram showing the location of the gustatory area in dysgranular cortex (shaded area) of the rat. Abbreviations: AI = agranular insular cortex; E = entorhinal cortex; GI = granular insular cortex; LF = lateral frontal cortex; M = motor cortex; OLB = olfactory bulb; PIR = piriform cortex; Prh = perirhinal cortex; SI = primary somatosensory cortex; SII = secondary somatosensory cortex. (Used with permission from John Wiley and Sons, Inc).

**Figure 32.5** Autoradiographic label in monkey cortex following an injection of tritiated amino acids into the thalamic gustatory relay, VPMpc. (Used with permission from John Wiley and Sons, Inc.).

Figure 32.5). Because this area receives projections from the thalamic taste relay, by definition, it wears the mantle of primary taste cortex. From this robust terminal field at the fundus of the superior limiting sulcus, the gustatory projection area tapers into the inner operculum and the body of the rostral insula.

Taste evoked activity has been recorded from a number of regions beyond the boundaries of primary taste cortex: Brodmann areas (BAs) 1 and 2 on the inner operculum, the precentral extension of BA 3b on the lateral convexity, and the middle and posterior insulae (imaging studies); all of these areas, as well as the dysgranular and agranular regions of the insula and the OFC, are populated predominantly, if not exclusively, by second-, third-, and even higher-order cortical taste neurons. Based upon a series of electrophysiological experiments in the insular and opercular cortices, Scott and Plata-Salamán (1999) estimate that the taste-responsive area in the rostroradial insula encompasses  $50\text{ mm}^3$ , which is slightly larger than the area defined by less sensitive, anatomical methods. See Pritchard (2012) for a more detailed description of cortical taste anatomy in primates.

Every investigator who has described single neuron responses in primary taste cortex dating back to Sudakov et al. (1971) has commented on the paucity of taste neurons located there. Based upon their extensive recordings, Scott and Plata-Salamán (1999) estimate that only 6.5% of the cells in the rostral insular-opercular cortices respond to sapid situation of the tongue. It is worth noting that these experiments sampled neurons within primary taste cortex (anatomically defined) as well as within the dysgranular body of the insula, where many if not most cells are second, or even third-order cortical taste neurons. As in subcortical taste areas, gustatory neurons are scattered among cells that respond to oral tactile stimulation.

### 32.3.5.2 Physiology.

**RODENT** There has been unprecedented interest in the response properties of cortical taste neurons during the last decade. Just as in the thalamus, previous studies of cortical taste activity in anesthetized rats struggled with obstinate neural spindling and lethargic responses. Because many of the early studies on anesthetized rats (see Yamamoto (1984) for an early review) and one study on awake rats (Yamamoto et al., 1989) were done in the same laboratory, evaluating the impact of general anesthesia on cortical taste activity is relatively straightforward.

Spontaneous activity of cortical taste neurons in awake rats is almost twice as high as in anesthetized and paralyzed rats (4.4 vs 2.4 spikes/s, respectively; Yamamoto et al., 1989). Likewise, the responses evoked by the four basic taste stimuli are twice as robust in awake rats (8.0 spikes/s). Cortical taste neurons in rats are broadly tuned ( $H = 0.54$ ), a characteristic that is not affected by anesthesia. Yamamoto et al. (1989), using awake rats, divided his sample of 35 cortical taste neurons into two groups: type I cells that they hypothesized code taste quality, and type 2 neurons that attend to hedonic value. The type I neurons are almost equally divided among the four best stimulus categories: sweet ( $N = 6$ ), salty ( $N = 7$ ), sour ( $N = 7$ ), and bitter ( $N = 9$ ). Such uniform chemosensitivity had not been reported previously, regardless of anesthetic state or species, at any level of the gustatory neuraxis. The responses of type 2 neurons vary according to the palatability of the stimulus rather than the chemical moiety.

Unlike thalamic taste cells in both rats and monkeys, cortical gustatory neurons do not respond to tactile stimulation in either anesthetized (Yamamoto et al., 1989) or awake rats (Yamamoto et al., 1981); thermal responses are observed under both conditions.

Descriptive information about taste neurons in awake animals is important because it not only provides baseline information about the system and its fundamentals, but it also provides a basis for cross-synaptic and across species comparisons. The real advantage to using awake, behaving animals in electrophysiological experiments, however, is the ability to examine the brain-behavioral interface.

Beginning about a decade ago, there has been renewed interest in temporal coding in the gustatory system by individual neurons as well as by neuron ensembles. Collectively, these studies have shown that a substantial amount of information is embedded within the temporal firing pattern of individual neurons, local neuron pools, and even functionally-related but anatomically distant sites (Katz et al., 2002; Gutierrez et al., 2010). Although it remains to be demonstrated to what degree the brain uses this information, it is clear that summing the number of action potentials across several seconds provides an

incomplete view of neural processing (Katz et al., 2001, 2002).

Katz et al. (2001) demonstrated that the temporal discharge pattern of individual neurons in the GC of awake rats contains important data that are lost when the spike record is collapsed across several seconds. For example, when the summed activity during a 2.5 sec. period is analyzed, Katz et al. (2001) reported that 14% of GC neurons respond to gustatory stimulation. When the same neural records were divided into 500 ms periods and reanalyzed, 28% of the cells met the criterion for a taste neuron. This doubling in the number of taste-responsive neurons was enough to more than offset the loss of 38% of the neurons that originally met the taste criterion across the 2.5 s period, but were now reclassified as non-responsive. When this temporal analysis switched to a running average of 500 ms bins, the percentage of gustatory neurons increased further to 41%. Stapleton et al. (2006), comparing the lick-by-lick responses in a fixed ratio 5 experiment, reported that 34% of the neurons in the GC respond to sapid stimuli.

All experiments that use awake subjects include some provision for discarding trials in which part or all of the evoked response is caused by concurrent somatosensory stimulation. The fine-grained temporal analysis used by Katz et al. (2001) makes it possible to dissociate the contributions of the gustatory and somatosensory system during each 500 ms epoch. Using this approach, Katz et al. (2001) demonstrated that activity during the first 200 ms following stimulus onset is driven by somatosensory rather than gustatory stimulation. The intensity of the sapid stimulus dominates the next 600 ms, but after 800 ms, the neural record reflects stimulus palatability (Katz et al., 2001; Sadacca et al., 2012).

This new appreciation for the importance of temporal coding combined with advances in multi-electrode recording technology have provided a unique opportunity to investigate how taste information is processed by neural ensembles. Although the picture is far from complete, a decade of research has shown that coincident activity among taste neurons is commonplace, and we believe, networked processing will eventually be seen as the rule rather than the exception in sensory coding.

Early studies that examined the responses of cortical taste neuron pairs in anesthetized/paralyzed rats reported that the responses of 55% of these dyads are correlated with one another (Nakamura and Ogawa, 1997). Although more than 60% of correlated neuron pairs respond best to the same basic taste stimulus, coincident activity is also evident in 14% of the taste/non-taste neuron pairs (see also Katz et al., 2002). Because this synchronous activity is marked by tight cross-correlations and was derived from single electrodes to neuron pairs separated by less than 50 m (Nakamura and Ogawa, 1997), these dyads were most likely elements of local neuron ensembles.

Halpern (1985) demonstrated that taste perception and taste-guided behavior may take place as quickly as a few hundred milliseconds in the case of a rat licking a fluid spout. Many other experiments have shown that gustatory information also operates across many seconds for more complex behaviors such eating a meal. There is evidence that neural ensembles function within this broad, but behaviorally relevant, time scale. For example, Stapleton et al. (2007), using electrode microarrays implanted in the GC of awake rats, showed that small neural ensembles respond differentially within 150 ms of a single lick on a fluid spout. McDonald et al. (2012) reported that rats can identify the quality and intensity of a NaCl stimulus on the basis of two licks. It is noteworthy that 18% of the neurons they sampled responded to water, but not salt. Insular activation by water also has been reported in fMRI studies of human subjects (de Araujo et al., 2003a).

Katz et al. (2002), using similar techniques, demonstrated that neuron pairs show coincident activity during the 75–500 ms following the onset of sapid stimulation. Dyads of taste neurons show a mean cross-correlation half-width of 300 ms, which indicates that these cells are separated from one another by multiple synapses and perhaps considerable distances. Indeed, a number of these coupled neurons were located in opposite hemispheres, which is essential for a complex process like ingestive behavior that involves multiple brain areas. Simultaneous recordings in the GC and the gustatory OFC during a taste-guided motor task show that ensemble responses are not only coordinated, but also plastic. Whereas activity in the GC is related to properties of the taste cue that guides response selection, OFC activity reflects the spatiotemporal properties of taste-guided the motor behavior. A more expansive set of experiments by Gutierrez et al. (2010) used simultaneous recordings in the GC, OFC, amygdala, and nucleus accumbens to demonstrate that synchronous activity in this multi-site ensemble is entrained by the rat's licking, increases as a function of learning, and improves taste discrimination in a GO/NOGO task (see also Pennartz et al., 2012).

Ensemble recording, by exploiting the temporal information within the neural record, portrays taste coding – and by extension taste-guided behavior and ingestive behavior – as a dynamic process that employs multiple cortical and subcortical brain areas. It remains to be determined whether the information extracted in these studies is utilized by the nervous system or if it is simply a derivative analysis that merely benefits the experimenter/observer (Katz et al., 2001). However, the utility of this information for the rat has been shown. Time-shifting the individual spikes in a neural record lessens the ability of an ensemble to discriminate between different tastants (Katz et al., 2002). It is hard to imagine that networked temporal information is not being used by the nervous system,

especially since ensembles have better predictive value of taste quality than either the rate or temporal components of individual neurons (Stapleton et al., 2007). It is also worth noting that predictive value increases directly with ensemble size (Stapleton et al., 2007).

The ensemble coding literature has important implications for the labeled line and across neuron pattern theories of taste quality coding. Both theories use a static measure of taste coding: action potentials over an extended time period. The dynamic and labile nature of ensemble activity creates a shifting landscape that undermines the neural basis of best-stimulus categories and, by extension, the labeled line theory of quality coding. By definition, the concept of ensemble or network processing supports and builds upon the across neuron theory of quality coding (Erickson, 1967) by adding temporal processing.

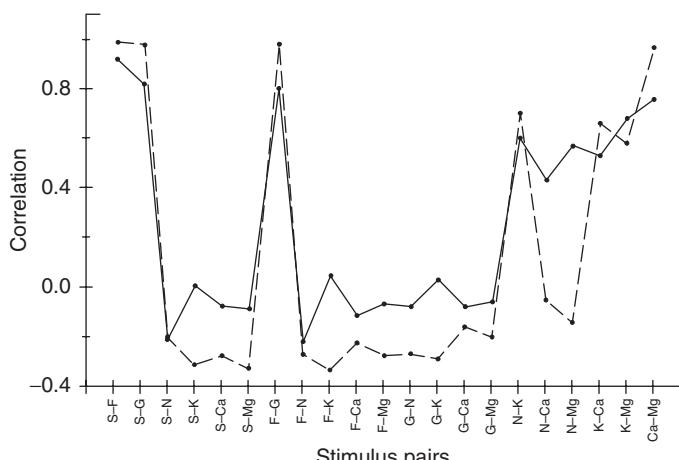

**PRIMATE** Numerous electrophysiological studies have described the properties of taste-responsive neurons in the insula and operculum of alert nonhuman primates (Scott et al., 1986b; Ogawa et al., 1989; Yaxley et al., 1988; Scott et al., 1991; Ito and Ogawa, 1994; Rolls and Baylis, 1994). Because most of these studies were done by Scott and colleagues, it is relatively easy to make study-to-study comparisons of their data. These experiments examined thresholds, concentration-response functions (Scott et al., 1991) and quality coding (Smith-Swintosky et al., 1991), as well as responses to arrays of sweet (Plata-Salamán et al., 1993), salty (Scott et al., 1994), sour (Plata-Salamán et al., 1995), and bitter (Scott et al., 1999) stimuli. Other studies examined complex gustatory stimuli such as amino acids (Plata-Salamán et al., 1992) and taste mixtures (Plata-Salamán et al., 1996).

The spontaneous rate of gustatory neurons in the insula is a languid 3.2 spikes/s, which from a statistical standpoint, provides few opportunities for inhibition and, predictably, few (1.9%) are found. This spontaneous

rate places the insula between the NTS (1.2 spikes/s) and VPMpc (9.4 spikes/s). Response rates are also slow with the most effective stimulus, 1.0M glucose, only evoking a net 5.1 spikes/s. Like the thalamus (Pritchard et al., 1989, which tested 1.0M sucrose), most neurons in the insula respond best to a sweet stimulus (1.0M glucose = 38%), with 0.3M NaCl-best neurons (34%) a close second; the remainder respond best to 0.001M QHCl (22%) or 0.01M HCl (5%). Insular taste neurons, like those in the medulla and thalamus, are broadly tuned ( $H = 0.70$ ). One of the most important findings from this prodigious literature is that the electrophysiological data collected from the monkey for this array of salty, sweet, sour, and bitter stimuli are highly correlated with the human psychophysical data ( $r = +0.91$ ; see Figure 32.6; Scott and Plata-Salamán, 1999). The close correspondence between the primate neural data and the human psychophysical ratings suggests that the nervous system completes taste quality coding within the insula, if not earlier.

Just as in the NTS (Yaxley et al., 1985), the shift in hedonic value from positive to negative that occurs over the course of a meal has no effect on the response magnitude of gustatory neurons in the insular-opercular cortex (Rolls et al., 1988; Yaxley et al., 1988; Ifuku et al., 2003; Ogawa, et al., 2005). Humans also report that the hedonic value of food decreases over the course of a meal (Rolls et al., 1981), but noninvasive imaging studies have obtained contradictory data (Small et al., 2001; Tataranni et al., 1999; Gautier, 2001; Del Parigi et al., 2002); thus, the neural basis of this effect may not be the same in humans and monkeys.

As in the thalamus, the insula also contains many non-gustatory neurons (Scott and Plata-Salamán, 1999). Cells that respond during mouth movements are common (23.8%) and interspersed with neurons that respond to tactile stimulation of the oral cavity (3.7%), approach of

**Figure 32.6** Correlations between taste quality between electrophysiological data from the monkey insula (solid lines; Smith-Swintosky et al., 1991) and human psychophysical reports (dotted lines; Kuznicki and Ashbaugh, 1979). (Used with permission from the American Physiological Society).

the stimulus delivery syringe (1.2%), tongue extension (0.3%) and olfactory stimulation. Other cells respond to stimulus viscosity (53%), temperature (35%), fat content (8%), grittiness (8%), and astringency (8%) of sapid stimuli and a subset of neurons respond to capsaicin (Critchley and Rolls, 1996; Rolls, 2005). Half of all insular neurons respond to at least one of these characteristics (Verhagen et al., 2004<sup>3</sup>). The proximity of gustatory, olfactory, and somesthetic (touch, temperature, nociception) neurons in the insula raises the possibility that this may be one locus involved with flavor perception.

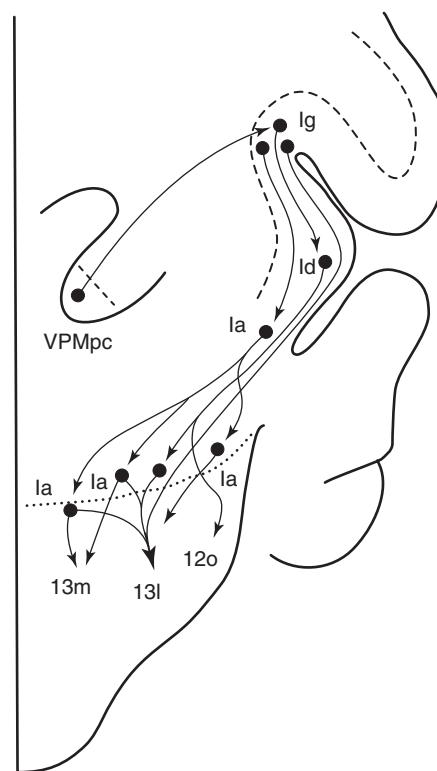

### 32.3.6 Higher-order Gustatory Cortices

**32.3.6.1 Anatomy.** The OFC in rodents and primates, which receives projections from most if not all sensory modalities, including taste, has been implicated in executive functions related to emotion, reward evaluation, social behavior, and decision-making (Schoenbaum et al., 2006; Frederique and Cattarelli, 1996; Ongur and Price, 2000).

**RODENT** In rats and hamsters, gustatory afferent projections to the orbital cortex originate in the insula (Jasmin et al., 2004; Reep and Winans, 1982; Reep et al., 1996).

**PRIMATE** In the macaque, the higher-order taste cortices form an elaborate matrix that stretches from the body of the insula, through the orbital surface, and across much of the posterior OFC (Carmichael and Price, 1995; Mesulam and Mufson, 1982; Morecraft et al., 1992; Barbas, 1993; see Figure 32.7). Most studies have focused on the cortex between the medial orbital sulcus and the precentral operculum (area PrCO), which contains the medial orbitofrontal (mOFC) and the caudolateral orbitofrontal (cLOFC) taste areas.

Gustatory afferent information reaches the OFC through a multisynaptic pathway that originates in primary GC. The initial segment of this insulo-orbital circuit terminates in the dysgranular and agranular regions of the insula. Neurons in the dysgranular insula also project to the agranular insula, and then both areas project to parts of the posterior orbital cortex (Carmichael and Price, 1995). Tracking the ascent of gustatory information to the OFC is complicated by repeated convergence, divergence, and overlap of the individual projections. Although the entire circuit between primary taste cortex and the OFC is not fully understood, it is clear that the final leg of the pathway to the OFC originates within the dysgranular and agranular insulae, and the posterior orbital cortex rather than primary taste cortex (Carmichael and Price, 1995, 1996; Mufson and Mesulam, 1982; Mesulam and Mufson, 1985; Barbas,

**Figure 32.7** Diagram of the gustatory thalamocortical and cortico-cortical circuitry of the monkey. The thalamus and insula, depicted in the coronal plane, have been blended with the ventral surface of the OFC, shown in the horizontal plane. The dotted line marks the insulo-orbitofrontal boundary. As described in the text, most of the gustatory projections to the OFC originate in the agranular insula rather than primary taste cortex or the dysgranular insula. Abbreviations: Brodmann areas 12o, 13l, 13m; Ia = agranular insula; Id = dysgranular insula; Ig = granular insula.

1993; Baylis et al., 1995; Pritchard, unpublished observations, 2005). Thus, gustation resembles other sensory systems whose projections to the OFC originate in sensory association cortices rather than in the primary sensory cortex (Carmichael and Price, 1995; Barbas, 1993, 2007). These studies also suggest that the route from primary taste cortex to the mOFC is more direct, that is, it involves fewer synapses than the pathway that eventually leads to the cLOFC taste area.

The mOFC is located between the medial and lateral orbital sulci and consists primarily of BAs 13m and 13a (Pritchard et al., 2005). Unlike the rest of the OFC where only 3.8% (range = 1.6 to 7.3%; Thorpe et al., 1983; Rolls et al., 1990, 1996; Rolls and Baylis, 1994) of the cells respond to sapid stimulation of the tongue, taste stimuli activate 20% of the neurons in this part of the mOFC. In the surrounding cortex, primarily BAs 13b, 13l, 12m, 11l, and 11m, and the medial agranular insula, 8% of the

<sup>3</sup>All of the stimulus modalities listed above were tested, except astringency.

neurons respond to taste stimulation<sup>4</sup> (see Figure 32.8). Lara et al. (2009) reported that taste neurons account for 11% of the cells in the mOFC. A second taste area, the cLOFC, is located in BA47/12o, but only 2% of the neurons there respond to taste stimulation (Rolls et al., 1990).

### 32.3.6.2 Physiology.

**RODENT** The OFC is next “frontier” for ensemble-based research. Complicated surgical and experimental paradigms using free-moving rats that include ensemble recordings from the OFC and GC and probably the amygdala and the nucleus accumbens as well, will be needed to determine how these anatomically intertwined areas integrate and differentiate sensory, motivational, and experiential information as rodents transition sensation into action (see Gutierrez et al., 2010, above).

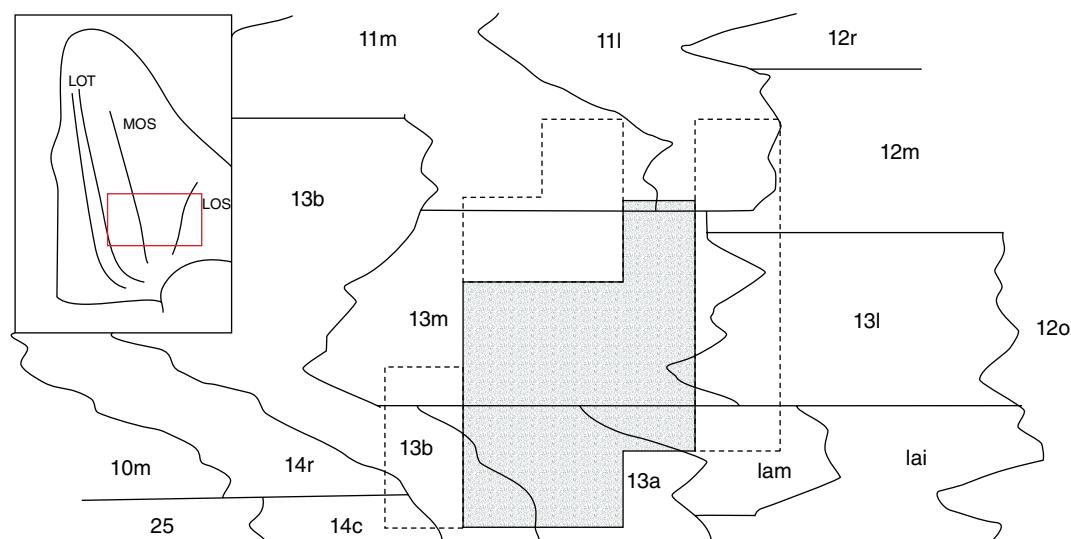

**PRIMATE** The electrophysiological data accumulated by Scott and colleagues in the insula and its good correspondence with the human psychophysical data of Kuznicki and Ashbaugh (1979) suggest that the brain has deciphered the code for taste quality either within the insula, or at the subcortical level. Regardless of whether some residual quality coding takes place in the dysgranular and agranular gustatory association cortices, it appears that their primary function is to mobilize taste information that guides feeding behavior and nourishment. The progression from sensory

<sup>4</sup>It is possible the percentage of taste neurons in BA 13l has been underestimated due to limited sampling.

analysis to sensory support of behavior that began in the insula continues in the OFC where it rises to new levels.

The widespread but sparse distribution of taste-responsive neurons in the posterior OFC has been a challenge for systematic, in-depth analysis of gustatory neurons in this area of the brain. To date, the neural coding properties of OFC taste neurons have only been examined in two areas: the mOFC (Pritchard et al., 2005; Lara et al., 2009) and the cLOFC (Rolls et al., 1990). The mOFC is one of the earliest OFC sites to receive projections from the gustatory association areas in the insula (Carmichael and Price, 1995).

Gustatory neurons in the mOFC, like those in the insula, are broadly tuned to representative stimuli of the four basic taste qualities (mOFC  $H = 0.79$ ; insula  $H = 0.70$ ), with each stimulus activating 50–60% of the neurons sampled. The broad tuning in the insula and the mOFC contrasts sharply with neurons in the cLOFC where the entropy coefficient is extremely low ( $H = 0.39$ ) and 82% of the population responds to glucose; salty, sour, and bitter stimuli each activate less than 12% of the population. It is not clear how meaningful the entropy statistic is for cLOFC neurons, given that they are more intimately involved with reward, emotion, and other executive functions than sensory processing, per se (see below). To point, despite such narrow tuning to gustatory stimuli, cLOFC neurons showed significantly more sideband sensitivity to visual, olfactory, auditory, and somatosensory information than neurons in the mOFC (Pritchard et al., 2005) or the insula (Rolls and Baylis, 1994; Critchley and Rolls, 1996; Rolls, 2004; Thorpe et al., 1983; Scott and Plata-Salamán, 1999). The multimodal character of cLOFC neurons has

**Figure 32.8** Diagram of the mOFC (unfolded) showing the core and perimeter gustatory areas. The inset indicates the location of this map relative to the ventral surface of frontal cortex. (Adapted from Pritchard et al., 2005.)

fueled speculation that the area plays a role in flavor perception (de Araujo et al., 2003b).

Recent insights into the function of the OFC have used its longstanding role in emotion as a point of departure for a related role: evaluation of reward and risk related to decision-making (Tremblay and Schultz, 1999; O'Neill and Schultz, 2010; Rempel-Clower, 2007; Summerfield and Tsetsos, 2012). This view of the OFC is supported by studies in both the animal and human literatures.

The presence of so many non-responsive neurons and low to middling percentages of gustatory neurons in the forebrain “taste” areas strongly suggests that the optimal stimuli or paradigms are not being tested. This point has been driven home by electrophysiological experiments that engage a much higher percentage of OFC neurons when the test paradigm examines cue-guided behavior, reward evaluation, and reward contingencies instead of passive consumption of sapid stimuli (e.g., Pritchard et al., 2005). By using a delayed color matching test, Hosokawa et al. (2007) demonstrated that 31% of cOFC neurons code the relative preference of positive and negative reinforcement. Other mOFC neurons show proportional responses when presented with cues associated with two different rewards (Schultz et al., 1998; Padoa-Schioppa and Assad, 2006; Padoa-Schioppa, 2007). Changing the reward contingencies caused some neurons to increase (or decrease) their responses; these fluctuations resulted in some cells changing from non-responders to responders (Tremblay and Schultz, 2000a,b).

Baeg et al. (2009) has also reported that OFC neurons can track a monkey’s behavioral response when the relationship between cue relevance and reward availability changes. The ability to adjust to fluctuating reward contingencies is critical for both man and beast. Using a manipulation known as reward devaluation, the neural correlate of this behavior has now been demonstrated. Responses of OFC neurons are modulated by postigestive factors (perhaps stomach distension or elevated blood glucose levels) that decrease the rewarding value of food which, in turn, reduces the subject’s incentive to eat or drink. For example, when a monkey is allowed to drink or eat one food to the point of satiety (sensory specific satiety), the rewarding value of that item is devalued and loses its ability to act as a reinforcer. This paradigm was used by Scott et al. (1986a) and Yaxley et al. (1985) to determine if the responses of neurons in the NTS and insula, respectively, are affected by satiety; neither was. The taste-evoked responses of neurons in the cOFC, however, decrease as a function of satiety (Rolls et al., 1989). In this experiment, the responses evoked by glucose decreased as the monkey consumed it to the point of satiety; the responses evoked by NaCl were unaffected. This is an example of how reward devaluation, which reflects a decrement in the response magnitude to consumption

of the satiating fluid, impacts behavior. The relationship between satiety-induced reward devaluation and changes in neural activity is more complex and not as decisive in the mOFC (Pritchard et al., 2008). Response magnitude decreases as satiety develops for most neurons, but in a more graded fashion than in the cOFC. Response magnitude increases with satiety for a small group of neurons, but the most interesting cells are those initially classified as non-gustatory that begin responding to sapid stimulation of the tongue after the monkeys reached satiety. The presence of emergent taste neurons suggests that satiety is not strictly a passive process. The ability of OFC neurons to track changes in reward contingencies caused by internal and external factors enables it to support taste-guided reward-evaluation, risk assessment, and decision-making. Damage to the OFC should undermine these processes, and as predicted, OFC-lesioned monkeys demonstrate normal satiety, but show no evidence of satiety-induced reward devaluation (Izquierdo et al., 2004; Murray and Izquierdo, 2007).

## 32.4 CONCLUSION

Rodents and humans do not share the same station in life, but our gustatory systems evolved for the same purpose: identification and consumption of safe, nutritious food, while rejecting hazardous and toxic substances. A side-by-side comparison of the rodent and primate gustatory systems reveals many structural similarities, some differences, and yet a commonality of purpose. As noted above, our knowledge of the gustatory system of both the rat and primate is uneven within and between species. More has been learned about the anatomy and physiology of the gustatory hindbrain from rodents than humans; conversely, most of our knowledge about taste processing in the forebrain has been derived from primates, although research on rats is beginning to make important inroads there. If we put aside the differences that enable each species to survive within its ecological niche, what can we learn about the functional organization of taste by looking at the common features that have survived millions of years of evolution? In other words, are there enough common features in rodents and primates to support assembly of a complete, generic species blueprint of the gustatory system?

The peripheral gustatory apparatus, including the anatomy of individual taste buds and their distribution in the oral cavity, are remarkably similar, not only in rodents and humans, but also across the class Mammalia. The most striking interspecies difference, tongue shape, is driven by non-gustatory functions such as grooming, dietary choices, and mastication rather than taste issues, *per se* (Bradley, 1971).

In rodents and primates, taste buds are innervated by the same three cranial nerves, VII, IX, and X, which terminate in the NTS of the medulla. Although it is possible that the rodent NTS has more (or perhaps slightly different) subnuclei than the primate, functionally, it seems to matter little. In both species, gustatory neurons dominate the rostral-lateral NTS with more medial and caudal areas dedicated to visceral sensation.

Many published reports in rodents have demonstrated that multiple forebrain areas, including the cerebral cortex (e.g., Di Lorenzo and Monroe, 1995; Cho et al., 2002; see also Lundy, 2008), modulate gustatory responsivity of NTS neurons; similar studies have demonstrated that the cerebral cortex modulates auditory (Winer, 2006), vestibular (Akbarian et al., 1994; Nishiike et al., 2000), and somatosensory (Wise and Jones, 1977) transmission through the brainstem. The widespread nature of this phenomenon, across both species and sensory modalities, makes it likely that it is common practice. Descending projections may improve information transmission of relevant information across multiple synapses (Nuñez and Malmierca, 2007) or act as a cognitive filter by sharpening the responses properties of individual neurons (Di Lorenzo and Monroe, 1995).

A side-by-side comparison of the rodent and primate gustatory systems is complicated by the PBN, a visceral and nociceptive relay in both rodents and primates that does not play a role in taste perception in primates (Pritchard et al., 2000; Scott and Small, 2009). This significant interspecies difference raises an obvious question: what does the PBN contribute to taste-guided behavior in rodents? Lesion-behavioral studies in rats are addressing this issue (Grigson et al., 1994, 1998), but for the present, it appears that either the PBN is essential for one or more taste-guided behaviors unique to rodents, or that neural control of these behaviors in primates resides in other brain areas. Ironically, this anatomical issue is most likely to be resolved with behavioral experiments.

Electrophysiological studies directed at the thalamic gustatory relay have revealed very little about its function in either rodents or primates, but from what is known about other sensory systems, the gustatory thalamus in both species may filter information destined for primary taste cortex (Saalmann and Kastner, 2009). Lesion-behavioral experiments may provide additional insight into how the thalamus contributes to taste-guided behavior (Grigson et al., 2000; Mungarndee et al., 2008; Reilly and Pritchard, 1996a,b,c), but the most revealing experiments are likely to involve simultaneous stimulation and recording from the thalamus and primary gustatory cortex.

For many years, knowledge about cortical processing of gustatory information lagged behind what was known about other sensory systems. That began to change after chronic recording techniques developed in other sensory

systems were introduced to the field of taste. Electrophysiological investigations on awake, behaving monkeys have shown that primates are an excellent surrogate for human taste perception. Insights provided by primate research are guiding studies of human taste perception and decision-making being conducted with state of the art non-invasive imaging techniques. Recent electrophysiological experiments in awake rats have provided compelling evidence that the gustatory system is a very dynamic, labile, and distributed system that shapes ingestive behavior.

In summary, rats have different needs and in some ways their neural repertoire is more limited than humans, but after comparing the two species side-by-side, their functional and even the anatomical similarities are more striking than their differences.

## Development of the Taste System

ROBIN F. KRIMM, SHOBA THIRUMANGALATHU, and LINDA A. BARLOW

### 33.1 A GENERAL INTRODUCTION TO THE PERIPHERY OF THE TASTE SYSTEM

Taste or gustation is a contact mediated chemosense, where chemical stimuli are detected and transduced by clusters of specialized epithelial cells known as taste buds. In most vertebrates, taste buds reside in the epithelium of the oral cavity and the pharynx, although some fish have external taste buds embedded in epidermis of head and the trunk. In mammals, the majority of taste buds are found on the dorsal surface of the tongue, and in rodents, taste buds are present in the soft palate. Regardless of location, taste buds share a common organization in that each bud comprises a heterogeneous collection of ~60–100 fusiform cells. Taste buds receive afferent innervation from sensory neurons of the cranial nerve ganglia; those located anteriorly are innervated by VIIth cranial nerve fibers – as are external taste buds in fishes, those situated in the posterior tongue are innervated by sensory neurons of cranial nerve IX, whereas taste buds in pharynx and larynx are supplied by cranial nerve X. Taste information from all three cranial nerves is transmitted to the first taste relay in the hindbrain, the nucleus of the solitary tract (NST). Each of these elements, taste buds, sensory neurons, and hindbrain relay, develop initially independently from one another, each arising from different regions of the embryonic head. As development proceeds, these elements must establish proper connections so that a functional taste system is present at birth, and when feeding commences.

Here we review the recent data on the cellular and molecular regulation of taste system development, focusing primarily on the development of taste buds and their innervation; showcasing advances resulting from use of cutting edge molecular genetic tools. Specifically, we discuss new

data on cellular, tissue-level, and molecular mechanisms of taste bud development, where the historical view of a nerve dependent model has shifted to the current one where taste buds develop via tongue-intrinsic processes. Taste buds house a collection of three cell types (I, II, and III), which are present in consistent ratios, and we discuss significant advances in our understanding of molecular regulation of taste cell fate within buds. We further highlight accumulating evidence for distinct molecular regulation of early development of taste buds in the anterior versus posterior tongue. Finally, we review recent major advances in our understanding of the development of gustatory innervation, and the molecular and cellular mechanisms that govern sensory neuron development, emphasizing advances in our understanding of how these cells connect with their proper targets, that is, taste buds peripherally, and the NST centrally.

### 33.2 ANATOMY OF THE TASTE EPITHELIUM

The majority of studies of taste epithelium development have focused on lingual taste buds of rodents. In mice and rats, taste buds reside in specialized epithelial structures, termed gustatory or taste papillae, on the tongue surface. Anteriorly, a single taste bud is situated in each of a dispersed array of fungiform papillae, while posteriorly, several hundred taste buds are housed in a single midline circumvallate papilla, as well as in bilateral foliate papillae. Additionally, rodents possess a collection of taste buds embedded directly in the epithelium of the soft palate, in the posterior palatine field, as well as in a region known as the *Geschmackstreifen* (literally “taste stripe”); these palatal buds are not housed in papillae. Fungiform papillae

are relatively simple structures; each is mushroom-shaped with the epithelium surrounding a mesenchymal core comprising neural and vascular components, as well as connective tissue. The posterior taste papillae, by contrast, are significantly more complex. The circumvallate papilla possesses a large connective tissue core, which is surrounded bilaterally by deep epithelial invaginations or trenches. The trenches, replete with taste buds, are continuous with the epithelial ducts of paired sublingual salivary glands, which empty their contents into the taste trenches. Likewise, foliate papillae possess hundreds of taste buds embedded in invaginated epithelial folds that are contiguous with the ducts of lingual serous glands. As posterior papillae are fed by lingual salivary glands, the development of the glands and posterior papillae is linked, and thus more complex. Here, we first address development of the more simply organized fungiform field, and then review posterior taste papillae development, emphasizing similarities and important differences between the two taste domains.

### 33.3 ESTABLISHING THE EMBRYONIC ORIGINS OF TASTE BUDS AND PAPILLAE

In mice, development of fungiform papillae is evident at mid-gestation (embryonic day (E) 12.5), when taste placodes (epithelial thickenings) appear in bilateral rows along the lingual surface. In addition to their columnar morphology, taste placode cells express a number of gene products that distinguish them from non-placodal cells, including expression of a secreted protein, Sonic hedgehog (Shh) (Hall et al., 1999). Subsequently, taste placodes undergo morphogenesis beginning at E14.5, to form papillae, each with an invaginated epithelium surrounding a mesenchymal core. However, fungiform taste buds do not differentiate until the first postnatal week, when each of the three taste bud cell types is identifiable via expression of marker proteins (El-Sharaby et al., 2001a,b; Ohtubo et al., 2012; Zhang et al., 2006; Glover, Nguyen and Barlow, pers obs). Thus, taste bud development is intricately entangled with that of the taste papillae. For this reason, taste placodes have been considered to be taste papillae precursors within which a subset of cells is eventually established as taste bud cells. Alternatively, however, taste placodes could be taste bud precursor cells, which instruct local epithelium and mesenchyme to form the surrounding papilla during embryogenesis, and then differentiate into functional taste bud cells after birth. To distinguish between these two hypotheses, we employed an inducible genetic lineage tracing approach to follow the fate of taste placode cells and their progeny (Thirumangalathu et al., 2009). In fact, we showed that taste placodes which express Shh (Shh+)

are precursors for taste receptor cells within buds, and do not contribute to the papilla structure housing buds.

Taste bud cells possess numerous characteristics consistent with their epithelial location, including epithelial morphology as well as regular renewal of new taste cells throughout adult life (Miura and Barlow, 2010). However, taste cells also have significant similarities with neurons; a subset is electrically excitable, fire action potentials and form synapses on afferent nerve fibers (Chaudhari and Roper, 2010). Nonetheless, historically taste buds were considered to arise from the local epithelium (Cook and Neal, 1921; Johnston, 1910; Landacre, 1907; Stone, 1940). These descriptive results were confirmed experimentally some time ago using complementary approaches in amphibian and mouse models (Barlow and Northcutt, 1995; Stone et al., 1995). However, recently, a report has emerged ascribing neural crest cells as the embryonic source of taste buds (Liu et al., 2012b).

The neural crest is a fascinating embryonic population of cells, which arises from the dorsal region of the developing brain and spinal cord early in development. While these cells initially reside in the early neural ectoderm, they undergo an epithelial-to-mesenchymal transition, emerge from the neural tube and migrate in stereotypic streams to a variety of locations in the head and trunk. Once they arrive at their ultimate locations, neural crest cells contribute to a diverse array of cell types including pigment cells, as well as sensory and autonomic neurons and glia in both the head and trunk. However, the neural crest repertoire is greatly expanded in the head; cranial neural crest gives rise to the cartilage and bones, as well as all the connective tissues of the face, supplies the dentine-producing cells of teeth, is the source of all smooth muscle wrapping the arterial vasculature of the head, and further contributes to numerous specialized glands of the head and neck (Le Douarin et al., 2007; Le Douarin and Kalcheim, 1999). Because the neural crest contributes to such a wide array of tissues in the adult, it had also been suggested that it supplies cells to taste buds (Reutter, 1978). This hypothesis was particularly attractive, given the neural characteristics of taste cells, and the fact that *bona fide* sensory neurons in the cranial ganglia derive from the neural crest (D'Amico-Martel, 1982; Narayanan and Narayanan, 1980) and see below).

In previous studies, however, a neural crest contribution to taste buds had been ruled out. In both mouse and amphibian models, when neural crest cells were genetically labeled prior to their emergence from the neural tube and then followed through development, labeled cells were never detected in taste buds (mouse: (Thirumangalathu et al., 2009); amphibian: (Barlow and Northcutt, 1995)). Moreover, in oral epithelial explants from amphibian embryos, taste buds developed despite the complete absence of neural crest cells (Barlow, 2000b, 2001; Barlow and Northcutt, 1997; Parker et al.,

2004). However, using molecular genetic labeling in mice, Mistretta and colleagues now report large numbers of labeled cells in postnatal taste buds (Liu et al., 2012b).

The difference between results from this new study compared with those from the previous ones are likely attributable to differences in the genetic models employed. In both studies (Liu et al., 2012b; Thirumangalathu et al., 2009), Cre lox systems were used where a tissue-specific promoter, in this case Wnt1, was used to drive Cre recombinase in the neural crest prior to its migration from the neural tube. In embryos carrying Wnt1Cre and a Cre reporter allele, Rosa26-LacZ, most pre-migratory neural crest cells are indelibly labeled, such that all neural crest derivatives are likewise labeled (Chai et al., 2000; Danielian et al., 1998; Jiang et al., 2002). Using this approach, we found no neural crest-descendent cells in the lingual epithelium of embryos nor in the taste buds, taste papillae or tongue epithelium in postnatal mice (Thirumangalathu et al., 2009). Mistretta and colleagues, by contrast, report that although exceedingly rare, occasional single neural crest cells were encountered associated with taste placodes in embryos. Predominantly, however, they employed a less well-characterized Cre allele, P0-Cre, to map the fate of neural crest cells in postnatal mice. Specifically, in this transgenic allele, a cassette encoding Cre driven by a fragment of the promoter for P0, an important myelin protein, has been randomly incorporated in the mouse genome (Yamauchi et al., 1999). While native P0 is not expressed in migrating neural crest (Hagedorn et al., 1999), P0-Cre is (Kawakami et al., 2011; Yamauchi et al., 1999), resulting in labeling of early migrating crest in embryos that possess a reporter allele. Using this Cre-lox approach, Mistretta and coworkers found that lingual epithelium and multiple taste placodes were labeled in embryos, and that the extent of labeled cells in the tongue surface was tremendously expanded in postnatal mice. Importantly, however, P0-Cre also labels other embryonic domains in addition to neural crest, including the early oral endoderm and ectoderm, as well as the notochord, indicating that not all genetically labeled cells within P0-Cre embryos derive from neural crest precursors (Yamauchi et al., 1999). This ectopic expression pattern further raises the question of whether P0-Cre is expressed in lingual epithelium postnatally, which would account for the dramatic differences in the results obtained with Wnt1Cre, where epithelial labeling is extraordinarily infrequent, versus those obtained with P0-Cre, where over 80% of taste buds and large swaths of tongue epithelium are labeled. These questions remain to be addressed through a full characterization of the P0-Cre transgenic allele. See Buckingham and Meilhac (2011) for a general discussion of the use of genetic tools for lineage tracing.

### 33.4 CELL AND TISSUE-LEVEL INTERACTIONS GOVERN EARLY TASTE BUD DEVELOPMENT

#### 33.4.1 The Role of Gustatory Nerves

Historically, the primary model for taste bud development had been one of neural induction, where gustatory nerve fibers invade the embryonic lingual epithelium and induce taste bud formation (Mistretta and Liu, 2006; Oakley and Witt, 2004; Olmsted, 1920; Torrey, 1940). This hypothesis is supported by descriptive data, where in all cases, nerve fibers penetrate taste papilla epithelium long before taste buds differentiate, as well as by denervation studies in postnatal rats, where interruption of the nerve supply within the first postnatal week permanently reduces taste bud number despite recovery of the gustatory innervation (see Krimm and Barlow (2007) for review). However, as reviewed previously (Barlow, 2000a; Krimm and Barlow, 2007), early taste bud development has now been shown to be nerve independent. Specifically, in amphibian embryos, taste buds complete their entire developmental program, including taste cell differentiation, in the complete absence of nerves (Barlow, 2001; Barlow et al., 1996; Barlow and Northcutt, 1997). Similarly, in rodents, embryonic development of taste bud precursor cells occurs in cultured tongue explants, including specification and patterning of taste precursors, as well as initial aspects of papilla morphogenesis (Hall et al., 2003; Ito and Nosrat, 2009; Ito et al., 2010; Mistretta et al., 2003; Nosrat et al., 2001). Moreover, these same features of taste bud development occur independently of innervation *in vivo*; specifically, fungiform taste buds are induced and patterned, and papillae undergo morphogenesis in mouse embryos null for the neurotrophin, BDNF or its receptor TrkB, which are required for development of gustatory innervation (Fritsch et al., 1997; Ito and Nosrat, 2009; Ito et al., 2010; Thirumangalathu et al., 2009) and see below). In contrast to amphibians, however, taste cell differentiation in postnatal rodents likely depends upon an intact innervation (Krimm et al., 2001; Liebl et al., 1999; Mistretta et al., 1999; Nosrat et al., 1997; Oakley et al., 1998).

#### 33.4.2 Signaling Between the Embryonic Epithelium and Mesenchyme

Taste buds and their papillae are often categorized as ectodermal appendages, similar to teeth, feathers, and hair follicles (Mistretta and Liu, 2006; Pispa and Thesleff, 2003). Development of these later ectodermal specializations requires extensive reciprocal signaling between epithelial and mesenchymal compartments, interruption

of which results in failure to develop teeth, feathers, or hair (Morgan et al., 1998; Thesleff et al., 1991; Tucker and Sharpe, 1999). The tongue possesses an extensive subepithelial mesenchyme, the lamina propria, which is derived from the cranial neural crest (Chai et al., 2000). In the anterior third of the tongue, fungiform papillae, as well adjacent non-gustatory filiform papillae (the vast majority of papillae covering the tongue surface) all have a similar structure with epithelium bounding mesenchyme in the core. More posteriorly, in the middle third of the rodent tongue, fungiform taste buds are mostly absent, and papillae are non-gustatory (Mistretta, 1972). It appears that signals from the mesenchyme, TGF $\beta$  pathway inhibitors in particular and see below, restrict fungiform taste papillae to the anterior domain, as genetic loss of this inhibition results in development of taste bud precursors in the tongue's middle third (Beites et al., 2009). Similarly, culture studies suggest a role for lingual mesenchyme in the pattern of taste buds that form in the anterior third of the tongue (Kim et al., 2003). Thus, signals from lingual mesenchyme appear to regulate the pattern of developing taste buds in rodents. Interestingly, in amphibian embryos, taste buds differentiate in the absence of cranial mesenchyme (Barlow and Northcutt, 1997; Parker and Barlow, 2000), suggesting that in this vertebrate group taste bud specification is independent of mesenchymal signals. In mammals, it has not been determined whether initial formation of taste buds is likewise mesenchyme-independent, nor has a patterning role for mesenchyme been ruled out for amphibian taste buds. Resolution of these questions will likely reveal which aspects of epithelial-mesenchymal interactions are common to all vertebrates, and which may regulate specialized features of taste epithelium in each vertebrate sub-class.

### 33.4.3 Molecular Regulation of Anterior Taste Bud Development

As mentioned earlier, taste buds have both epithelial and neural characteristics, and thus molecular regulation of the development of these receptor organs may resemble that of skin or neural epithelium, or may comprise an amalgam of these mechanisms that is unique to taste. An additional consideration is that the developmental profile for taste epithelium may be more comparable to that of gut. Specifically, the oropharyngeal cavity is the gateway to the GI tract, and as such is contiguous with the gut axis. The idea that taste receptors are more "gut-like" than "skin appendage-like" is reinforced by the fact that taste receptor and transduction proteins are expressed by chemosensory cells in the stomach and intestine (Höfer et al., 1996; Kokrashvili et al., 2009; Sternini et al., 2008). However, even within a broad tissue type, such as the gut, the mechanisms governing development are organ specific (Udager et al., 2010; Zorn and Wells, 2009), likely

reflecting the divergence in the function of each region during evolution, for example, stomach – digestion, small intestine – absorption. Thus the tissue level and molecular mechanisms for taste bud development are unlikely to mirror those driving formation of only one these specialized tissues, but rather will represent a combination of mechanisms entirely unique to taste.

A host of important signaling pathways are expressed in the developing tongue epithelium, commencing as taste placodes form, and we have significant functional data for several of these. Of prime importance to date, are the Sonic hedgehog (Shh) and Wnt/ $\beta$ -catenin pathways.

**33.4.3.1 Sonic Hedgehog (Shh).** Sonic hedgehog is a key signaling molecule that regulates multiple aspects of vertebrate organogenesis (Ingham and McMahon, 2001), and in particular, functions as a morphogen in the development of epithelial appendages, that is, hair, feathers, and teeth (Chuong et al., 2000). In the developing tongue, Shh is expressed by taste placode cells, while expression of its receptor (and target gene) Ptch1, and downstream target Gli1, are initially broad, and then become restricted to the epithelium and mesenchyme immediately surrounding placodes; these expression patterns suggest that Shh+ taste placodes signal to the local epithelium and mesenchyme during embryonic development. As Shh null mutants have major oral malformations including absence of the tongue (Incardona and Roelink, 2000), functional studies of Shh's role in taste epithelial development have been limited to the manipulation of embryonic tongue explants. Pharmacological inhibition of Shh, with the steroidal alkaloid cyclopamine or a function-blocking antibody, results in larger and more fungiform placodes, and triggers taste placode formation ectopically, in the middle third of the tongue normally devoid of taste buds (Hall et al., 2003; Liu et al., 2004; Mistretta et al., 2003). Treatment of cultured tongues with excess Shh ligand, by contrast, blocks placode development (Iwatsuki et al., 2007). In sum, these data indicate that Shh acts to repress taste fate in the anterior and middle zones of the tongue, serving an important function in taste organ patterning. Interestingly, inhibition of Shh results in increased Shh expression in these excess and enlarged taste papillae, suggesting that Shh is an indirect negative regulator of its own expression, and implicating additional molecular players in taste patterning.

**33.4.3.2 Wnt/ $\beta$ -Catenin.** Wnt signaling molecules are a family of evolutionarily conserved secreted glycoproteins, which function in the specification, patterning, differentiation, and regeneration of numerous epithelial appendages (Gordon and Nusse, 2006). Wnt ligands bind specifically to members of the Frizzled family of receptors

and to LRP5/6 co-receptors to activate several signaling cascades, of which the  $\beta$ -catenin or “canonical” pathway is best studied and understood (Angers and Moon, 2009; Bejsovec, 2005). In brief, Wnt ligand binding to its receptors results in the dissociation of an intracellular destruction complex, which normally acts to maintain low levels of cytosolic  $\beta$ -catenin. When this complex is inactivated,  $\beta$ -catenin accumulates and moves to the nucleus, binding with TCF/LEF transcription factors to turn on Wnt target genes. Several reporter constructs have been built to identify cells experiencing active Wnt signaling, and these have been employed in both *in vitro* and *in vivo* models. Specifically, the TOPGAL mouse line carries an engineered allele where TCF/LEF response elements turn on expression of the LacZ gene when Wnt signaling drives  $\beta$ -catenin into the nucleus (DasGupta and Fuchs, 1999).

Use of the TOPGAL reporter mouse has revealed that Wnt signaling is active in lingual epithelium of embryos, including in taste placodes as they first form at E12.5, while the lingual subepithelial mesenchyme is devoid of Wnt/ $\beta$ -catenin-responsive cells (Iwatsuki et al., 2007; Liu et al., 2007). Tests of Wnt function *in vivo* therefore have entailed either activating or deleting the canonical Wnt effector gene,  $\beta$ -catenin, exclusively within the lingual epithelium (Liu et al., 2007). Mice carrying transgenes with promoters for human cytokeratins 5 or 14 (K5 (Diamond et al., 2000); K14 (Andl et al., 2004) were used to drive expression of Cre recombinase in developing tongue epithelium, coincident with the development of taste placodes (Farbman and Mbiene, 1991; Mbiene and Roberts, 2003). When the Wnt pathway is triggered by Cre-mediated activation of a non-degradable allele of  $\beta$ -catenin (Harada et al., 1999), the entire tongue surface is transformed into enlarged taste papillae, each housing large clusters of Shh+ taste bud precursor cells. By contrast, in embryos with epithelial deletion of  $\beta$ -catenin, Shh+ taste placodes fail to form; likewise, Shh+ taste bud precursor cells are absent in embryos in which canonical Wnt signaling is broadly inhibited via epithelial over-expression of a secreted Wnt antagonist, Dkk-1 (Liu et al., 2007). Thus, Wnt signaling is both required and sufficient for taste bud precursor and papilla development, and functions as an initiator of taste placode formation, genetically upstream of Shh. However, Shh is also a negative regulator of Wnt signaling, as cultured tongues treated with Shh inhibitors exhibit expanded placodes with commensurate increased TOPGAL signaling (Iwatsuki et al., 2007).

To date, the Wnt gene(s) involved in taste bud initiation has not been identified. One obvious candidate is *Wnt10b*, a ligand in the canonical pathway, whose expression is restricted to taste placodes (Iwatsuki et al., 2007). However loss of *Wnt10b* does not phenocopy the loss of  $\beta$ -catenin or overexpression of Dkk-1, as taste placodes still form in *Wnt10b* KO tongues, inferring that other Wnts must

be involved (Iwatsuki et al., 2007). Likewise, deletion of Lef1, one of several downstream transcriptional activators in the canonical pathway, results in reduced taste papillae with reduced Shh expression, yet taste papillae are not completely absent implicating additional Wnt pathway transcription factors (Iwatsuki et al., 2007). Additionally, *Wnt5a*, a ligand for the planar cell polarity pathway (Wansleeben and Meijlink, 2011), is expressed in deep lingual mesenchyme including muscle layers (Cervantes et al., 2009; Paiva et al., 2010), but taste placodes are unaffected in *Wnt5a* KO embryos; although the tongue is dramatically shortened likely due to failure of development of the lingual musculature (Liu et al., 2009). Overall, of the 19 Wnt ligands in mouse, a total of 5 have been shown to be expressed in the developing tongue, including both canonical ligands, that is, signal via  $\beta$ -catenin (*Wnt4*, *Wnt10a*, *Wnt10b*) (Iwatsuki et al., 2007; Liu et al., 2007), and non-canonical ligands, that is, signal via alternative pathways (*Wnt5a*, *Wnt11*) (Kim et al., 2009; Lin et al., 2011). This extensive ligand expression repertoire suggests that Wnts function in numerous aspects of tongue and taste bud development, hinting that a complex balance among canonical and non-canonical Wnt pathways is required (Liu and Millar, 2010).

### **33.4.3.3 Bone Morphogenetic Proteins (Bmps).**

BMPs belong to the large superfamily of TGF $\beta$  secreted proteins, comprising ~20 genes, of which BMP2, 4, and 7 are expressed in the developing taste epithelium (Beites et al., 2009; Hall et al., 2003; Jung et al., 1999). BMPs bind specific heterodimeric transmembrane receptors, resulting in serial phosphorylation events, including that of SMAD transcription factors. Upon phosphorylation, these SMADs translocate to the nucleus to activate target gene expression (Guo and Wu, 2012). Most tests of BMP function in embryonic taste bud development to date have utilized cultured tongue explants. Specifically, BMP 2, 4, and 7 have shifting roles in taste bud development (Zhou et al., 2006). When tongue rudiments are treated with any of the three BMP ligands commencing prior to formation of taste placodes, the number and size of placodes are expanded. However, if tongue explants are exposed to BMP after taste placodes have been specified, then the number of placodes declines. Intriguingly, the secreted BMP antagonist, Noggin, has the same effect on taste placodes regardless of the timing of treatment; more taste placodes form than in untreated control explants. By contrast, follistatin, another secreted blocker of BMP function, has no impact on taste placode development *in vitro* (Zhou et al., 2006).

In contrast to the culture studies, Calof and colleagues have shown that repression of BMP4 signaling by follistatin restricts taste placode formation to the anterior

tongue. In follistatin knockout embryos, taste placodes form in the middle third of the tongue, a domain typically devoid of taste organs (Beites et al., 2009). The difference between the *in vivo* and *in vitro* results may be due to the likelihood that follistatin manipulation *in vitro* occurred well after follistatin's first function *in vivo*. Finally, expression of BMP4 has been placed genetically downstream of Wnt/β-catenin (Liu et al., 2007), and is impacted by Shh signaling *in vitro*; inhibition of Shh in lingual explants results in expanded BMP4 expression in expanded papillae (Hall et al., 2003). Likewise, BMP ligand treatment represses Shh expression in tongue cultures (Zhou et al., 2006). Thus, the Shh, BMP and Wnt/β-catenin pathways interact extensively, and likely repeatedly, as an organized taste epithelium emerges through the stages of specification, patterning, morphogenesis and cell differentiation.

#### **33.4.3.4 Fibroblast Growth Factors (Fgfs).**

The Fgf family of secreted factors comprises over 20 ligands, which bind 4 Fgf receptor proteins, each with multiple alternative splice variants resulting in distinct proteins and functions (Itoh and Ornitz, 2011; Thisse and Thisse, 2005). Among these, Fgf8 is expressed transiently in the early lingual epithelium prior to placode formation (Jung et al., 1999), whereas subsequent Fgf2, Fgf7, and Fgf10 expression is restricted to the tongue mesenchyme and muscle layers (Nie, 2005). Likewise, distinct Fgf receptors are expressed in a temporally complex pattern in both epithelium and mesenchyme (Nie, 2005).

Although Fgf pathway members are expressed throughout the anterior and posterior tongue, the most extensive examinations of Fgf function to date have focused on development of posterior taste buds (Kapsimali et al., 2011; Petersen et al., 2011), and thus will be discussed below in the section dedicated to the posterior taste papillae. Nonetheless, in the tongues of mouse embryos null for Fgf10, we found qualitatively that anterior fungiform taste papillae are expanded, whereas in tongues in which a pair of negative regulators of Fgf signaling, Spry1 and Spry2, have been deleted, fungiform taste papillae are reduced (Petersen et al., 2011). These data indicate that Fgf signaling, at least in the case of Fgf10, negatively regulates development of taste buds in the anterior tongue, but does so by mechanisms that have yet to be defined.

#### **33.4.3.5 Epidermal Growth Factor (Egf).**

EGF is the founding member of the EGF family of secreted factors that include the neuregulins, and TGF-alpha, among others (Normanno et al., 2005). EGF ligands bind to EGF and/or ErbB receptors to selectively activate specific intracellular pathways, including PI3 kinase/AKT, MEK/ERK, and p38 MAPK. Both EGF ligand and the

Egf receptor are initially expressed broadly in the lingual epithelium, but only the Egf receptor is then progressively excluded from taste placodes, suggesting a role for this pathway in non-taste epithelium (Liu et al., 2008). EGF function was implicated in taste bud development over a decade ago, where EGF KO embryos were found to have fewer fungiform papillae (Threadgill et al., 1995), a finding reinforced by examination of Egfr KO tongues of postnatal mice (Sun and Oakley, 2002). Most recently, EGF function in early taste bud development has been assessed pharmacologically in cultured embryonic tongues (Liu et al., 2008). Excess EGF represses fungiform papilla formation in explants, whereas inhibition of Egfr resulted in expanded and fused papillae. Each of the three pathways downstream of Egfr activation appear to contribute to EGF's role in taste placode development; EGF repression of taste placodes could only be rescued when all three downstream pathways, PI3K/AKT, MEK/ERK, and p38 MAPK, were simultaneously inhibited. In sum, EGF likely functions to promote non-taste epithelial fate, thus the interaction between EGF and Wnt/β-catenin signaling, which promotes taste fate, should prove to be an exciting area to investigate.

#### **33.4.4 Development of the Circumvallate Taste Papilla and Von Ebner's Gland Complex (CVP/VEG)**

In contrast to the anterior fungiform papillae, taste buds in the posterior tongue reside in large and more complex structures, the circumvallate and foliate taste papillae. Each of these papillae houses several hundred taste buds, and is supplied by lingual salivary glands. The majority of studies of development of posterior taste buds has focused on the single circumvallate papilla (CVP) of rodents, which is associated with specific tubuloacinar serous glands, the Von Ebner glands – VEG; the ducts of these glands are continuous with the trench lumens of the CVP such that together they form the CVP/VEG complex. Biochemical (Hamosh and Burns, 1977) and immunocytochemical studies (Roberts and Jaffe, 1986) have demonstrated that the CVP/VEG complex initially produces the digestive enzyme lingual lipase. As nutrition for neonatal mammals comprises primarily milk triglycerides, these are initially digested with the help of lingual lipase during the period when the pancreas is still immature and pancreatic lipase is scarce. Whether this enzymatic profile shifts with weaning, as is the case for the enteroendocrine cells in the intestine (Henning, 1981), remains to be determined.

Like fungiform papillae, the CVP is first evident as a large placode in the posterior midline of the embryonic tongue. In mice, the CV placode forms by E12.0, followed by morphogenesis of bilateral epithelial trenches and a central mesenchymal core emerges replete with vascular

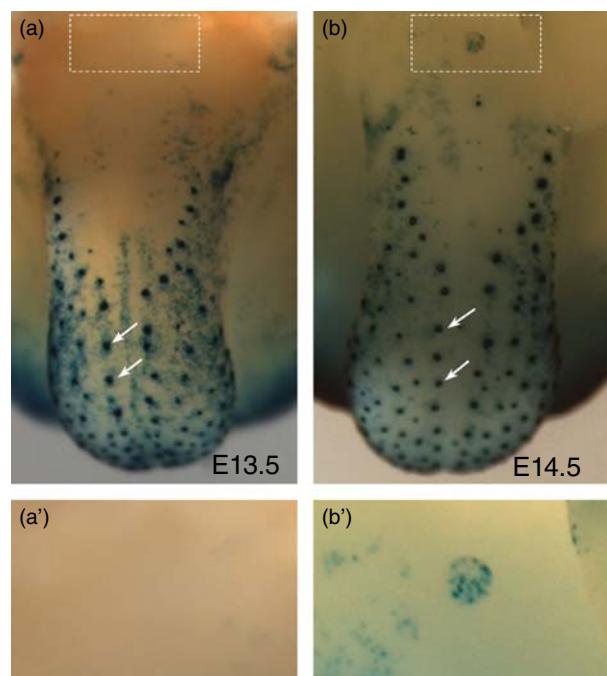

and neural components (AhPin et al., 1989; Graziadei and Graziadei, 1978; Jitpukdeebodintra et al., 2002; Petersen et al., 2011; Sbarbati et al., 2000; Wakisaka et al., 1996). Precursors of the VEGs are thought to be located at the tips of the invaginating trenches as early as E15.5, based upon keratin gene expression patterns (Lee et al., 2006), while branching morphogenesis of the glands begins around birth (Jitpukdeebodintra et al., 2002; Lee et al., 2006; Sbarbati et al., 2000, 2001; Sohn et al., 2011). As is the case for fungiform papillae, taste buds first differentiate within the CV trench epithelia during the first postnatal week, and over several weeks, the number and cell complement of CV taste buds in rodents increases to the adult levels (El-Sharaby et al., 2001b; Hosley and Oakley, 1987; Miller and Smith, 1988; Oakley et al., 1991; Sbarbati et al., 1999, 2001; Zhang et al., 2008).

### 33.4.5 A Comparison of the Molecular Regulation of Early Development of the Circumvallate Versus Fungiform Taste Papillae

As discussed above, the Wnt/ $\beta$ -catenin, Shh, and BMP pathways regulate taste bud development in the anterior tongue, and these signaling pathways are also involved in development of the CVP. However, in a number of instances, these pathways appear to have quite divergent functions in the specification and patterning of the anterior versus posterior taste fields.

**33.4.5.1 Wnt/ $\beta$ -catenin.** The first example is the role of Wnt/ $\beta$ -catenin signaling. As discussed earlier, Wnt/ $\beta$ -catenin is both required and sufficient for initiation of fungiform taste bud development (Iwatsuki et al., 2007; Liu et al., 2007). Consistent with this requirement, Wnt signaling is evident in the earliest stages of fungiform placode development (Iwatsuki et al., 2007; Liu et al., 2007). By contrast, we find that Wnt/ $\beta$ -catenin activity is not present in the circumvallate placode when it first forms (data not shown), nor is it evident as morphogenesis begins at E13.5 (Figure 33.1A) (Iwatsuki et al., 2007). Instead, Wnt activity appears in the CVP at E14.5 (Figure 33.1B), thus implicating the Wnt/ $\beta$ -catenin pathway in later aspects of CVP development.

Interestingly, *Wnt10b*, a ligand for the canonical Wnt pathway, is expressed by both CV and fungiform placodes early on, however, loss of *Wnt10b* had no effect on the CVP, while fungiform papillae were reduced in number and size (Iwatsuki et al., 2007). Similarly, loss of Lef1, an effector of Wnt/ $\beta$ -catenin signaling resulted in fewer and smaller fungiform papillae at birth, while the CVP appeared normal at E14.5 (Iwatsuki et al., 2007). These results suggest that compared with fungiform development where Wnt initiates placode formation, Wnt signaling is not required for

**Figure 33.1** Tongues from mouse embryos harboring the Wnt reporter allele, BATGAL, when reacted for X-gal histochemistry, reveal extensive Wnt/ $\beta$ -catenin signaling in the anterior fungiform taste placodes at both E13.5 (a) and E14.5 (b) (examples indicated with white arrows). However, BATGAL reporting is not evident in the posterior CVP until E14.5. Compare E13.5 where no X-gal product is evident (a, a'), with E14.5 where the CVP has extensive staining (b, b'). Areas inside dashed boxes in a and b are shown in a' and b' respectively.

CV placode specification, and instead may function in CVP morphogenesis and/or differentiation of taste buds within the CVP trench epithelium.

The Wnt planar cell polarity (PCP) pathway has also been investigated in taste epithelial development. While loss of Wnt5a, a ligand for the PCP pathway, has no impact on fungiform taste papillae, the CVP is smaller in Wnt5a mutants (Liu et al., 2012a), suggesting that the Wnt/PCP may play a role in morphogenesis of the CVP but not of fungiform papillae. Consistent with this observation, Wnt 11, another PCP pathway ligand, appears to direct cell shape changes in the apical CVP epithelium through its interaction with the Rho kinases (Kim et al., 2009). These observations are intriguing, and indicate that the role(s) of non-canonical pathway in the development of the CVP needs further exploration.

**33.4.5.2 Sonic Hedgehog (Shh).** Shh is an important negative regulator of specification and patterning of fungiform taste buds. In the anterior tongue, Shh is expressed in taste placode cells as these structures

first form. Shh is also expressed in the CV placode at E12.0 (in mice), and Shh expression is evident in the epithelial trenches of the CVP by late gestation (Hall et al., 1997; Lee et al., 2006; Petersen et al., 2011). While inhibition of Shh results in excess and enlarged fungiform placodes and papillae, Shh inhibition during CVP development results in stunted CVP trenches with reduced proliferation and differentiation, suggesting that Shh promotes CVP and VEG development (Kim et al., 2009), as is the case for Shh function in submandibular salivary gland morphogenesis (Jaskoll et al., 2004). Examination of Ectodysplasin (Eda) signaling also sheds light on Shh's role in CVP/VEG development. The Eda pathway comprises the tumor necrosis factor-like ligand, EDA A1, and its receptor EDAR. Eda pathway mutants have an abnormal CVP with diminished Shh expression, suggesting that Shh functions downstream of Eda signaling. However, addition of exogenous Shh to the tongue explants did not fully rescue gland development in these mutants suggesting that Shh must act in concert with other factors to support normal development of the CVP/VEG (Wells et al., 2010).

### **33.4.5.3 Bone Morphogenetic Proteins (Bmps).**

In cultured tongue explants BMP2, 4, and 7 and their secreted antagonist Noggin have opposing inhibitory or activating roles thereby balancing their functions in setting up a stereotypical array of fungiform taste field (Zhou et al., 2006). Follistatin (Fst), a BMP antagonist, is expressed in lingual mesenchymal and regulates the size, pattern, and differentiation of fungiform taste papillae through its interaction with epithelial BMP7 (Beites et al., 2009); genetic deletion of follistatin results in development of ectopic fungiform taste papillae. However, the CVP and VEG appear completely normal in *Fst*<sup>-/-</sup> mutant tongues, revealing yet another signaling pathway that differentially regulates the posterior and anterior taste fields.

### **33.4.5.4 Fibroblast Growth Factors (Fgfs).**

As discussed earlier, several FGFs and their receptors are expressed in the developing tongue, suggestive of a role in taste development (Jung et al., 1999; Nie 2005). In fact, loss of *Fgf10* results in enlarged and more numerous fungiform papillae, whereas enhanced Fgf signaling, via deletion of negative regulators of receptor tyrosine kinase signaling (Spry2 and Spry1), results in diminished fungiform papillae (Petersen et al., 2011). By contrast, the CVP is lost in *Fgf10* null embryos, whereas multiple CVPs develop in Spry mutants. In fact, loss of Spry2 results in a duplicated CVP, replete with differentiated taste buds, and in Spry1/2 double knockout tongues, multiple CVP form.

As in mouse CVP development, Fgf signaling is also required for development of the posterior taste buds in the pharyngeal cavity of zebrafish (Kapsimali and Barlow,

2012; Kapsimali et al., 2011). The timing and pattern of expression of Fgfs and their receptors are consistent with a role in taste bud development. In fact, loss of Fgf signaling (genetically or pharmacologically) blocks pharyngeal taste bud development. Thus, as pharyngeal taste buds in zebrafish are not housed in papillae, results of this study support the results in mouse, that there is an evolutionarily conserved requirement of Fgf signaling for posterior taste epithelium development.

In sum, the results of the above studies provide strong evidences for differential regulation of taste bud specification and patterning in the anterior versus posterior tongue. In fact, in some cases, pathway function in the anterior tongue may be opposite to that in the posterior tongue, for example, Shh, Fgf. What could account for these differences? One likely explanation is that the anterior tongue and resident fungiform taste buds are derived from ectoderm, whereas the posterior lingual epithelium, housing the CVP and foliate papillae, arises from the endoderm. Certainly this is the case in amphibians, where lineage tracing in embryos of an aquatic salamander revealed that most taste buds derive from endoderm (Barlow and Northcutt, 1995), yet those located most anteriorly are ectodermal in origin (Barlow, 2000b). However, in mammals, endoderm versus ectoderm assignations have been based solely on descriptive differences in lingual epithelial morphology. Only recently has the germ layer of origin for the disparate taste papillae been defined in mice, using molecular genetic lineage tracing. Abigail Tucker and colleagues employed a *Sox17-2A-iCre* allele that drives Cre recombinase expression in early endoderm crossed with a reporter line to demonstrate an endodermal origin for the posterior foliate and CV papillae, as well as for their associated minor lingual glands. The anterior fungiform taste papillae were not derived from the labeled endoderm, and thus were assigned an ectodermal origin (Rothova et al., 2012). Thus, differences in early patterning of taste epithelium may reflect the different embryonic histories of the two germ layers; an idea that is now readily testable.

## **33.5 MOLECULAR REGULATION OF TASTE BUD CELL LINEAGE**

While initial patterning of anterior and posterior taste papillae are differentially regulated, mechanisms governing cell fate among specified taste precursors may be more similar with respect to taste bud location. However, no studies have addressed establishment of taste bud cell fate in a regionally comprehensive way, so this question remains an open one. Nonetheless, the Notch pathway, which acts widely in cell fate specification in a variety of embryonic tissues (Gridley, 1997; Muskavitch, 1994), clearly functions in taste cell fate choice during development.

### 33.5.1 Notch Signaling

In contrast to the previous sections where we discussed the roles of secreted factors in taste development, the Notch pathway is contact-mediated signaling system (Bray, 2006). Notch transmembrane receptors, of which there are four in mammals (N1, N2, N3, and N4), bind membrane-spanning ligands on adjacent cells. These ligands comprise four Delta-like members (Dll-1, Dll-2, Dll-3 and Dll-4), and two Jagged genes (Jag1, Jag2). Notch receptor binding to ligand triggers a succession of proteolytic cleavages of the N receptor, resulting in a free intracellular element (NICD), which translocates to the nucleus to affect gene expression in conjunction with CBF1/RBPkappaJ. In particular, expression of several bHLH transcription factors, including Ascl1 (previously named Mash1) and Hes1, are regulated by Notch signaling; activation of the pathway promotes Hes1 expression which in turn represses Ascl1 transcription. Notch pathway genes are expressed in the developing taste epithelium in mouse, although these expression data have been generated primarily for the developing CVP (Seta et al., 2003). In particular, expression of N pathway genes commences once the CV placode begins morphogenesis, suggestive of a role in cell fate decisions in developing taste epithelium, rather than in specification or patterning of taste versus non-taste fields. Similarly, Ascl1 is expressed in the developing taste placodes of the anterior tongue and of the soft palate but commencing after placode-specific expression of Shh has peaked, again suggestive of cell fate decisions within already specified taste placodes (Nakayama et al., 2008). Notch function in the anterior tongue has not been explored, however, the Notch pathway has been shown to play a role in selection of cell fate in taste buds located in the posterior oral cavity in zebrafish (Kapsimali et al., 2011). Specifically, a reduction in Notch signaling results in an overproduction of serotonin+ taste receptor cells (likely homologs of Type III cells in mammals), with a commensurate absence of calbindin 2b+ (Calb2b) taste bud cells (potential homologs of mammalian Type II taste cells), while enhanced Notch signaling favors a Calb2b+ over a serotonin+ taste cell fate. See Kapsimali and Barlow (2013) for a recent discussion of fish versus mammalian taste cell types.

### 33.5.2 Transcription Factors and Taste Bud Development

Cell signaling via diffusible and cell contact-mediated pathways are non-cell autonomous regulators of taste epithelial development, while the response of cells to developmental signaling is mediated by cell intrinsic regulation of gene expression. Thus, a wide array of transcription factors is expressed at progressive stages in taste placode and

papillae, the timing of which are suggestive of functions in discrete aspects of taste epithelial development. Specifically, several transcription factors are expressed in taste precursor cells coincident with the first emergence of taste placodes, suggesting roles in specification and patterning; these include Six1, Six4, Sox2, and Prox1. An additional set of transcription factors, comprising Mash1/Ascl1 and Hes1, which are typically regulated by Notch signaling, are expressed later on, once papilla morphogenesis is underway, and likely function in cell fate choice within specified taste precursors. These two groups are discussed in turn below.

Six1 is a homeobox transcription factor, which has crucial functions in vertebrate organogenesis and in specification of sensory fields as well as in cell fate decisions in sensory organs such as the inner ear (Ahmed et al., 2012) and olfactory epithelium (Chen et al., 2009). Six1 is initially expressed broadly in the epithelium and mesenchyme of the developing tongue (Suzuki et al., 2010a), focalizes to taste placodes by mid-gestation, and persists in fungiform epithelial cells through embryogenesis. Fungiform taste papillae are affected in Six1 knockout embryos, as both their number and size dramatically increase (Suzuki et al., 2010b). Importantly, the distribution of fungiform papillae is distorted compared with that of wild type, and this may in part be due the impact of loss of Six1 on tongue development in general, as tongue morphology is also disturbed. Six4, another homeobox transcription factor, has a pattern of expression similar to that of Six1 in the developing tongue and fungiform papillae, but loss of Six4 alone does not affect the tongue nor the taste papillae. However, embryos null for both Six1 and Six4 have a more severe taste phenotype than the Six1 knockouts; not only are taste papillae enlarged and more numerous, these papillae appear to undergo precocious morphogenesis (Suzuki et al., 2011). However, it is not clear if Six1 and Six4 loss of function impacts taste placodes cell-autonomously, or if early Six1/Six4 dependent events in the tongue epithelium and mesenchyme indirectly impact patterning and morphogenesis of taste papillae in the anterior tongue.

Sox2 is an HMG-box transcription factor, most well known for its function in maintenance of stem cell fate in a variety of adult tissues. However, Sox2 is also required for many aspects of embryonic development, including differentiation of taste bud cells (Okubo et al., 2006). Sox2 is expressed broadly throughout the lingual epithelium of the developing tongue, and is most highly expressed in taste placodes and papillae. While taste placodes form in the tongues of Sox2 hypomorphic embryos, that is, those possessing an allele of Sox2 with reduced expression, these placodes fail to give rise to taste bud precursor cells, as evidenced by the lack of placode-specific Shh expression. Intriguingly, while Sox2 is required for taste bud development, it is not sufficient; overexpression of

Sox2 within lingual epithelium represses differentiation of non-gustatory (filiform) papillae, but does not trigger taste bud development. Importantly, Sox2 is genetically downstream of canonical Wnt signaling, and thus the Wnt pathway likely requires downstream factors in addition to Sox2 in order to initiate the full developmental program of taste placodes.

A third transcription factor, Prox1, is also expressed in early taste placodes, and in particular, in Shh+ taste precursor cells (Nakayama et al., 2008). While Prox1 function has not yet been assessed in taste development, it is known to control cell fate decisions in both the retina (Dyer et al., 2003; Dyer, 2003) and the inner ear (Dabdoub et al., 2008) of vertebrates, and its *Drosophila* homolog, *prospero*, was originally identified as a determinant of neural fate in the central nervous system (CNS) of flies (Doe et al., 1991). Thus, one potential role for Prox1 would be to regulate cell fate assignment in the taste cell precursor population, an hypothesis that remains to be tested.

*Ascl1* (formerly *Mash1*) is a bHLH transcription factor that is regulated by Notch pathway activity, and functions in neural fate selection in a wide variety of tissues, including the olfactory epithelium (Beites et al., 2005; Calof et al., 2002; Cau et al., 2002, Murray et al., 2003; Shou et al., 1999). *Ascl1* expression and function have not been defined in the fungiform papillae, but have been assessed in developing palatal taste buds and those of the CVP. *Ascl1* expression initiates after that of Shh and *Prox1* in palatal taste placodes (Nakayama et al., 2008), suggesting a role in cell fate determination, rather than in the initial specification of taste bud precursors. Consistent with this hypothesis, cells expressing AADC, a marker of Type III taste cells, are absent in *Ascl1* knockout embryos examined immediately prior to birth, whereas gustducin-immunoreactive Type II taste cells are present, and appear in normal numbers in mutant soft palate taste buds (Seta et al., 2011). Thus, *Ascl1* appears to function in the selection of Type III taste cell fate in rodents, a result consistent with those from studies of taste bud cell fate decisions in zebrafish embryos (Kapsimali et al., 2011). Specifically in zebrafish, *Ascl1*-/- mutants fail to develop serotonin+ taste cells, which are likely homologous to the Type III cells of mammals, but *Calb2b*+ taste cells (likely Type II cells) do form, and may even be increased in number in *Ascl1* mutants.

*Hes1* is another bHLH transcription factor which is transcriptional target of the Notch pathway. *Hes1* expression has only been reported for the posterior CVP where it localizes to the epithelium of the papilla late in embryonic development (Ota et al., 2009; Seta et al., 2003), again consistent with a function in taste bud cell lineage decisions. In fact, embryos that lack *Hes1* have an overabundance of Type II taste cells at birth, compared to wild type or heterozygous null littermates, suggesting that *Hes1* acts

in a dose-dependent manner to repress selection of Type II fate (Ota et al., 2009). This hypothesis is particularly attractive as these authors further showed via chromatin immunoprecipitation analysis, that *Hes1* binds to regulatory sites upstream of well known Type II taste cell markers, *IP3R3* and *PLCB2* (Ota et al., 2009).

Most recently, the homeodomain transcription factor, *Skn-1a* (*Pou2f3*), has been shown to be required cell autonomously for Type II taste cell fate (Matsumoto et al., 2011). Specifically, *Skn-1a* is expressed in taste cells responsive to sweet, bitter and umami, and *Skn-1a*−/− mice fail to form type II taste cells. Instead, in the absence of *Skn-1a*, the number of type III cells is expanded.

### 33.6 FORMATION OF THE GUSTATORY SENSORY GANGLIA

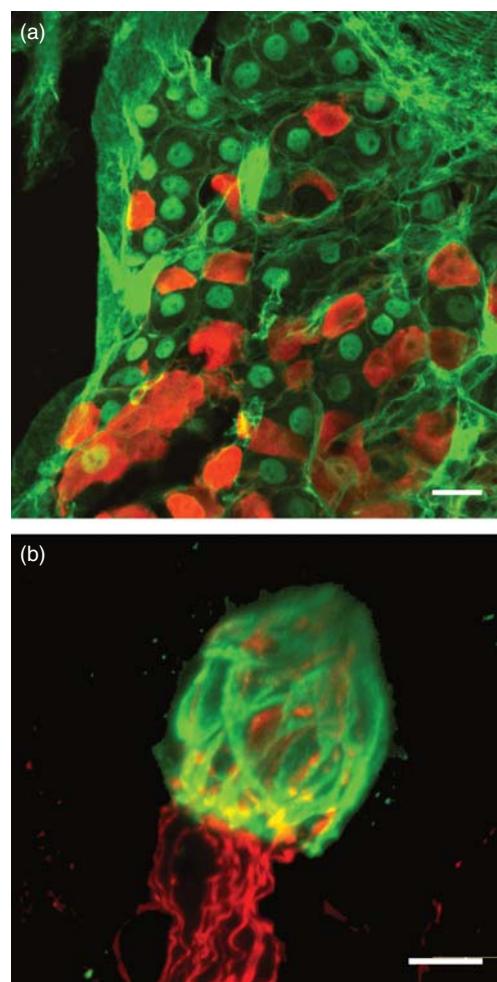

Gustatory neurons are contained within the geniculate, petrosal, and nodose cranial ganglia. These neurons project into the tongue and palate to innervate taste buds and into the hindbrain to innervate specific neurons within the nucleus of the solitary tract (NTS). Cranial ganglia tend to have mixed embryonic origins, with some neurons arising from neural crest and others from epibranchial placodes, which are transient ectodermal thickenings. All cranial placodes, including the epibranchial placodes, arise from a common panplacodal primordium (Schlosser, 2006; Schlosser, 2010). Multiple transcription and signaling factors regulate panplacodal primordium formation and specify the epibranchial placodes that will form the geniculate, petrosal, and nodose ganglion (recent reviews include Ladher et al., 2010; McCabe and Bronner-Fraser, 2009; Schlosser, 2010). Until recently, it was unclear whether the gustatory ganglia also contained neural crest-derived neurons in addition to placodal-derived neurons. However, recent fate mapping experiments in salamanders revealed that gustatory neurons are derived entirely from epibranchial placodes and that neural crest-derived neurons within the gustatory ganglia are strictly somatosensory (Harlow and Barlow, 2007). Furthermore, the bulk of somatosensory neurons within the geniculate ganglion of mice are placodal in origin (Harlow et al., 2011; Quina et al., 2012; Yang et al., 2008). Genetic labeling of ectoderm specifically demonstrated that geniculate neurons are of placodal origin (Harlow and Barlow, 2007), while genetically labeled neural crest cells (using *Wnt1-Cre*) differentiate primarily into glial cells (Harlow et al., 2011). There are a few neural crest-derived neurons within the geniculate, and while they are likely somatosensory neurons as in the axolotl, they are insufficient to account for most of the geniculate somatosensory neurons. Interestingly, the reason neural crest cells do not form neurons in the geniculate ganglion is because neuronal differentiation

is suppressed by the transcription factor Homeobox A2 (Hoxa2), which is specifically in the cells derived from neural crest (Yang et al., 2008). Removal of Hoxa2 results in a substantial increase in neural crest-derived neurons in the geniculate. Furthermore, these neurons express other markers typical of trigeminal somatosensory neurons (i.e., Neurogenin-1 and TrkA). Together, these findings indicate that gustatory neurons are derived solely from epibranchial placodes and that Hoxa2 expression suppresses neural crest cells from becoming somatosensory neurons in gustatory ganglia.

To form the gustatory ganglia, epibranchial placode cells differentiate into neuroblasts and subsequently delaminate, migrate, and coalesce (Baker and Bronner-Fraser, 2001). In chick, placodally derived neurons differentiate en route and arrive at their final location as differentiated neurons (Blentic et al., 2011). This means that all gustatory neurons start out in placodes and migrate to their ultimate destination. This is very different than neural crest-derived dorsal root ganglia (DRG), where migrating progenitors populate the ganglia after their arrival (Carr and Simpson, 1978; Krispin et al., 2010). This difference requires that placodally derived neurons to migrate to the ganglion for a much longer time than is required for neural crest migration. The path that gustatory neurons take during their inward migration is determined by neural crest cells (Begbie and Graham, 2001). Specifically, neural crest cells from rhombomere 2 normally facilitate the inward migration of the geniculate ganglion toward the hindbrain (Begbie and Graham, 2001). However, the migration path of these neurons appears to be plastic; genetic deletion of the rhombomere 2 neural crest population in double mutant *Hoxa1<sup>-/-</sup>/Hoxb1<sup>-/-</sup>* embryos does not prevent geniculate ganglion cell migration. Instead, geniculate neurons follow a slightly different path and merge with the trigeminal ganglion. This indicates that in the absence of rhombomere 2 neural crest cells, geniculate ganglia follow rhombomere 4 neural crest cells, which is the same path used by the trigeminal ganglion. When placodally derived neurons aggregate, adherens junctions form between the cells (Shiau and Bronner-Fraser, 2009). N-cadherin is required for normal placodal neuron aggregation, and the location and distribution of N-cadherin appear to be controlled by Slit1-Robo2 signaling. Based on these findings, it appears that gustatory ganglia are formed from neurons that migrate from epibranchial placodes following a path delineated by neural crest cells and then coalesce under N-cadherin control.

Neuronal differentiation within the gustatory ganglia is controlled by transcription factors, including neurogenin 2 (Neurg2). In the absence of Neurg2, placodal neuroblasts that give rise to the geniculate and petrosal ganglia fail to delaminate, migrate, and express neural differentiation markers (Fode et al., 1998; Takano-Maruyama

et al., 2012). Several transcription factors, including Islet 1 and Tlx3, are expressed in most sensory neurons and may be important for specifying sensory neuronal fate in developing gustatory neurons (D'Autreux et al., 2011; Logan et al., 1998; Sun et al., 2008). The geniculate ganglion contains both a visceral sensory subpopulation that innervates taste buds and a somatic subpopulation, which innervates the pinna of the ear. Recently, it has been demonstrated that the transcription factor Phox2b is expressed in roughly half of neurons in the geniculate ganglion, and the transcription factor Brn3a (Pou4f1) is expressed in the other half (D'Autreux et al., 2011; Quina et al., 2012); Figure 33.2A). Based on the expression of

**Figure 33.2** (a) An adult geniculate ganglion labeled with anti-Brn3a (green) and Phox2b-Cre; tdTomato (red). Although the populations are somewhat mixed the Brn3a positive nuclei appear to be primarily on one side of the ganglion, while the Phox2b positive neurons are concentrated on the other side of the geniculate ganglion. (b) An adult taste bud showing Phox2b positive (red) nerve fibers innervating an anti-troma 1 labeled taste bud. Scale bar in A = 20  $\mu$ m, scale bar B = 10  $\mu$ m. (See plate section for color version.)

these two factors in other ganglia and in the CNS, it is likely that Phox2b defines and regulates gustatory neuron formation, whereas the somatic transcription factor Brn3a is expressed in the somatic subpopulation. Consistent with this hypothesis, neurons that express Phox2b during development innervate taste buds in adulthood (Figure 33.2B). It was originally reported that in the absence of Phox2b, the geniculate and/or petrosal ganglia degenerate (Dauger et al., 2003). However, more recent studies report that these ganglia are not lost; instead, Brn3a is up-regulated in the visceral neurons of the geniculate, nodose, and petrosal ganglia, which stimulates differentiation of somatosensory neuron characteristics at the expense of gustatory characteristics (D'Autreux et al., 2011). Therefore, it could be that Phox2b specifies visceral neurons by suppressing Brn3a. It is unclear whether these neurons also change their projection path and innervate somatosensory targets instead of taste buds in the absence of Phox2b. There also appears to be some overlap in the Phox2b and Brn3a neuron subpopulations, and it is unclear whether these neurons are taste or somatosensory. Another variant homeodomain factor (Hmx1) is expressed in many but not all of Brn3a-positive neurons (Quina et al., 2012). Hmx1 appears to be important for the development of the somatosensory neurons that project through the posterior auricular nerve to innervate the ear pinna (Quina et al., 2012). Therefore, it is possible that the Brn3a-positive, Hmx1-negative neurons are also Phox2b-positive and gustatory in nature. In conclusion, Phox2b influences the differentiation of epibranchial placodal sensory neurons into visceral neurons, and co-expression of Brn3a and Hmx1 promote somatosensory neuron development in the same ganglia.

### 33.7 REGULATION OF GUSTATORY NEURON NUMBER

Waves of apoptosis and proliferation delineate epibranchial placodes and facilitate their formation (Washausen et al., 2005). As mentioned earlier, recent evidence in chick indicates that unlike the DRG, all gustatory neurons are produced in the epibranchial placodes and migrate into the developing geniculate and petrosal ganglia as differentiated neurons. If this is also true in rodents, then dividing cells in the geniculate (peak division is E12 in rat and approximately E10-E11 in mice) would primarily be glia (Altman and Bayer, 1982). Consistent with this idea is the finding that no ganglion cells double-labeled with BrdU and anti-neurofilament 150, which marks neuronal precursors, can be found in the geniculate ganglion at E11.5 or E13.5 (Patel et al., 2010; Patel and Krimm, 2012). However, cell death occurs over a very long period in the developing rodent without any corresponding decrease in total neuron

number (Carr et al., 2005). This finding would indicate that neurons are continually being added to the ganglia, even in late embryonic development. Perhaps neurons are still migrating from placodes at this time, but neuronal proliferation seems more likely. Therefore, whether the rodent gustatory ganglia acquire additional neurons by proliferation following migration from placodes within the ganglia is still an issue to be resolved.

The final number of neurons within the gustatory ganglion that are available to innervate taste buds is determined by proliferation and migration of neural precursors, as well as cell death within the ganglia. Cell death in the geniculate ganglion appears to peak at two time points: before target innervation (E12.5 in rats and E10-E11 in mice) and during target innervation (E16.5 in rats and E14-E15 in mice) (Carr et al., 2005). Neuron survival within the gustatory ganglia is regulated by neurotrophins. Mice lacking brain-derived neurotrophin (BDNF) and neurotrophin 4 (NT4) lose approximately half of their geniculate ganglion and nodose/petrosal ganglion complex during development (Conover et al., 1995; Erickson et al., 1996; Liebl et al., 1997; Liu et al., 1995; Patel and Krimm, 2010). Hybrid *Bdnf*<sup>-/-</sup>/*Ntf4*<sup>-/-</sup> animals lose 90–94% of their geniculate and nodose/petrosal neurons and also more taste buds than either group alone (Ito and Nosrat, 2009; Patel and Krimm, 2010). Mice lacking the primary receptor for both BDNF and NT4, TrkB, also lose most of the geniculate ganglion early in development (Fritsch et al., 1997). In addition to BDNF and NT4, neurotrophin 3 (NT3) also regulates neuronal survival in gustatory ganglia. Mice lacking NT3 lose approximately 47% of neurons in the geniculate ganglion and 44% in the nodose/petrosal ganglion complex (Liebl et al., 1997), and mice lacking both NT3 and BDNF lose more taste buds than BDNF mutants (Ito et al., 2010). Thus, at least three different neurotrophins regulate the number of neurons within the gustatory ganglia.

The timing of neurotrophin dependence differs among the neurotrophins and may be indicative of their individual mechanisms (Farinas et al., 1998; Farinas et al., 1996; Liebl et al., 1997). In the mouse geniculate ganglia, neurons become NT4-dependent on E11.5 and BDNF-dependent at E13.5 (Patel and Krimm, 2010; Patel and Krimm, 2012). Because gustatory axons have reached their targets by E13.5, but not by E11.5, BDNF is a target-derived neurotrophin, while NT4 is not. However, BDNF is also expressed in the geniculate ganglion and may support another aspect of gustatory neuron development in this location (Harlow et al., 2011; Huang and Krimm, 2010). While neuron survival is one possibility, ganglionic BDNF seems more likely to influence neuron differentiation, because the loss of BDNF specifically in the geniculate ganglion appears to slow gustatory neuron development (Harlow et al., 2011). BDNF and NT4 function at different

but overlapping times to support gustatory neuron survival. Specifically, NT4 dependence continues until E16.5, and BDNF dependence continues through E18.5 (Patel and Krimm, 2010; Patel and Krimm, 2012). Therefore, neurons do not switch from being NT4-dependent to being BDNF-dependent. It is also likely that the neuronal subpopulations supported by NT4 and BDNF are overlapping, because each neurotrophin supports neurons innervating the tongue and the palate to the same degree (Patel et al., 2010). These two neurotrophins bind to the same receptors: TrkB and p75. It may be that instead of separate NT4- and BDNF-dependent subpopulations, some gustatory neurons are TrkB-ligand sensitive and die if either neurotrophin is removed, while others are TrkB-ligand insensitive and only die when both TrkB ligands are removed. Interestingly, although much of the functions of NT4 and BDNF appear to be overlapping, they support neuron survival through different mechanisms. BDNF prevents cell death by inhibiting activated caspase 3 activation, whereas NT4 does not prevent activated caspase 3 activation and instead prevents cell death through an unknown mechanism (Patel and Krimm, 2010; Patel and Krimm, 2012). Therefore, it appears that gustatory neurons do not simply switch dependence from one neurotrophin to another; rather, they have overlapping dependence on these factors, which regulate cell survival via different mechanisms.

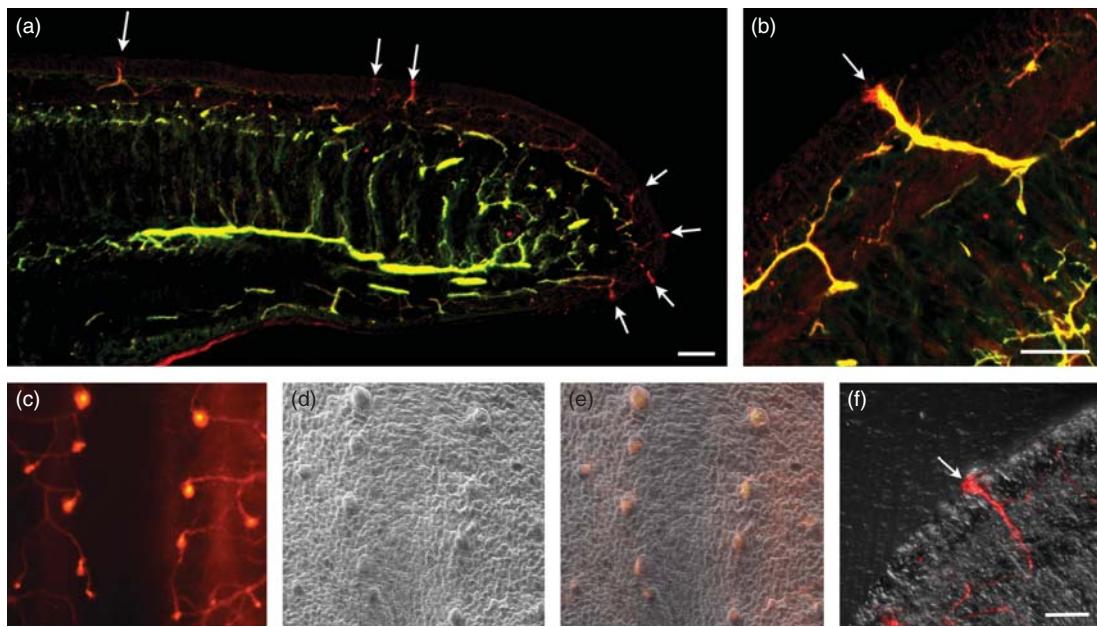

### 33.8 DEVELOPMENT OF THE GUSTATORY INNERVATION OF THE TONGUE

Neurite extension occurs as neuronal precursors become post-mitotic and begin to differentiate. *In vitro*, geniculate axon outgrowth requires the addition of an exogenous neurotrophin. BDNF, NT4/5, and GDNF are all capable of supporting neurite outgrowth, but NT3 and NGF are not (Rochlin and Farbman, 1998; Runge et al., 2012). However, axons *in vivo* still reach the tongue in the absence of both BDNF and NT4 (Ma et al., 2009), indicating that neurotrophins redundantly support axon growth *in vivo*. To innervate the tongue, gustatory axons must navigate from the geniculate ganglion to the lingual epithelium of the dorsal tongue and the petrosal ganglion to the CV placode. Gustatory axons grow into the tongue as it develops (Mbiene, 2004; Rochlin and Farbman, 1998). Axons of the chorda tympani reach the epithelial surface as early as E11.5 (in mouse), and axonal endings are both lateral and caudal to the fungiform papillae they will eventually innervate (Patel and Krimm, 2012; Rochlin and Farbman, 1998; Rochlin et al., 2000). From E11.5 to E13.5, axons grow from lateral/caudal to rostral/medial as the tongue expands. Gustatory axon pathways are precisely restricted from the time of tongue formation through papillae morphogenesis,

resulting in distinctive lingual territories for each nerve (Mbiene and Mistretta, 1997). By E13.5, chorda tympani axons have reached the fungiform placodes but have not innervated the epithelial surface. From E14 to E15, fibers defasciculate and penetrate the epithelial surface, forming a distinctive ending called a neural bud (Lopez and Krimm, 2006b). The progression of neural bud formation occurs from caudal to rostral on the tongue surface, and epithelial surface innervation is complete by E15.5 (Figure 33.3). Innervation of the CVP placode occurs at roughly the same time as fungiform placode innervation.

Because chorda tympani axons follow precise, spatially restricted pathways to the tongue (Mbiene and Mistretta, 1997), and because initial targeting is so accurate (Lopez and Krimm, 2006b), a series of molecular cues from the environment must guide these axons to the lingual epithelium. Two families of factors that mediate target innervation in the taste system are the semaphorins and the neurotrophins, which are repulsive and attractive, respectively. The semaphorin, Sema3A, is expressed in the developing tongue (Giger et al., 1996) in a gradient that decreases from medial to lateral across the tongue surface (Rochlin and Farbman, 1998; Rochlin et al., 2000). Because chorda tympani innervation progresses from lateral to medial, Sema3A is in the appropriate location to prevent premature and aberrant growth of trigeminal and gustatory fibers into the mid-region of the tongue. Consistent with this idea, sensory axons in *Sema3a*<sup>-/-</sup> mutants prematurely reach the epithelium (Dillon et al., 2004). In addition, as geniculate axons near the epithelial surface, Sema3A prevents premature penetration of the epithelium (Dillon et al., 2004; Vilbig et al., 2004). Another member of this family, Sema3F, is also expressed by lingual epithelium, although its function remains unclear (Vilbig et al., 2004).

The neurotrophin, BDNF, is the only specific chemoattractant that has been identified for gustatory neuron development. It is expressed in developing fungiform placodes and circumvallate before they are innervated (Nosrat et al., 1996, 2001; Nosrat and Olson, 1995; Figure 33.4A). Gustatory axons will grow toward a BDNF source (Hoshino et al., 2010). The neurotrophin, NT4, which shares the same receptors as BDNF, is also chemoattractive (Runge et al., 2012), but is not specifically expressed in fungiform placodes during development (Huang and Krimm, 2010; Nosrat et al., 1996; Nosrat and Olson, 1995). Overexpression of BDNF in inappropriate locations disrupts the normal gustatory innervation pattern to the tongue surface (Krimm et al., 2001; Lopez and Krimm, 2006a; Ringstedt et al., 1999). Specifically, when BDNF is overexpressed in the entire tongue epithelium, axons preferentially innervate the non-taste filiform papillae-containing regions of the tongue, which are ectopically expressing BDNF, instead of gustatory regions (Lopez and Krimm, 2006a). Removal of functional BDNF also disrupts innervation to the tongue

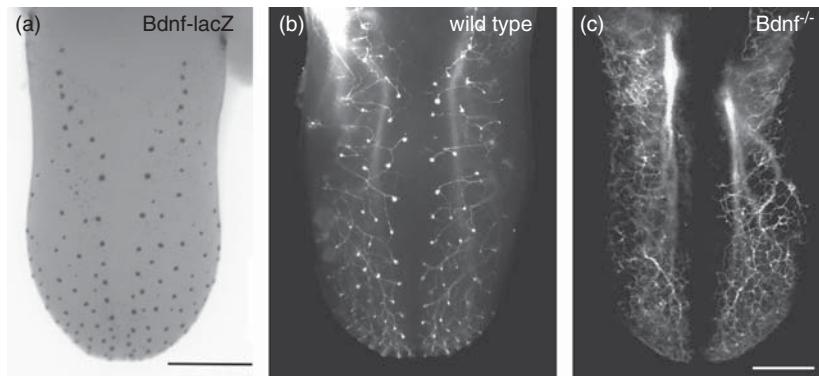

**Figure 33.3** (a) A section though an E16.5 mouse tongue in which innervation is labeled with anti-beta tubulin (green) and P2X3 (red). Branches from the chorda tympani can be seen branching toward the dorsal tongue surface. The epithelium is innervated in specific regions by P2X3 positive nerve bundles (arrows), which can be seen at higher power in (b). A region of the E16.5 tongue can be viewed from the dorsal surface in C, D, and E. DiI-labeled fiber bundles innervate the tongue surface and form a “neural bud” in (c), a Scanning Electron Microscope (SEM) image of the same region (d) can be aligned with the SEM (e) to determine which papillae are innervated and which are not innervated. A section through the DiI-labeled tongue illustrates that “neural buds” form where fibers innervate the epithelial surface. The scale bar in A = 200  $\mu$ m, the scale bar in b and f = 50  $\mu$ m. The scale bar in f also applies to c, d, and e. (See plate section for color version.)

surface (Figure 33.4B, 33.4C). Mice lacking BDNF show aberrant innervation patterns with increased branching (Ma et al., 2009). Furthermore, there is a critical period for this effect. When BDNF is conditionally removed from the lingual epithelium under the control of the Keratin 14 promoter, innervation to the tongue tip is disrupted, similar to what is observed in *Bdnf* null mutants. However, innervation to the mid-region and back of the tongue is normal. This is because Keratin 14 expression develops in a rostral to caudal fashion across the tongue surface, which prevents *Bdnf* expression in the tongue tip by E13.5 but not in the more caudal region of the tongue until E14.5. Meanwhile, innervation develops first in the caudal portion of the tongue and proceeds rostrally and medially as the tongue develops. Therefore, BDNF is removed from the tongue tip before fungiform placodes are innervated, whereas the more caudal part of the tongue is innervated before BDNF is removed by K14-Cre mediated gene recombination. These findings demonstrate that although BDNF is expressed in multiple tissues, it is specifically BDNF in the lingual epithelium in developing fungiform placodes that is important for target innervation. This study also demonstrates that BDNF removal must occur before chorda tympani fibers innervate the fungiform placodes for targeting to be disrupted. Taken together, these studies

show that BDNF is both necessary and sufficient for inducing chorda tympani axons to innervate their appropriate targets during development.

Although the neurotrophin BDNF is well established as an important chemoattractant required for gustatory axons to locate and innervate the fungiform placodes, other unknown chemoattractive factors must play roles. Gustatory axons have no difficulty reaching the tongue when both BDNF and NT4 are removed *in vivo* (Ma et al., 2009), and the *in vitro* chemoattractive properties of the mammalian tongue are not affected by the presence of BDNF or NT4 (Vilbig et al., 2004). These studies demonstrate that neither of these TrkB-ligands are required to guide axons to the tongue. Therefore, it is likely that another chemoattractant present in tongue is involved. Both the mammalian tongue (Vilbig et al., 2004) and the axolotl oropharyngeal endoderm (Gross et al., 2003) are chemoattractive. In addition to the tongue, developing gustatory regions probably also produce an additional chemoattractant that is not a neurotrophin. In the absence of BDNF a few gustatory axons successfully innervate fungiform placodes (Ma et al., 2009). However, this does not occur until approximately E18.5, which is four days after these neurons would normally innervate the correct target. It is clear that navigating axons from the ganglion to their

**Figure 33.4** (a) Beta-galactosidase-staining in a E14.5 *Bdnf-lacZ* mouse tongue illustrates the pattern of *Bdnf* expression in the tongue during embryonic development. *Bdnf* is specifically expressed in the fungiform placodes, but not the surrounding epithelium. This pattern of expression is important for chorda tympani axons to correctly innervate the tongue surface. The normal pattern of innervation to the tongue surface is illustrated in (b) at E16.5. In mice lacking *Bdnf*, axons fail to innervate specific regions of the tongue and form a neural bud (c), instead there is a great deal of branching to the surface of the tongue. Scale bar = 500  $\mu$ m, the scale bar in c also applies to c.

proper gustatory targets is a complicated developmental task, which likely involves many different guidance cues.

Once the gustatory epithelium is innervated, the taste system continues to develop. Taste buds differentiate and continue to grow in size, and these processes are influenced in part by geniculate neurons. During postnatal development, taste buds grow to a size that can be predicted by the number of neurons that innervated them at an earlier age (Krimm and Hill, 2000). Because gustatory nerve fibers are required to maintain a full complement of taste buds, even in adulthood (Guth, 1957; Nagato et al., 1995; Oakley et al., 1990), it seems likely that factors released from nerve fibers influence the postnatal growth of taste buds. The peripheral taste system is also plastic, in that while the number of circumvallate taste buds increases through a long period of postnatal development (Hosley and Oakley, 1987), the number of fungiform taste buds concomitantly decreases (Liebl et al., 1999; Patel and Krimm, 2012). It is not clear what causes these changes in taste bud number, but one possibility is a change in innervation. Petrosal neurons innervating the CVP may show increased branching, while geniculate neurons innervating fungiform taste buds may lose branches postnatally. These alterations could influence the number of taste buds. Consistent with this hypothesis, sheep geniculate neurons have a postnatal reduction in branching (Mistretta et al., 1988; Nagai et al., 1988). The mechanisms for this phenomenon are unclear, but it could be regulated at least in part by BDNF. At birth, BDNF is present in all taste bud cells (Huang and Krimm, 2010), but it becomes restricted to a subset of taste cells during postnatal development (Yee et al., 2003). It is possible that this normal reduction in BDNF results in reduced taste bud innervation. Consistent with this scenario, BDNF overexpression in the taste cells that would normally lose BDNF expression postnatally, results in more innervation

and slightly larger taste buds in the adulthood (Nosrat et al., 2012). Interestingly, the increase in taste bud size was primarily due to increases in one subpopulation of taste cells: an NCAM-positive subpopulation that also normally expresses BDNF (Yee et al., 2003), rather than the gustducin-positive taste cells in which BDNF was overexpressed (Nosrat et al., 2012). This indicates that the postnatal role of BDNF is taste cell specific. Whether this is a direct effect of BDNF on taste cells or whether it is due to the increased taste bud innervation observed in BDNF overexpressors is still unclear.

### 33.9 DEVELOPMENT OF GUSTATORY AXON PROJECTIONS TO THE CNS

In addition to innervating taste buds during development, primary gustatory neurons project to specific locations in the CNS. Central branches of gustatory axons from the geniculate, petrosal, and nodose ganglia terminate in the rostral portion of the nucleus of the solitary tract (NST). The terminal field for petrosal neurons is caudal to that of the geniculate neurons, although some overlap exists. The terminal field begins to form by E15, when geniculate ganglion axons invade the rat NST (Zhang and Ashwell, 2001). The first synaptic thickenings in the rostral NST are detectable at E17, and synaptic vesicles are observed by E19 (Zhang and Ashwell, 2001). Interestingly by E14.5, before synapses are structurally mature, the postsynaptic cell in the NTS develops voltage gated channels and has functional neurotransmitter receptors for both Glutamate and GABA (Suwabe et al., 2012). These receptors may initially respond to paracrine stimulation, but their presence early in development indicates that functional connections

can be made as soon as afferent fibers enter the rostral NTS and before synapses show a mature morphology. As a result, in addition to extrinsic growth factors and intrinsic transcription factors, activity may shape the initial formation of these circuits.

Virtually nothing is known about the factors that coordinate the formation of central connections in the taste solitary nucleus. However, the transcription factor Phox2b may play a role. The central projections of Phox2b-expressing gustatory neurons presumably contact Phox2b-expressing NST neurons (D'Autreux et al., 2011; Dauger et al., 2003). As with peripheral neurons, NST development is also disrupted in the absence of Phox2b (D'Autreux et al., 2011; Dauger et al., 2003), which suggests that Phox2b may coordinate the initial development of peripheral and central gustatory connections.

The terminal fields of all three gustatory nerves continue to grow through postnatal day 15 (PN15) and then decrease in size (Mangold and Hill, 2008; Sollars et al., 2006). In fact, there is almost total overlap of the chorda tympani (CT), greater superficial petrosal (GSP), and glossopharyngeal terminal (IX) fields in rat on PN15. Each field decreases in size sometime after PN15 to occupy a distinctive area in the NST, and the zone of overlap is considerably reduced (Mangold and Hill, 2008). The age at which the terminal fields reach their mature size varies for the different primary afferents. Both the GSP and IX nerve fields reach maturity at PN25, but the chorda tympani is not fully mature until PN35 (Mangold and Hill, 2008). This postnatal refinement of terminal field size is likely due to competition between terminal fields for the same synaptic space (Corson and Hill, 2011). The chorda tympani terminal field is refined by the elimination branches in one NST subdivision (the rostralateral region), while branches in another subdivision (the rostrocentral regions) are stable (Wang et al., 2012). In addition to terminal field refinement, the number of chorda tympani synapses onto GABAergic NST targets is also reduced between postnatal days 15 and 25 of development (Wang et al., 2012). On the postsynaptic cell side, dendrites acquire spines during early postnatal development (Suwabe et al., 2011). There are also postnatal changes in NST neuron dendritic fields (Lasiter et al., 1989; Liu et al., 2000; Suwabe et al., 2011). It is unclear whether changes in the terminal fields influence dendritic arbor development or if changes in dendritic arbors reduce available synaptic space for developing axons during postnatal development.

Postnatal development of the gustatory system is heavily influenced by environmental factors. For example, maternal sodium restriction during development specifically blocks the development of chorda tympani nerve responses to sodium (Hill and Przekop, 1988) and results in enlarged chorda tympani and glossopharyngeal nerve terminal fields (King and Hill, 1991; Krimm and Hill,

1997; May and Hill, 2006; Sollars et al., 2006). Furthermore, the density of chorda tympani arbors and synapses is also greater in sodium-restricted animals (May et al., 2008). Because sodium restriction also results in a loss of sodium-specific activity in developing nerve fibers (Hill and Przekop, 1988), it is likely that a reduction in nerve activity is responsible for preventing gustatory terminal field refinement under the conditions of developmental sodium restriction.

Unfortunately, understanding the mechanism of sodium deprivation on terminal field development has been complicated by the fact that sodium deprivation has multiple effects during development. A long period of sodium deprivation results in a loss of sodium driven activity in the chorda tympani nerve. However, a brief period of embryonic deprivation (E3-E12) results in an enlarged chorda tympani field later in development (Krimm and Hill, 1997; Mangold and Hill, 2008). This occurs even though the CT shows normal levels of activity. Furthermore, this effect is not specific for sodium deprivation; protein deprivation during development can also lead to enlarged gustatory terminal fields (Thomas and Hill, 2008). Embryonic dietary restriction (E3-E12), which does not disrupt CT activity, does not impact chorda tympani field development in the same way as dietary sodium restriction throughout development (E3-PN28), which does disrupt CT activity (Mangold and Hill, 2007). Surprisingly, early dietary restriction has a much greater effect on gustatory terminal field size than chronic dietary restriction (Mangold and Hill, 2007). It is possible that the timing of sodium repletion at E12 causes the development of an enlarged terminal field during the postnatal period. Sodium repletion occurring during a critical developmental phase could influence the expression of specific growth factors, which in turn could impact gustatory terminal field development. Manipulations that separate the roles of activity versus growth factors on the postnatal development of the rostral NST terminal field, would contribute considerably to our understanding of how dietary manipulations and/or taste sensory function influence development of the rostral NST.

## Psychophysical Measures of Human Oral Sensation

DEREK J. SNYDER, CHARLES A. SIMS, and LINDA M. BARTOSHUK

### 34.1 INTRODUCTION

The measurement of conscious experience defines psychophysics, a field of study that has significantly advanced our understanding of sensory and hedonic processes. In the chemical senses, psychophysical tests are used extensively to guide product development and quality control efforts in food science (e.g., Lawless and Heymann, 2010; Chapters 11, 47 and 48 this volume), and their use in basic research has revealed the broad influence of oral sensation and dysfunction on health-related behaviors and overall quality of life (e.g., Bartoshuk et al., 2004a). From a medical perspective, oral sensory disturbances may be relatively benign, but sometimes they are profoundly life-altering (e.g., Bromley and Doty, 2003; Chapter 39 this volume). As such, chemosensory experience and its consequences represent a vital clinical and consumer issue requiring careful evaluation.

Measuring this experience, however, is an extremely challenging task. By definition, individual experience is subjective: We can *describe* our experiences and track them over time, but we cannot directly *share* the experiences of another person. This observation presents a serious dilemma, as it is meaningless to *compare* descriptions that mean different things to different people. Because we use comparisons of real-world experience throughout life to convey what is acceptable (e.g., pleasure) and what is not (e.g., pain, disgust), it is important to measure these experiences well: We need to know how the sensory properties of food change with illness and age, how the sweet taste of sucrose differs between women and men, and so on. Early scholars in psychophysics relied on threshold measures to address these questions, and some researchers still believe

they can be answered only in vague terms — but recent advances in suprathreshold scaling capture sensory and affective differences with improved reliability and precision, supporting the notion that perceptual experiences can be measured and compared.

This chapter evaluates contemporary methods of oral sensory assessment, noting their origins and evolution. Threshold psychophysical tests remain popular and useful for many types of oral sensory evaluation, even as suprathreshold intensity scales provide an increasingly comprehensive and realistic picture of overall function. Efforts to identify suitable suprathreshold tools include an examination of labeled scales, which are used (often inappropriately) to compare experiences between individuals and groups. When performed correctly, psychophysical oral sensory measurement is especially informative in concert with parallel methods (e.g., multiple standards, genetic testing, oral anatomy), an approach that permits confirmation of results and (where necessary) correction for unanticipated scaling problems. Finally, the chapter describes tests of suprathreshold oral sensory function, including their potential for clinical and industrial use.

### 34.2 THRESHOLDS VS. INTENSITY: HOW SHOULD ORAL SENSATION BE MEASURED?

When we enjoy a meal, we can tell easily if the soup is too salty or the cocktails watered down. These judgments demonstrate that intensity is a continuous concept (i.e., intervals of strength) rather than a binary one (i.e., present or absent), yet debate continues regarding the ability of various measurement strategies to capture sensory

experience. Some psychophysicists avoid suprathreshold methods because they believe that degrees of intensity are immeasurable or at best ordinal (e.g., Brindley, 1960; Laming, 1997), while others contend that thresholds offer insufficient or inaccurate information about the range of sensory function (e.g., Moskowitz, 1977a). In the case of oral sensation, neither of these views is entirely correct: Taste threshold differences may carry important clinical and research implications when interpreted carefully, and suprathreshold oral sensory measures possess unique diagnostic and predictive capabilities when used correctly.

### 34.2.1 Threshold Procedures

Thresholds have been used for sensory evaluation ever since Fechner described them in his *Elemente der Psychophysik* (1860/1966), one of the first published works of experimental psychology. An expansion of work by Weber, Fechner's elaboration of the three threshold methods — the method of limits, the method of adjustment, and the method of constant stimuli — established psychophysics as a science. Although thresholds present both conceptual and practical challenges (e.g., Engen, 1972; Lawless and Heymann, 2010), their basic definition is straightforward: The *absolute or detection threshold* for a stimulus is the lowest concentration at which its presence can be detected as something, whether or not it is qualitatively discernible. The , which is often slightly higher than absolute threshold, is the lowest concentration at which the primary quality of a stimulus (e.g., sweet, painful) can be identified. Finally, the *difference threshold* is the smallest increase in suprathreshold stimulus concentration that can be detected (i.e., the “just noticeable difference” or jnd). Clinical assessments of gustatory function have historically focused on the absolute threshold, while food scientists often use difference thresholds to evaluate flavor changes or off-tastes.

Of the classical threshold methods, various iterations of the method of limits are used for taste evaluation most often. In the most basic version of this procedure, participants report whether or not they perceive a taste sensation from a given stimulus (i.e., “yes” or “no”). Concentration is increased from an undetectable level until participants report a sensation, and then it is decreased from a clearly detectable level until participants report an absence of sensation. (Taste stimuli are generally presented in logarithmic steps, as this spacing approximates equal intervals of perceived intensity.) Over several ascending and descending runs, the average concentration of transition points serves as an estimate of threshold (McBurney and Collings, 1977). One popular variant of this method involves the presentation of ascending series only, introduced to address concerns about adaptation to suprathreshold stimuli during descending series (e.g., Pangborn et al., 1963).

While elegant, this procedure raises concerns that warrant serious consideration. Test efficiency is extremely important; too few trials make the procedure unreliable, but too many trials can lead to stimulus adaptation and participant fatigue. In addition, signal detection theory (Green and Swets, 1966) shows that individuals set different criteria when deciding how much sensory change warrants a response: One person may anticipate a difference and respond to the slightest hint of change, while another may want to be highly confident that change has occurred before responding. As a result, participants tend to show bias toward responses already made (i.e., habituation errors), yet they may also change their responses prematurely when they believe an actual change is forthcoming (i.e., anticipation errors). Shifts in these criteria can occur over many trials, which further highlights the need for concise testing protocols.

Based on these concerns, efforts to balance task difficulty, bias, and test duration have yielded several refinements in the reliability of threshold measurement. In the “up-down” or “staircase” method, the concentration of the target stimulus depends on the outcome of the previous trial; a positive response proceeds to a lower target concentration, while a negative response proceeds to a higher one (Cornsweet, 1962). This arrangement improves test efficiency because it focuses on observations around threshold. Meanwhile, forced-choice discrimination paradigms address response bias by requiring participants to identify a target stimulus on each trial. When up-down and forced-choice elements are combined (e.g., Jesteadt, 1980), an increase in the number of correct vs. incorrect trials required to change concentration reduces the likelihood of chance (i.e., false-positive) performance at that level (Wetherill and Levitt, 1965), and a reduction in the ratio of target vs. background stimuli in each trial lowers chance performance and may curb adaptation effects (e.g., Lawless et al., 1995; Murphy et al., 1995). These modifications have proven especially useful in the chemical senses, which adapt and fatigue easily compared to other sensory systems (e.g., Linschoten et al., 1996). On the other hand, the fact that thresholds are so susceptible to change reflects a fundamental idea that is often overlooked: Thresholds are a statistical construct rather than a fixed biological constant. As such, they must be considered in the context of the specific tasks used to derive them, and they can be compared only with values measured under similar conditions.

Two general approaches dominate modern taste threshold measurement: Chemical taste thresholds typically involve whole-mouth sampling of dilute solutions (although regional testing is also feasible), while electro-gustometry involves localized taste sensations elicited by weak electrical current applied to specific regions of the tongue.

**34.2.1.1 Chemical Taste Thresholds.** Building on the advances in methodology described above, one of the most widely accepted and rigorous methods for determining taste detection thresholds is an up-down, two-alternative forced-choice (2-AFC) staircase (McBurney and Collings, 1977; see also Wetherill and Levitt, 1965). This test comprises multiple trials of two stimuli in which participants distinguish tastant from water. Testing begins at a stimulus concentration that can be perceived, proceeding to a lower concentration (in logarithmic steps) following two correct trials and a higher concentration following one incorrect trial. Such an arrangement produces a series of “reversals” over time, and the geometric mean of the second through seventh reversal concentrations is defined as threshold. Subsequent testing has revealed potential confounds that may be avoided with careful test administration. For example, saliva contains sufficient NaCl to act as an adapting solution (McBurney and Pfaffmann, 1963), which can raise NaCl thresholds and induce a water taste that may be confused with solute taste (e.g., Bartoshuk, 1974; Hertz et al., 1975). To avoid this possibility, participants should rinse thoroughly before sampling any test solution.

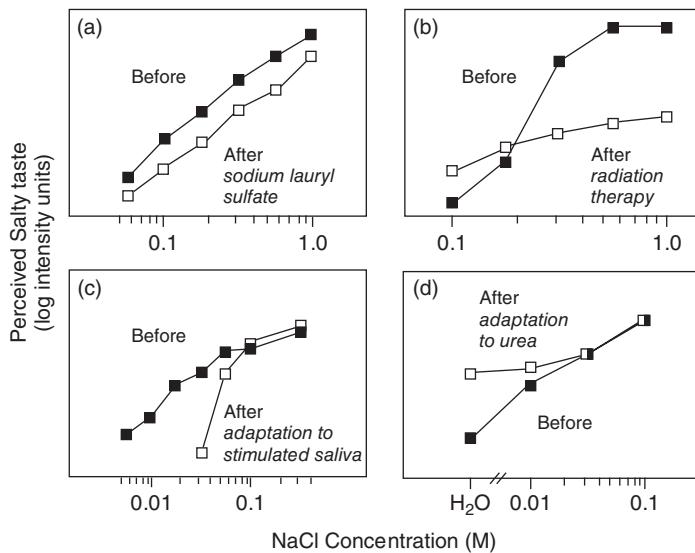

In the clinic, streamlined methods for determining taste detection thresholds include the 3-drop and 8-cup techniques — which, like the up-down 2-AFC staircase, differ from Fechner’s original methods mainly in terms of stimulus delivery and criterion performance. In the 3-drop technique, one drop of tastant and two drops of water are presented in each trial, and threshold is defined as the lowest concentration at which the participant chooses the target correctly in at least two of three trials (Henkin et al., 1963). The 8-cup technique is a sorting task in which four cups of tastant and four cups of water are presented; threshold is defined as the lowest concentration at which the participant separates the cups into tastant and water groups without error (Harris and Kalmus, 1949b). When directly compared, the 3-drop technique produces significantly higher detection thresholds for NaCl and sucrose than does the 8-cup technique (Weiffenbach, 1983), a difference attributed mainly to adaptation state (i.e., water rinses occur in the 8-cup task, but not in the 3-drop task) and the volume of liquid sampled (Lawless, 1987). Nevertheless, both are far less stringent than the up-down 2-AFC staircase (Frank et al., 2003).

Recognition thresholds for taste are distinct from detection thresholds, as a concentration range exists in which dilute solutions can be discriminated from water but cannot be identified in terms of taste quality. However, the challenge in determining taste detection and recognition thresholds for a given person is that the two test procedures must be equivalent in difficulty to permit valid comparison. Signal detection theory has been used successfully to assess the influences of age and other factors on the ability to taste

(e.g., Matsuda and Doty, 1993). While it has also been used to develop up-down, forced-choice recognition threshold measures that match the task demands of the detection threshold (Collings, 1974), this application remains biased because individuals do not choose randomly among taste qualities when guessing (Weiffenbach, 1983). Moreover, the fact that taste solutions can produce tactile sensations (e.g., tingle, burn) suggests that individuals with severe taste loss retain some ability to discriminate tastant vs. water, which clouds the interpretation of taste threshold results. Accordingly, instructions for participants should be explicit in terms of the types of sensation to be reported and judged.

Chemical taste thresholds enjoy widespread use in research and clinical settings, where they have been used extensively to document regional and whole-mouth losses associated with aging, health status, and medication use (e.g., Cowart, 1989; Doty et al., 2001; Heath et al., 2006; Ileri-Gurel et al., 2013; Mojet et al., 2001; Schiffman, 1997), as well as individual differences associated with genetic taste status (e.g., Desai et al., 2011; Reed et al., 1995). One reason for the apparent popularity of thresholds is that their values are expressed in terms of a physical unit of intensity (i.e., molarity), which gives the impression of objectivity compared to suprathreshold ratings. In reality, thresholds are neither more reliable nor more accurate than other sensory measures, since they are statistical approximations of ever-changing sensitivity (Lawless and Heymann, 2010). Reflecting this fact, test-retest reliability for chemical taste thresholds is low (McMahon et al., 2001; Stevens et al., 1995); as with thresholds in other sensory systems, many trials are often required to achieve a stable result. Thus, even with abbreviated methods, the time required to measure taste thresholds remains a discouraging feature, particularly considering that they yield only the lower boundary of the psychophysical function. By comparison, suprathreshold procedures approximate the entire taste function in much less time.

A broader concern with taste thresholds regards their validity as a measure of overall taste function, particularly at suprathreshold levels approximating real-world sensation. In general, the decision to use thresholds in lieu of suprathreshold measures is reasonable provided there is strong concordance between threshold and suprathreshold experiences. While such a relationship appears to occur for olfactory sensation (e.g., Cain and Stevens, 1989), taste thresholds and suprathreshold taste intensity can dissociate in substantial and unexpected ways, compromising predictions of suprathreshold sensation from threshold values alone. As Figure 34.1 shows, some manipulations (e.g., exposure to sodium lauryl sulfate, a detergent found in many toothpastes) suppress taste sensation uniformly across the perceptible range (Panel a; DeSimone et al., 1980), but others affect specific regions of

**Figure 34.1** Examples of alterations in the psychophysical functions for taste stimuli. All panels show magnitude estimate ratings for several concentrations of NaCl. Panel (a): NaCl intensity following exposure to 0.05% sodium lauryl sulfate; similar effects occur for sucrose and quinine (DeSimone et al., 1980). Panel (b): NaCl intensity in a patient during (day 5) and after (day 94) radiation treatment for head/neck cancer; similar effects occur for other taste qualities (Bartoshuk, 1978). Panel (c): NaCl intensity following adaptation to stimulated saliva (0.051 M sodium); average of five replicates (Bartoshuk, 1978). Panel (d): NaCl intensity following adaptation to 0.82 M urea (McBurney and Bartoshuk, 1973).

the dose-response function: Radiation therapy can impair taste sensation at high concentrations while leaving it intact near threshold (Panel b; Bartoshuk, 1978), and taste thresholds can shift without affecting suprathreshold taste intensity during both aging (Bartoshuk et al., 1986) and adaptation (Panels c-d; Bartoshuk, 1978; McBurney and Bartoshuk, 1973; see also Bartoshuk, 1974; McBurney, 1966). This disagreement alone does not preclude the use of threshold testing, as it remains useful to identify taste anomalies regardless of their effect on real-world experience: Compensatory oral sensory interactions may sustain whole-mouth sensation following nerve damage, rendering individuals unaware of underlying sensory disturbance (e.g., Bartoshuk et al., 1987; Lehman et al., 1995), so taste threshold dysfunction signals a need for further examination. On the other hand, a normal taste threshold should not be interpreted by itself as evidence of stable function, but should be confirmed with suprathreshold and/or spatial testing.

**34.2.1.2 Electrogustometry.** An alternative to chemical measures of taste sensitivity, electrogustometry involves the application of weak anodal electric currents to specific regions of the mouth (Krarup, 1958; Mackenzie, 1955). Several mechanisms for electric taste have been proposed (Bujas, 1971; DeSimone et al., 1981; DeSimone et al., 1984; Kashiwayanagi et al., 1981), the most likely of which involves “ion accumulation”: Electric current indirectly stimulates taste by transporting positively charged ions in saliva toward taste receptors, concentrating them to levels where they can be detected (Herness, 1985). Because saliva is mildly acidic and contains salts, electrogustometry sometimes evokes sour or salty taste sensations (e.g., Bujas, 1971; Grant et al., 1987; Murphy et al., 1995).

The chief advantage of electrogustometry is its convenience; it is portable, avoids the use of chemical solutions, permits regional stimulation of taste bud fields, and provides values that can be compared across individuals, time points, locations within the mouth, or treatment conditions (e.g., Frank and Smith, 1991). In fact, electrogustometry shows high test-retest reliability and bilateral correspondence compared to chemical taste thresholds (Murphy et al., 1995), suggesting that it may be superior for clinical use. Accordingly, normative data have been described for some groups (e.g., Tomita et al., 1986), and electric taste thresholds have been used to identify substantial taste losses associated with aging, denervation, and disease (Grant et al., 1987; Groves and Gibson, 1974; Le Floch et al., 1990; Murphy et al., 1995; Nakazato et al., 2002; Ovesen et al., 1991; Pavlidis et al., 2013).

That said, electric taste threshold data should be interpreted with care, especially regarding their ability to capture the full breadth of taste function (e.g., Stillman et al., 2003). First, taste loss varies across quality, but electrogustometry does not stimulate all taste qualities, particularly non-ionic modalities like sweetness and bitterness (Frank and Smith, 1991). Mounting data indicate that oral sensory alterations are often quality-specific, especially for bitter taste (Bartoshuk et al., 2002a; Grushka et al., 1986; Lehman et al., 1995; Yanagisawa et al., 1998), so methods that fail to assess bitter taste may fail to identify clinically relevant damage. Second, electrogustometric thresholds correlate well with regional (Krarup, 1958; Tomita et al., 1986), but not whole-mouth chemical taste thresholds (Murphy et al., 1995), and suprathreshold functions for electrical and chemical taste also show poor agreement (Salata et al., 1991). Again, as with chemical taste thresholds, electrogustometry should not be discounted simply

because it is discontinuous with real-world taste experience, but its limitations should be considered as part of a comprehensive taste evaluation.

### 34.2.2 Direct Scaling of Suprathreshold Intensity

While threshold methods provide only the lower limit of physical energy that can be perceived (e.g., decibels of sound, molar concentration), suprathreshold or “direct” scaling methods measure perceived intensity across the full dynamic range of sensation (e.g., Stevens, 1946).

**34.2.2.1 Magnitude Estimation.** Fechner assumed that the jnd was the basic unit of psychological intensity, so he created a suprathreshold scale in which stimulus intensity was described in terms of the number of jnds above absolute threshold. Though not universally accepted, this view prevailed for nearly a century until S. S. Stevens observed that the jnd does not behave like a proper unit: An 8 jnd stimulus is not twice as intense as a 4 jnd stimulus; it is actually more intense (Stevens, 1961). This finding shows that suprathreshold scales based on threshold values provide a distorted view of intensity experiences.

Stevens introduced direct scaling methods with ratio properties, the most popular of which is magnitude estimation (Stevens, 1956). In the most popular version of this procedure, subjects provide a number reflecting the perceived intensity of a stimulus; they then give a number twice as large to a stimulus that is twice as intense, a number half as large to a stimulus half as intense, and so on. The size of the numbers is irrelevant; only the ratios among numbers carry meaning. Accordingly, when magnitude estimate data are pooled, they are typically “normalized” to bring ratings into a common register while preserving the ratios among them. This practice ensures that one individual’s data are not unduly weighted just because they used larger numbers (Marks, 1974).

Over several years, Stevens used magnitude estimation to compare the growth rates of psychophysical functions across sensory modalities (Stevens, 1959; Stevens, 1962; Stevens and Galanter, 1957), but he was not particularly interested in studying how functions for a specific stimulus vary among people. This distinction is important because magnitude estimates describe only how perceived intensity varies with stimulus intensity *within* an individual; they cannot reflect meaningful differences of absolute perceived intensity *between* individuals or groups (Marks, 1974). Because group comparisons are such a basic element of scientific inquiry, this limitation has not been fully appreciated, but its consequences are severe. As the following section illustrates, the identification of robust variation in

oral sensation has figured prominently in efforts to measure group differences accurately.

#### 34.2.2.2 Measuring Oral Sensory Differences: Magnitude Matching.

##### INDIVIDUAL DIFFERENCES IN ORAL SENSATION

Discovered by the chemist A. L. Fox (1931), individuals differ significantly in their ability to taste thiourea compounds like phenylthiocarbamide (PTC) and 6-n-propylthiouracil (PROP) (e.g., Barnicot et al., 1951; Fox, 1932); most individuals perceive bitterness (i.e., tasters), but others are “taste blind” and perceive nothing (i.e., nontasters). Early reports suggested that nontasting is a recessive trait with a single genetic locus (Blakeslee, 1932; Snyder, 1931), while other studies measured the proportion of tasters by race, sex, and disease (e.g., Kalmus and Farnsworth, 1959; Parr, 1934; Sunderland and Cartwright, 1968; Whissell-Buechy and Wills, 1989). In response to the variety of methods used to measure PTC/PROP sensitivity, Harris and Kalmus (1949b) introduced a threshold technique that dominated research on taste blindness for over 25 years, largely because it produces a bimodal distribution of PTC/PROP detection thresholds that easily distinguishes nontasters and tasters (Olson et al., 1989; Whissell-Buechy, 1990). In the 1960s, Fischer used this technique to explore the behavioral implications of taste blindness, revealing associations between PTC/PROP sensitivity and food preferences, alcohol and tobacco use, and body weight (Fischer, 1967; Fischer et al., 1961, 1963). These studies were among the first to use PROP as a marker of taste blindness; unlike PTC, PROP is odorless and has well-defined safety limits as a thyroid medication (Lawless, 1980; Wheatcroft and Thornburn, 1972).

Encouraged by the potential benefits of direct scaling, Bartoshuk sought to compare the suprathreshold bitterness of PTC between nontasters and tasters. However, this comparison presents a problem: Magnitude estimates have *relative* meaning when subjects are used as their own controls (e.g., McBurney and Bartoshuk, 1973), but how can *absolute* bitterness be compared across groups? The answer to this question involves measuring PTC bitterness relative to an unrelated standard. As described previously, magnitude estimates are often normalized to obtain group functions, but this procedure addresses a different issue: Bringing data into common range invokes an arbitrary standard that conveys nothing about absolute perceived intensity, but group comparisons reference a standard that is assumed to be equally intense (on average) to the groups being compared. If this assumption holds, normalization yields valid across-group differences in absolute perceived intensity for stimuli of interest: If “10” denotes the intensity of a standard to nontasters and tasters, PTC ratings of

“40” for tasters and “20” for nontasters reflect a twofold intensity difference.

To quantify oral sensory variation accurately, appropriate standards for comparison must be identified. This pursuit has been strongly informed by research on “cross-modality matching,” the ability to match qualitatively different sensations (Stevens and Marks, 1965). Because thioureas share the N-C=S chemical group, Bartoshuk reasoned that the taste intensity of a compound lacking the N-C=S group should be equal, on average, to nontasters and tasters. If so, group averages of PTC bitterness can be compared by rating it relative to, for example, NaCl saltiness. With this procedure, tasters find PTC and PROP more bitter than do nontasters (Hall et al., 1975; Lawless, 1980), and subsequent reports extensively document oral sensory variation extending far beyond the N-C=S group: Tasters perceive more intense taste and oral tactile sensations overall (e.g., Bartoshuk, 2000), and a subset of tasters known as “supertasters” consistently gives the highest ratings to taste stimuli, oral irritants (e.g., capsaicin, alcohol), fats, and retroranal odors (e.g., Bartoshuk et al., 2004b; Prescott et al., 2004).

**MAGNITUDE MATCHING** While the discovery of supertasters reinforced the breadth of individual differences in oral sensation, it also presented a problem: If supertasters of PROP perceive NaCl more intensely than do others, then NaCl is a poor standard for PROP-related comparisons, rendering observed differences based on PROP status inaccurate (albeit conservatively so). This problem was resolved by introducing stimuli from non-taste modalities as standards. For example, if taste and hearing are assumed to be unrelated, taste stimuli can be rated relative to auditory intensity. This procedure, formalized as “magnitude matching” (Marks and Stevens, 1980; Marks et al., 1988; Stevens and Marks, 1980) confirmed suspicion that the saltiness of NaCl varies with taster status (Bartoshuk et al., 1998). Magnitude matching addresses the problem of group comparisons by changing the task: Oral sensations cannot be compared directly across PROP taster groups, so subjects rate stimuli of interest relative to a non-oral sensory standard. As long as variability in the standard remains unrelated to variability in PROP bitterness, oral sensory experiences are comparable across taster groups.

The ability to observe accurate sensory differences in oral sensation has enabled identification of associations between sensory experience, dietary behavior, and disease risk (e.g., Duffy, 2007; Snyder et al., 2008a; Tepper et al., 2009). For example, PROP bitterness associates with decreased vegetable preference and intake (Dinehart et al., 2006; Drewnowski et al., 2000; Duffy et al., 2001), a known risk factor for colon cancer; it also associates with an increased number of colon polyps (Basson et al., 2005). PROP intensity also predicts avoidance of high-fat foods,

and some studies have shown that supertasters have lower body mass indices and more favorable cardiovascular profiles (Duffy, 2004; Tepper and Ullrich, 2002).

### GENETIC FACTORS IN ORAL SENSORY VARIATION

Based on family studies showing that nontaster parents produce nontaster children, taste blindness was thought for many years to arise from a single gene (Blakeslee, 1932; Snyder, 1931; Whissell-Buechy, 1990). However, modern genetic analysis suggests that the genetic contribution to PTC/PROP bitterness is much more complex (e.g., Bufo et al., 2005). Linkage analysis has identified candidate genes for taste blindness on chromosomes 5p15, 7, and 16p (Drayna et al., 2003; Reed et al., 1999), and subsequent mapping of chromosome 7q has identified sequence polymorphisms in a taste receptor gene (T2R38) that account for up to 85% of observed differences in PTC threshold sensitivity (Kim et al., 2003; Wooding et al., 2004). These relationships distinguish between nontasters and tasters, but their ability to identify supertasters is limited: Medium tasters and supertasters have similar PTC/PROP thresholds (e.g., Bartoshuk, 2000), and T2R38 variation does not fully predict the robust differences in suprathreshold PROP intensity observed between these groups (Hayes et al., 2008). In other words, PROP supertasting cannot be explained completely by threshold sensitivity or T2R38 genetics.

Taking a broader view, rising PROP intensity is associated with greater intensity for virtually all oral sensory stimuli, as described previously (e.g., Bartoshuk et al., 2004b; Prescott et al., 2004). Moreover, supertasters express the highest density of fungiform papillae, structures on the anterior tongue that contain taste buds and oral somatosensory end organs (Bartoshuk and Duffy, 1994). These differences suggest that PTC/PROP taster status is a function of two independent conditions: T2R38 expression and fungiform papilla density (Hayes et al., 2008). In this model, PROP supertasters carry the taster variant of the T2R38 gene (which confers the ability to taste PTC/PROP), but they also express a high density of fungiform papillae (which maximizes oral sensory input of all kinds) (Bartoshuk et al., 2001). Several gene products govern the development of fungiform papillae (e.g., sonic hedgehog, bone morphogenic proteins, epidermal growth factor, Wnt/β-catenin signaling), but their combinatorial impact on the quantity of papillae produced has yet to be fully determined (e.g., Liu et al., 2009). Nevertheless, it now appears that oral sensory variation arises from the expression of multiple genes mediating both receptor activity and underlying anatomical structure.

While the full breadth of oral sensory variation has been characterized by association with PTC/PROP bitterness, it is much more likely that PTC/PROP bitterness is but a single, highly robust example of broader oral sensory

variation. In other words, individual differences in sensation for any oral stimulus probably result from genetic variation in a specific receptor or transduction element, which is then amplified by differences in fungiform papilla density. Recent identification of polymorphisms associated with differential sweet, umami, and fat perception supports this view (Fushan et al., 2010; Keller et al., 2012; Raliou et al., 2009; Shigemura et al., 2009), as does an emerging interaction between PROP bitterness, T2R38 genetics, and sequence variation in the taste bud trophic factor gustin (Calò et al., 2011). As new oral sensory gene variants and expression patterns are discovered, it is highly likely that taster status will be defined more broadly, based on genotype-phenotype relationships across multiple aspects of oral sensation and anatomy.

**TASTER STATUS CLASSIFICATION** Overall, valid consensus values for the classification of PROP status are lacking, mainly because steady improvements in genetic and psychophysical testing have eclipsed previous estimates. Consequently, existing criteria are both idiosyncratic and variable, resulting in vigorous debate over which classification scheme best reflects differences in oral sensation (e.g., Drewnowski, 2003; Prutkin et al., 2000; Rankin et al., 2004). At the center of this issue, the validity of any boundary value depends on the instrument used to measure it, so when suprathreshold psychophysical tools produce distorted comparisons among subjects, the sorting criteria derived from those tools are also distorted. (Thresholds have remained a popular clinical measure for precisely this reason, even though they also have features that distort real-world sensory experience.) In other words, measurement scales may be numerous, but not all are created equal: For oral sensory evaluation, magnitude matching remains the “gold standard” technique.

Broadly speaking, the most effective assessment strategies integrate multiple correlates of function. As advances in anatomy and genetics permit more nuanced study, the best methods for oral sensory evaluation will encompass an array of techniques that complement and enrich sophisticated psychophysical measurement. Based on laboratory and questionnaire data collected over many years, this multivariate approach has yielded working guidelines for the determination of PROP status (Snyder et al., 2006):

- Nontasters and tasters of PROP are easily distinguished by genetic analysis of T2R38 (i.e., nontasters are recessive, tasters are dominant) (Kim et al., 2003), which reliably predicts PROP threshold differences (i.e., > 0.2 mM for nontasters, < 0.1 mM for tasters; Bartoshuk, 1979; Bartoshuk et al., 1994a). In a sample of 1400 healthy lecture participants, this difference corresponds roughly to a boundary value on the general Labeled Magnitude Scale (gLMS; see below) of

“weak” (i.e., 17 out of 100) for filter papers impregnated with saturated PROP (~0.058 M). Consistent with previous estimates (Bartoshuk et al., 1994a; Harris and Kalmus, 1949a), this cutoff yields ~25% nontasters in the sample.

- Supertasters of PROP are distinguished from medium tasters by psychophysical criteria. Existing population estimates of PROP taster status are based on a single-locus model, so this boundary value will remain arbitrary until the genetic basis of PROP bitterness is fully understood. If nontasters represent the lowest 25% of PROP paper ratings, a working definition of supertasting might include the top 25% of ratings; this logic suggests a gLMS boundary value of 80.
- Individuals with taster genotypes and nontaster PROP ratings probably reflect oral sensory pathology (see below). In these cases, oral anatomy can often be used to identify supertasters (e.g., Bartoshuk et al., 2004a), who show high fungiform papilla density (i.e., over 100 papillae/cm<sup>2</sup>; Bartoshuk et al., 1994a) and low PROP responses.

In recent years, as the parameters of oral sensory variation have expanded, the use of thiourea bitterness as a proxy for overall oral sensory ability has been questioned at considerable length, mainly because correlations with it are imperfect and sometimes quite low. Proposed alternatives to PROP intensity include the ability to perceive specific taste cues from thermal or irritant stimuli (Green and George, 2004; Green and Hayes, 2004); these methods show promise, but their broader predictive ability remains unclear because, like thiourea bitterness, they emphasize associations with a particular taste modality. Meanwhile, a more generalized concept of taster status has emerged, one that frames supertasting as an elevated response across multiple stimuli rather than a single class of compounds (Hayes and Keast, 2011; Lim et al., 2008; Reed, 2008). New measures like these may prove more veridical than PROP intensity, but they will require extensive study to determine boundary values, interactions with genetics and anatomy, and clinical significance. Thus, despite its flaws, PROP bitterness remains a useful screening tool, as it is currently the best characterized index of individual differences in oral sensation.

Whether taster group classifications are based on PROP bitterness or more general criteria, some researchers persistently claim that oral sensation has little effect on sensation, food behavior, or health (e.g., Drewnowski, 2003; Kranzler et al., 1998). Upon closer examination, many of these dissenting reports fail to show effects of interest because they incorporate methods known to distort or eliminate main effects, including inappropriate group

comparisons, poor scale instructions, and the use of threshold rather than suprathreshold taste tests (e.g., Bartoshuk, 2000; Bartoshuk et al., 2005). These problems are often reinforced by the inappropriate use of labeled intensity scales.

### 34.2.2.3 Measuring Oral Sensory Differences:

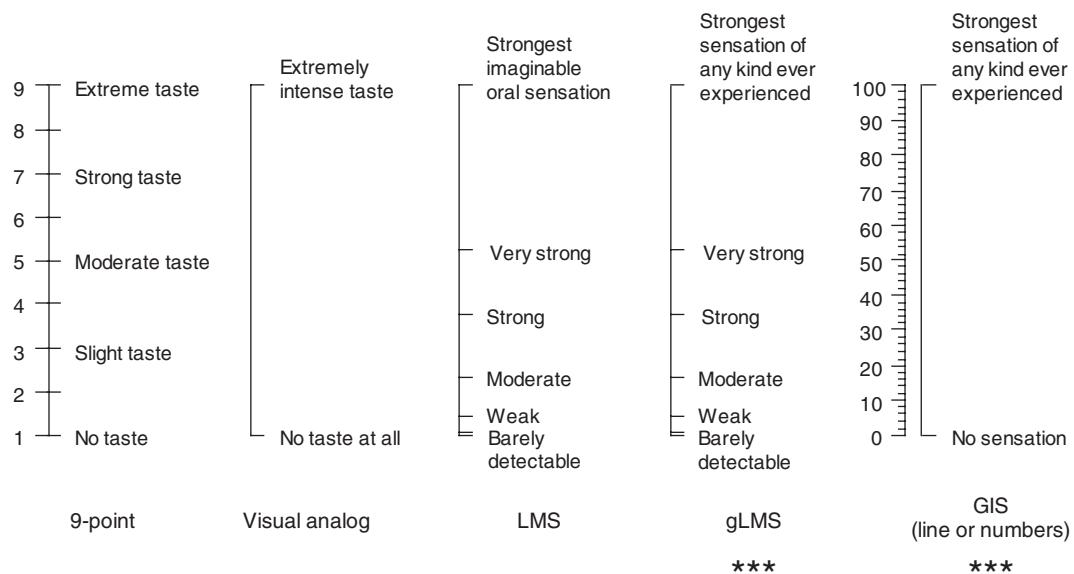

**Labeled Scales.** Measurement scales labeled with intensity descriptors (e.g., weak, strong, very strong) are used widely throughout the medical, scientific, and consumer disciplines. Although many of these category scales have been “validated,” the fact that a scale measures what it was intended to measure does not guarantee its ability to produce valid group comparisons. In fact, several reports have determined that category scales distort results when their labels fail to denote equal perceived intensities to everyone.

Category scales are much older than the formal psychophysics of Fechner, dating back at least to the astronomer Hipparchus (190–120 BC). In the modern era, category scales in common use include the Likert scale (1932), which was originally developed to measure attitudes, and the Natick 9-point scale, which was created by the military to quantify food preferences (Jones et al., 1955; Peryam and Girardot, 1952). When adapted for sensory use, these scales are typically anchored by descriptors spaced equally along a line (e.g., 1 = none, 3 = slight, 5 = moderate, 7 = strong, 9 = extreme), as shown in

Figure 34.2 (Kamen et al., 1961). The visual analog scale (VAS), a line labeled at its endpoints with the minimum and maximum intensity of a particular experience (e.g., Aitken et al., 1963; Hetherington and Rolls, 1987), came into widespread use during the 1960s and remains the favored sensory scale for medical assessments of pain; it is essentially a category scale without categories. Multiple versions of these scales have been used in oral sensory research, differing in terms of gradation, labeling, and stimulus specificity (Lawless and Heymann, 2010).

**PROPERTIES OF INTENSITY LABELS** We commonly use intensity descriptors to compare our experiences with the experiences of those around us (e.g., “This solution tastes *strong* to me. Does it taste *strong* to you?”). Because we use these words so frequently, they were incorporated as anchors on intensity scales.

Ratings from category scales generally have ordinal but not ratio properties (Stevens and Galanter, 1957), primarily because the equidistant spacing of labels does not reflect their actual perceived intensity (e.g., Berry and Huskisson, 1972; Lasagna, 1960): A sensation rated “8” on the Natick 9-point scale is more intense than a sensation rated “4,” but it is not necessarily twice as intense. Consequently, the 9-point scale is especially prone to ceiling effects (Bartoshuk, 2000; Lucchino et al., 1998). Borg (1970, 1982) addressed this problem by deriving the first category scale with ratio properties, and subsequent efforts

**Figure 34.2** Examples of labeled scales used for oral sensory evaluation. Asterisks indicate scales for group comparisons of oral sensation; scales without asterisks require an independent standard for such comparisons. Note the change in context from imaginable to experienced events in recent versions of the gLMS/GIS. LMS = Labeled Magnitude Scale; gLMS = general Labeled Magnitude Scale; GIS = Global Intensity Scale.

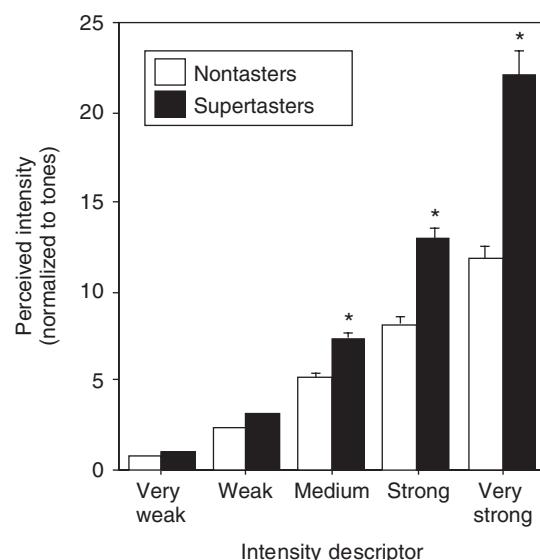

to define scale labels empirically have generated similar “quasi-logarithmic” spacing across multiple sensory and hedonic attributes (Borg, 1990; Gracely et al., 1978; Green et al., 1993; Moskowitz, 1977a; Schutz and Cardello, 2001), indicating that sensory and hedonic experiences possess similar intensity properties.

Another important feature of intensity labels is that they convey relative and variable magnitude. Adjectives modify nouns, so their absolute meaning is flexible, particularly in terms of size. S. S. Stevens (1958, p. 633) illustrated this concept, noting: “Mice may be called large or small, and so may elephants, and it is quite understandable when someone says it was a large mouse that ran up the trunk of the small elephant.” As this observation shows, “large” and “small” carry only relative meaning until their nouns are specified. Only when the context is defined can these words be placed in their proper perspective: A large mouse will always be smaller than a small elephant.

A similar point applies to intensity descriptors: The word “strong” varies in magnitude depending on whether it refers to a strong odor, a strong gust of wind, or a strong pain. Nevertheless, many comparisons made with labeled scales implicitly assume that scale descriptors denote the same absolute intensity regardless of the object described. Range theory, proposed by Borg (1982) and Teghtsoonian (1973), extended this idea by proposing that sensory ranges are essentially the same for all modalities and all people. While this idea would make across-subject comparisons much easier, it is incorrect (Bartoshuk et al., 2002b).

Indeed, intensity descriptor meanings vary among groups of people just as they do among different sensory modalities. This concept is illustrated by a study assessing the magnitudes denoted by scale descriptors for taste perception (Bartoshuk et al., 2004b). Participants used magnitude estimation to rate a variety of taste stimuli, a series of intensity descriptors, and a series of tones; taste intensity descriptors were then matched to sounds for nontasters and supertasters of PROP. As Figure 34.3 shows, the spacing among descriptors appears proportional for both groups, but the supertaster range is expanded: The descriptor “very strong” is almost twice as intense for supertasters as for nontasters, consistent with the idea that supertasters have a broader taste intensity range than do nontasters.

In short, labeled scales maintain their relative spacing, but they are elastic in terms of the domain to be measured and the individual’s experience with that domain. Because conventional labeled scales fail to account for this elasticity, they can be used for within-subject comparisons or for across-group comparisons in which groups are assigned randomly. However, across-group comparisons are invalid whenever subject classification (e.g., sex, age, weight, clinical status) produces groups for which scale labels denote different absolute intensities.

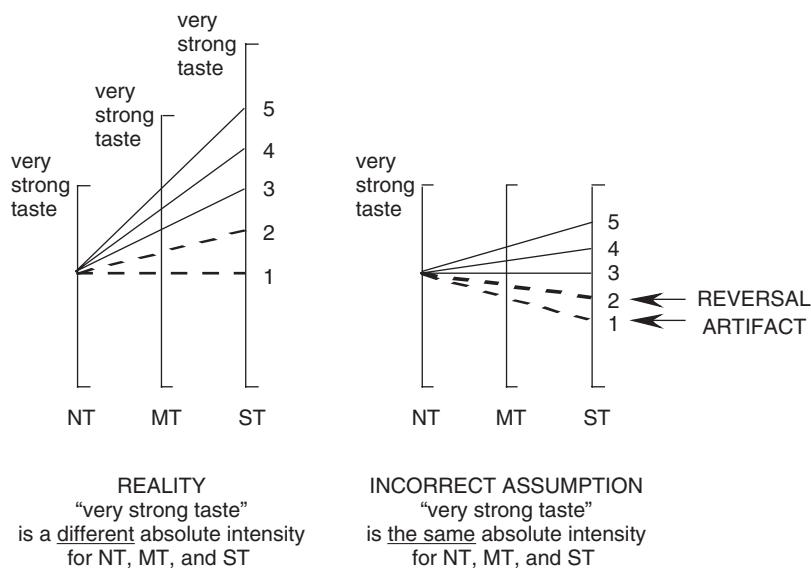

**Figure 34.3** Taste intensity ratings associated with adjective descriptors for nontasters and supertasters of PROP. Data were collected using magnitude estimation and normalized to ratings for a 1000 Hz auditory stimulus. (Modified from Bartoshuk et al., 2004b).

## CONSEQUENCES OF INVALID COMPARISONS

Figure 34.4 shows errors resulting from the false assumption that intensity descriptors denote the same absolute intensity to everyone. (This figure is idealized, but effects have been verified using taste and food stimuli; Bartoshuk et al., 2004a). The left side of the figure shows stimuli that produce equal perceived intensities to PROP nontasters. The diverging lines connecting nontaster and supertaster ratings indicate PROP effects of differing sizes; the intensity difference between groups for the label “very strong taste” is the same difference shown in Figure 34.3. When the label “very strong taste” is treated as if it denotes the same average intensity to nontasters and supertasters, supertaster data are compressed relative to nontaster data, as shown on the right side of Figure 34.4:

- Stimulus A appears more intense to supertasters than to nontasters, but the magnitude of the effect is blunted.
- The difference between nontasters and supertasters for stimulus C is equal to the difference between the labels, so it disappears.
- For stimulus D, the actual difference between nontasters and tasters is smaller than the difference in meaning for “very strong taste,” so group differences appear to go in the opposite direction. This phenomenon is known as a *reversal artifact* (e.g., Bartoshuk and Snyder, 2004).

Although the limitations of labeled scales for group comparison have been discussed at length (e.g., Bartoshuk et al., 2002b, 2005; Biernat and Manis, 1994; Birnbaum,

**Figure 34.4** Consequences of invalid comparisons. The left panel shows taste functions reflecting real differences between nontasters (NT), medium tasters (MT), and supertasters (ST) measured with magnitude matching. The right panel shows the consequences of incorrectly assuming that “very strong taste” indicates the same absolute perceived intensity to NT, MT, and ST. Valid effects appear truncated and may reverse direction inaccurately. (Modified from Bartoshuk et al., 2004b).

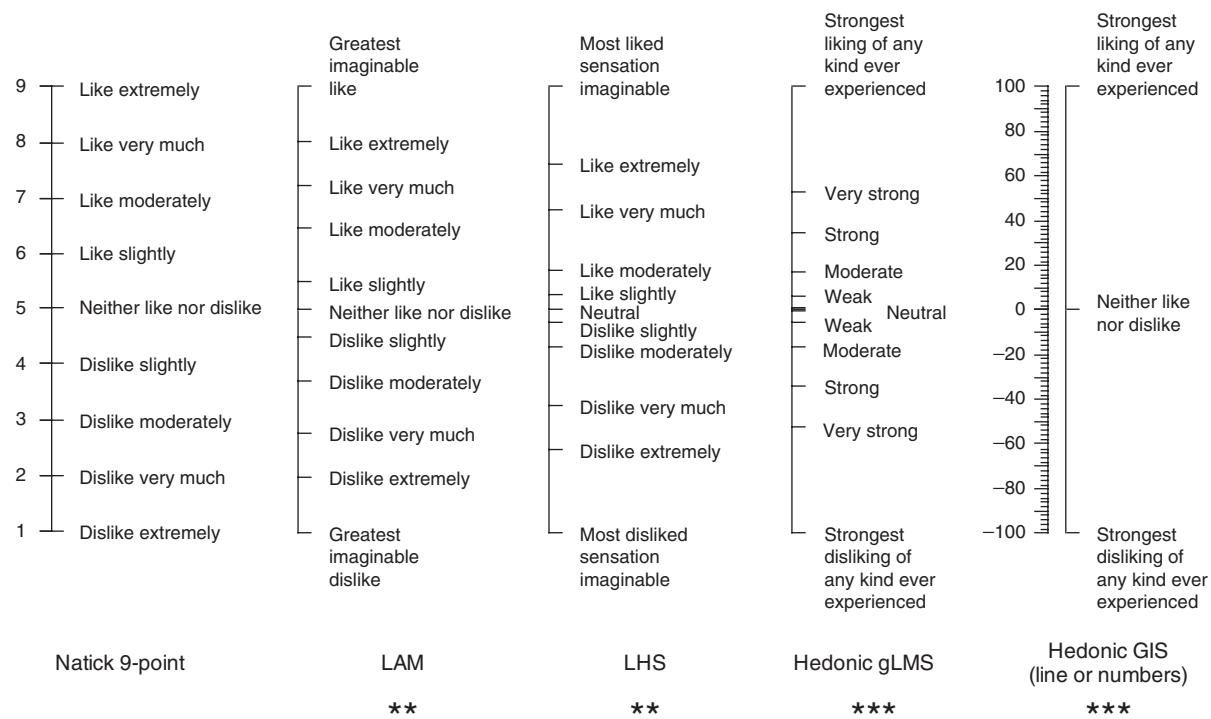

1999; Manis et al., 1991; Narens and Luce, 1983), some critics have argued that group effects with significant biological impact should be sufficiently robust to be detected with any and all methods (Drewnowski, 2003). Claims like these are distortions themselves: Biological effects exist whether they are measured or not, but measurement tools are useless if they cannot detect those effects realistically. Moreover, the popularity of a scale does not necessarily make it the right tool for the task at hand. Although improved labeled scales show promise, contrary reports arising from invalid scaling methods remain significant obstacles to research efforts in the chemical senses.

**GENERAL LABELED MAGNITUDE SCALE (gLMS)**  
Category scales assume ratio properties when real-world experience defines the spacing among labels. Given that intensity categories maintain their relative differences across individuals and modalities, might stretching this common intensity scale to its maximum produce a labeled scale allowing valid comparisons of oral sensory intensity? By this point, the Labeled Magnitude Scale (LMS) had been developed specifically to measure oral sensations (Green et al., 1993). As shown in Figure 34.2, the LMS is a ratio scale anchored by empirically-spaced intensity descriptors, including the top anchor “strongest imaginable [oral] sensation.” To generalize the LMS for experiences beyond oral sensation, Bartoshuk and colleagues replaced its top anchor with the label “strongest imaginable sensation of any kind.”

This scale, now known as the general LMS (gLMS), shares similar logic to magnitude matching: The top anchor of the gLMS is meant to function as a standard, so it must

remain unrelated to oral sensation to ensure valid comparisons of chemosensory function. This requirement appears to be satisfied for studies of oral sensory experience: Participants rarely describe oral sensations as their strongest imaginable sensory experience (Bartoshuk et al., 2002b), and the gLMS and magnitude matching produce similar oral sensory differences among PROP taster groups (Bartoshuk et al., 2004c). Data collected with the gLMS also show strong test-retest reliability (Galindo-Cuspinera et al., 2009).

Although it was developed for sensory use, the gLMS also shows promise as a hedonic scale. Building on the empirical finding that intensity labels for sensation and affect are similarly spaced (e.g., Moskowitz, 1977b; Schutz and Cardello, 2001), a “hedonic gLMS” was created by extending two gLMSs in opposite directions from a common midpoint; “neutral” is in the center, “strongest imaginable disliking” anchors one end, and “strongest imaginable liking” anchors the other (Bartoshuk et al., 2002b). This scale, shown in Figure 34.5, has proven quite useful in recent studies of food affect: Overall food acceptance increases with body mass index, suggesting that the obese experience greater palatability from foods than do the non-obese (Bartoshuk et al., 2006); supertasters of PROP experience greater overall food liking and disliking than do nontasters, which may explain their selective food preferences (Bartoshuk et al., 2010). As with its sensory counterpart, the hedonic gLMS is appropriate for group comparisons because oral sensory cues rarely elicit affective ratings at the endpoints of the scale (Bartoshuk et al., 2010). Other hedonic scales may perform similarly to the gLMS in terms of group comparisons, provided their

**Figure 34.5** Examples of labeled scales used for hedonic evaluation. Asterisks indicate scales suitable for group comparisons of food-related affect; scales without asterisks require an independent standard for such comparisons. Note the change in context from imaginable events (\*\*) to experienced events (\*\*\*) in recent versions of the gLMS/GIS. LAM = Labeled Affective Magnitude scale; LHS = Labeled Hedonic Scale; gLMS = general Labeled Magnitude Scale; GIS = Global Intensity Scale.

boundary labels are explicitly framed in terms of all affective experience; promising candidates shown in Figure 34.5 include the Labeled Affective Magnitude Scale (Schutz and Cardello, 2001) and the Labeled Hedonic Scale (Lim et al., 2009).

Because the gLMS contains an internal standard, data collected with it should not require normalization. However, when the top of the gLMS is related to an experience of interest, comparisons using raw gLMS ratings are invalid. With regard to chemosensation, this problem may be especially relevant in studies of trigeminal function; the gLMS fails as a standard for measures of pain intensity because pain is often associated with the top of the scale. Accordingly, some researchers embed several candidate standards in their experiments; if one standard fails, others may succeed. For example, “brightest light ever seen” has emerged as a suitable standard for pain psychophysics (Bartoshuk et al., 2004a).

The standards used in the laboratory often require cumbersome and expensive equipment. Because scale labels rely on memories of perceived intensity, remembered sensations have been proposed as standards. Although the precise relationship between real and remembered intensity is unclear (e.g., Algom, 1992), remembered oral

sensations appear to reflect effects observed with actual stimuli (e.g., Fast et al., 2001; Stevenson and Prescott, 1997). As indicated above, the incorporation of real and remembered stimuli as standards brings flexibility to data management; raw gLMS scores may be used (which invokes an internal standard), or they may be normalized to other variables (which converts the gLMS to a magnitude matching task), allowing confirmation of effects across a variety of assumptions. As a whole, these multimodal ratings coalesce into a snapshot of one’s sensory and affective world, enabling individual differences of interest to resolve on a diffuse yet stable background (Bartoshuk et al., 2004b).

### 34.2.3 Global Intensity Scales: Beyond the gLMS

The similarity of intensity descriptor usage across widespread modalities (sensory and hedonic, real and remembered) suggests a cognitive model for intensity perception. We learn the relative spacing among intensity descriptors early in life, and these ratios remain constant. However, the absolute sensory range covered by intensity descriptors is variable, so we stretch or compress our descriptive vocabulary to fit the extremes of whatever we

wish to describe. As a result, we may use the same words to describe just about anything, but our experience with the object at hand is critical in guiding our frame of reference. This concept raises several interesting psychophysical questions: How many intensity labels does a scale require? Are some labels more important than others? Which ones?

For example, the term “imaginable” is included in the top anchors of many intensity scales (e.g., “worst imaginable pain”), but is it really useful? Do all people imagine the same strongest sensation regardless of what they actually experience? When subjects rated both the most intense sensation of any kind ever experienced and the strongest sensation imaginable, the two were highly correlated when expressed relative to the brightest light ever seen (Fast et al., 2002). As such, “imaginable” sensations may be inappropriate standards for comparisons of experience, and the term has been removed from recent iterations of the gLMS, as shown in Figure 34.5; boundary labels now refer to the strongest intensity ever experienced.

With respect to other labels, the utility of remembered sensations suggests a more radical approach: Perhaps all labels should be abandoned except for those at the ends of the scale. The result (for sensation) would be a line denoting the distance from “no sensation” to the “strongest sensation of any kind ever experienced.” Alternatively, one could simply use numerical ratings (e.g., 0 to 100 for sensation, -100 to +100 for affect) provided the appropriate endpoint meanings were conveyed. Recent data indicate that these minimalist “global intensity scales” (GIS), shown in Figure 34.5, perform similarly to the gLMS (Snyder et al., 2008b). As with the gLMS, GIS values could be used to make group comparisons unless the strongest sensation ever experienced showed a group difference, in which case an alternative standard would be used.

### 34.3 REGIONAL VS. WHOLE-MOUTH SENSATION: WHERE SHOULD ORAL SENSATION BE MEASURED?

Given its broad behavioral and health implications, oral sensory variation shows considerable promise as a diagnostic aid in epidemiology, sensory and consumer evaluation, and the health professions. To date, comprehensive assessments of oral sensory function have been used mainly in basic and clinical research, but there is growing appreciation in food science that information regarding baseline oral sensory viability aids a full understanding of chemosensory response.

Several afferent nerves carry sensory information from the mouth, each carrying a particular array of information

from a particular area (e.g., Pritchard and Norgren, 2004). The chorda tympani (CT), a branch of the facial nerve (cranial nerve VII), carries taste information from the anterior, mobile tongue; the lingual branch of the trigeminal nerve (V) carries pain, tactile, and temperature information primarily from the same region (Lewis and Dandy, 1930; Zahm and Munger, 1985). Multimodal information (i.e., taste, touch, pain, temperature) is carried from the posterior tongue by the glossopharyngeal nerve (IX), from the palate by the greater superficial petrosal nerve (another branch of VII), and from the throat by the vagus (X) (Fay, 1927; Kanagasuntheram et al., 1969; Norgren, 1984; Reichert, 1934). Taste and oral somatosensory cues combine centrally with retronasal olfaction to produce the composite experience of flavor (e.g., McBurney, 1986, Rozin, 1982). This spatial distribution of input has led researchers to consider the impact of localized oral sensory damage, so modern protocols for oral sensory evaluation typically include judgments of intensity and quality for both regional and whole-mouth stimuli.

#### 34.3.1 Whole-Mouth Oral Sensation

In whole-mouth gustatory testing, chemical stimuli are sampled and moved throughout the mouth, stimulating all oral taste bud fields simultaneously; subjects rinse with water prior to each stimulus. Laboratory tests of oral sensation involve the presentation of chemical solutions at multiple concentrations spanning the functional range of perception (e.g., Bartoshuk et al., 1998; Tepper et al., 2001), but most clinical tests have streamlined this process to a single concentration for each of the common taste qualities (i.e., sucrose, NaCl, citric acid, quinine hydrochloride) (e.g., Frank et al., 2003). In addition, multiple concentrations may be used to derive suprathreshold taste functions, and other oral stimuli may be included to evaluate oral tactile sensation (e.g., capsaicin, alcohol) or individual differences (e.g., PROP). Having discussed the disadvantages of thresholds, we favor suprathreshold measurements involving magnitude matching or the gLMS/GIS with appropriate standards, so stimuli unrelated to oral sensation (e.g., sound, remembered sensations) should be incorporated.

Aqueous solutions are inconvenient for clinical, field, or large-scale use, so alternative methods of stimulus delivery have been explored, including paper strips, tablets, and edible films (Adler, 1972; Hummel et al., 1997; Mueller et al., 2003; Smutzer et al., 2008). In early studies, PTC crystals were placed directly on the tongue (Fox, 1932) or delivered on saturated filter papers (Blakeslee and Fox, 1932). As threshold techniques became dominant, the filter paper method faded from use until it was revived as a rough screening tool for lecture attendees (Bartoshuk et al., 1996). Today, PROP papers are made by soaking

laboratory-grade filter papers in a supersaturated solution of PROP heated to just below boiling. When dry, each paper contains ~1.6 mg (Bartoshuk et al., 1996); by comparison, patients with hyperthyroidism are prescribed 100–300 mg PROP daily (Cooper, 2005). Variants of this method have been described (e.g., Tepper et al., 2001; Zhao et al., 2003), but all share the common goal of introducing a small amount of crystalline PROP to the tongue surface.

Although intended as a rough estimate of PROP taster status, the filter paper technique shows promise because of its simplicity. Nevertheless, the technical disadvantages of this technique warrant careful consideration. To produce a taste, the paper must be completely moistened with saliva, which requires both healthy salivary function and a sufficient period of contact with the tongue. Some studies have reported excessive false-positive and false-negative responses to PTC/PROP filter papers, but these response rates may reflect minor variations in testing that confer bias (Azevedo et al., 1965; Lawless, 1980). Other critics have observed that filter paper testing shows only moderate concordance with threshold sensitivity (Hartmann, 1939), but threshold and suprathreshold measures of PROP bitterness almost always dissociate when proper scaling is used (e.g., Bartoshuk, 1989).

Despite these concerns, filter paper ratings and laboratory assessments of PROP bitterness show significant agreement (Bartoshuk et al., 1996; Kaminski et al., 2000; Zhao et al., 2003) and high test-retest reliability (Ly and Drewnowski, 2001; Zhao et al., 2003). One of the reasons that filter paper delivery functions so well may be that the exact concentration of PROP on each paper is trivial provided it is high. As filter papers soaked in saturated PROP dry, PROP crystals adhere to the paper; when a dried PROP paper is placed in the mouth, the crystals on the paper dissolve in saliva. Comparisons of PROP bitterness produced by filter papers vs. solution suggest that the concentration of PROP dissolved from the paper into saliva approaches the solubility limit of PROP. Because functions of PROP bitterness for nontasters, medium tasters, and supertasters diverge (Bartoshuk, 2000; Bartoshuk et al., 1994a), the most efficient way to sort subjects into these groups is to use the highest concentration possible. Based on this logic, papers made from saturated PROP (Bartoshuk et al., 1996) may be preferable to those made from lower concentrations (Zhao et al., 2003).

### 34.3.2 Oral Sensory Anatomy: Videomicroscopy of the Tongue

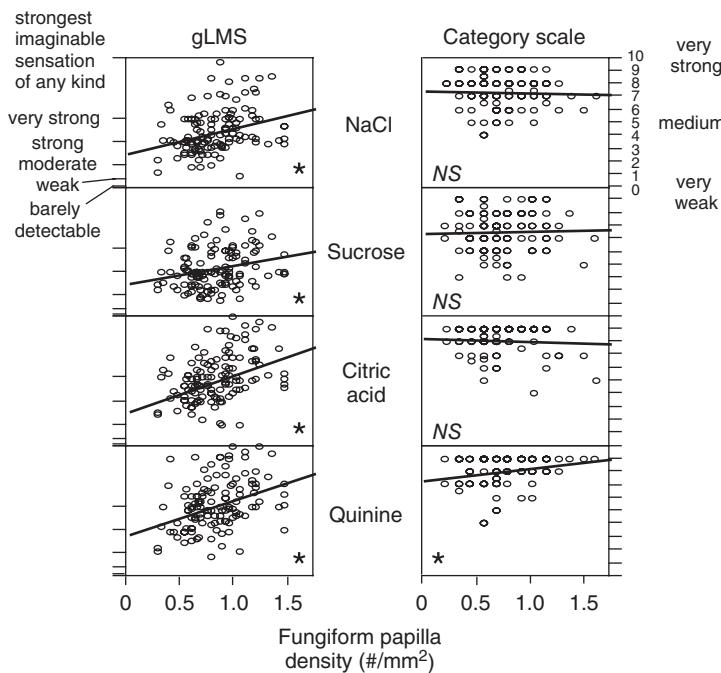

Several lines of evidence indicate that taste sensation varies with the number of taste buds stimulated. The most direct example of this relationship is that threshold and suprathreshold taste function increase with the size of the area stimulated on the tongue, presumably because a

larger stimulus area captures more taste buds (Doty et al., 2001; Hara, 1955; Linschoten and Kroese, 1991; Smith, 1971). Clinical data paint a complementary picture, as patients with lingual nerve damage show parallel losses of fungiform papillae and taste perception (Bull, 1965; Cowan, 1990; Ogden, 1989) that recover partially with nerve regeneration (Robinson et al., 2000; Zuniga et al., 1997). Finally, inbred strains of mice expressing differences in bitter avoidance (i.e., SWR/J tasters of sucrose octaacetate vs. C57BL/6J nontasters; Harder et al., 1984) show corresponding differences in taste bud density (Miller and Whitney, 1989) and gustatory nerve responses (Shingai and Beidler, 1985).

To explore variation in human oral anatomy, Miller and Reedy (1990a, 1990b) developed a method for visualizing the tongue *in vivo* (see also Shahbake et al., 2005). The anterior surfaces of human tongues are covered with two distinct types of papillae (i.e., raised structures); the larger fungiform papillae hold taste buds, but the smaller filiform papillae do not (e.g., Miller and Bartoshuk, 1991). When blue food coloring is applied to the tongue surface, it fails to stain fungiform papillae, which appear as pink circles against a blue background of filiform papillae. Fungiform papillae can then be counted with a magnifying glass and a flashlight. Videomicroscopy at higher magnification allows resolution of small blue dots on the surfaces of fungiform papillae; these dots are pores that function as conduits to the apical tips of taste buds.

Measured in this fashion, lingual anatomy has revealed robust positive associations between PROP intensity, fungiform papillae density, and taste bud density (Bartoshuk et al., 1994a; Delwiche et al., 2001; Miller and Reedy, 1990b; Zuniga et al., 1993). Fungiform papillae are dually innervated by CT and V (Gairns, 1953), which accounts for the elevated taste and oral tactile sensations experienced by supertasters (e.g., Essick et al., 2003; Prutkin et al., 2000). Videomicroscopy of the tongue has also enabled identification of some forms of oral sensory pathology. Human fungiform papillae and taste buds degenerate with lingual nerve damage (Zuniga et al., 1994 1997), but CT damage alone sacrifices taste buds while leaving fungiform papillae intact (Schwartz, 1998). Consequently, in individuals with taster genotypes and nontaster PROP ratings, high fungiform papilla counts signal anterior taste damage (e.g., Bartoshuk et al., 2004a).

Finally, the association between taste intensity and oral anatomy among healthy subjects can be used to evaluate the ability of various scales to provide valid across-group comparisons. To illustrate, Figure 34.6 compares two experiments in which the same stimuli were tasted. Subjects in one study rated perceived intensity with the gLMS, while subjects in the other study used a category scale. Note that the gLMS produces robust correlations between taste intensity and fungiform papillae density, while the category scale

**Figure 34.6** Perceived taste intensity as a function of fungiform papillae density. Graphs on left were obtained with the gLMS; graphs on right were obtained with a 9-point category scale. Asterisks indicate statistically significant effects ( $p < 0.05$ ); NS = not significant. All correlations on the left are significant, but only the correlation for quinine is significant on the right. (Modified from Snyder et al., 2004).

does so only for bitter taste (Snyder et al., 2004). By showing that conventional labeled scales can distort a valid and meaningful difference, this result further confirms that the gLMS (and, by extension, magnitude matching) is superior for comparisons of group experience.

### 34.3.3 Spatial Taste Testing

Because different nerves innervate different regions of the oral cavity, oral sensation can be absent in one area but remain intact in others. Remarkably, individuals with extensive taste damage are often unaware of it unless it is accompanied by tactile loss (Bull, 1965; House, 1963; Moon and Pullen, 1963; Pfaffmann and Bartoshuk, 1989, 1990; Rice, 1963), presumably because taste cues are referred perceptually to sites in the mouth that are touched, whether or not taste receptors at those sites are present or functional (Delwiche et al., 2000; Green, 2002; Todrank and Bartoshuk, 1991). As a result of this “tactile referral,” regional taste loss rarely produces whole-mouth taste loss, yet it remains clinically significant as a precursor to altered, heightened, and phantom oral sensations. Measures of regional taste function are an important tool for identifying the source of these complaints.

The integrity of specific taste nerves is assessed clinically via spatial testing (Bartoshuk, 1989), in which suprathreshold solutions of sweet, sour, salty, and bitter stimuli are applied with cotton swabs onto the anterior tongue tip, foliate papillae (i.e., posterolateral edges of tongue), circumvallate papillae (i.e., raised circular structures on posterior tongue), and soft palate. (A spatial taste

test involving filter paper strips impregnated with taste stimuli has also been described; Mueller et al., 2003.) Stimuli are presented on the right and left sides at each locus, and subjects make quality and intensity judgments using magnitude matching or the gLMS/GIS. Special care must be taken to avoid stimulating both sides of the mouth simultaneously (which impedes localization), triggering a gag reflex during circumvallate stimulation, or allowing palate stimuli to reach the tongue surface (which leads to inflated palate ratings). Following regional testing, subjects swallow a small volume of each solution and rate its intensity, thereby enabling comparisons of regional and whole-mouth sensation. Comparisons of psychophysical functions across oral loci indicate that taste cues are perceived at similar intensity on all tongue areas holding taste buds, but less so on the palate (Bartoshuk, 1988). Thus, oral sensory losses can be identified as significant local variations from otherwise stable perception across the tongue surface.

For many years, virtually the only feature of taste perception mentioned in textbooks was a map showing the areas on the tongue sensitive to each of the four basic tastes: sweet on the tip, salt and sour on the edges, and bitter at the rear. Spatial taste testing demonstrates that this “tongue map” is inaccurate, and further study reveals that it was based on faulty evidence all along. As a student, Hänig (1901) showed that thresholds for the basic tastes show slight variation across various tongue loci, but he never proposed that individual taste modalities are restricted to specific regions of the tongue surface. The mistake occurred years later when Boring (1942) plotted

the reciprocal of Hänig's threshold values as a measure of the sensitivity of each tongue area. Boring did not include numbers on his graph, so subsequent readers failed to realize that his data actually represented very small threshold differences, and a myth was born.

#### 34.3.3.1 Clinical Correlates of Localized Taste Loss.

Disorders of oral sensation are both widespread and variable, yet useful resources and appropriate medical treatment are frustratingly sparse (e.g., Deems et al., 1991; Hoffman et al., 1998). Because taste cues influence nutritional health, metabolism, and affect, their loss can be traumatic (e.g., Giduck et al., 1987; Mattes and Cowart, 1994; Tennen et al., 1991), yet in many cases the absence is hardly noticed (e.g., Bull, 1965; Goto et al., 1983; Tomita et al., 1986). To add another layer of complexity, gustatory disturbances are often associated with identifiable disorders and treatment interventions, but just as often they are of unknown origin and unpredictable onset (e.g., Bromley and Doty, 2003). Thus, a full oral sensory evaluation requires thorough examination of physical (e.g., oral anatomy, oral and salivary pathology, non-gustatory neurological damage), sensory (e.g., taste, oral somatosensation, retronasal olfaction), and emotional aspects of chemosensation (e.g., psychopathology, quality of life).

Spatial taste testing is most powerful when used in combination with genetic and anatomical data, as it reveals discrepancies between heredity and experience that arise via pathology (e.g., Snyder et al., 2006). Careful psychophysical study has revealed a great deal about the consequences of localized oral sensory damage; with the use of magnitude matching and the gLMS/GIS for valid across-group comparisons, oral sensory alterations have been implicated in an ever-growing array of health conditions. These relationships do not necessarily validate the methods used to discover them, but their concurrent relationship to measures of oral anatomy strongly suggests that improved psychophysical methods reflect meaningful differences in human experience. The examples that follow illustrate conditions in which modern oral sensory testing may facilitate diagnosis or intervention.

**ORAL DISINHIBITION** The term *dysgeusia* refers to a chronic taste that occurs in the absence of obvious stimulation (Snow et al., 1991). Many clinical complaints of dysgeusia result from taste stimuli that are not readily apparent to the patient (e.g., medications tasted in saliva, crevicular fluid, or blood; Alfano, 1974; Bradley, 1973; Fetting et al., 1985; Stephen et al., 1980), but some chronic taste sensations, known as phantoms, appear to arise centrally.

Neurological disorders can lead to taste phantoms (El-Deiry and McCabe, 1990; Hausser-Hauw and Bancaud, 1987), but CT damage appears to be a primary factor

in clinical accounts (Bull, 1965; Jones and Fry, 1984; Yamada and Tomita, 1989). Moreover, electrophysiological recordings from rodents and dogs show that blocking CT input produces elevated activity in brain regions receiving input from IX (Halpern and Nelson, 1965; Ninomiya and Funakoshi, 1982; Norgren and Pfaffmann, 1975; Ogawa and Hayama, 1984; Sweazey and Smith, 1987). These data indicate that CT inhibits IX normally, so CT loss should disinhibit IX. Human psychophysical data support this model: In both patient cohorts (e.g., head injury, craniofacial tumors, ear infections) and healthy subjects under anesthesia, unilateral CT loss leads to increased whole-mouth perceived bitterness via increased contralateral taste sensation at IX (Catalanotto et al., 1993; Kveton and Bartoshuk, 1994; Lehman et al., 1995; Yanagisawa et al., 1998), an effect that may occur preferentially for PROP supertasters (Snyder, 2010). The majority of oral sensory input rises ipsilaterally into the CNS (Norgren, 1990), so contralateral effects strongly implicate central modulation.

While under CT anesthesia, about 40% of healthy subjects experience taste phantoms contralaterally at IX; these sensations vary in quality and intensity, fading with the anesthetic (Yanagisawa et al., 1998). Topical anesthesia at the site of sensation abolishes these *release-of-inhibition* phantoms (Yanagisawa et al., 1998), presumably by suppressing spontaneous neural activity at their source (Norgren and Pfaffmann, 1975). Also, in one case report (Bartoshuk et al., 1994b), a bitter phantom arose bilaterally at IX following tonsillectomy. Spatial testing indicated complete IX loss, yet the phantom became more intense with whole-mouth topical anesthesia. This *nerve-stimulation phantom* was probably caused by surgical damage to IX and further disinhibited by CT anesthesia.

Similar to its interaction with IX, CT taste input also appears to inhibit trigeminal cues. This interaction may suppress oral pain during intake, and it may facilitate tactile referral of taste information following localized taste damage. Nevertheless, because supertasters have the most taste and trigeminal input, CT damage may lead to adverse sensory consequences due to extreme trigeminal disinhibition: Following unilateral CT anesthesia, PROP supertasters show increased ratings for the burn of capsaicin on the contralateral anterior tongue (Tie et al., 1999). In addition, severe childhood ear infections may compromise CT (e.g., Bartoshuk et al., 1996; Gedikli et al., 2001), leading to elevated tactile sensations from dietary fat that may promote sweet-fat food acceptance and long-term weight gain (e.g., Bartoshuk et al., 2012; Catalanotto et al., 2009; Kim et al., 2007; Snyder et al., 2003; Ventura et al., 2009).

Oral pain phantoms are another serious consequence of V disinhibition. The identification of burning mouth

syndrome (BMS) as such a phantom vividly illustrates the clinical relevance of modern oral sensory testing. BMS, a condition most often found in postmenopausal women, is characterized by severe oral pain in the absence of visible pathology (Grushka and Sessle, 1987). BMS is often described as psychogenic, but systematic psychophysical testing tells a different story. Most BMS patients show significantly reduced bitterness for quinine on the anterior tongue, consistent with CT damage (Bartoshuk et al., 1999; Grushka and Bartoshuk, 2000). Nearly 50% of BMS patients experience taste phantoms at IX (Grushka et al., 1986), and topical anesthesia usually intensifies BMS-related taste and oral pain (Ship et al., 1995). Finally, the peak intensity of BMS pain correlates with fungiform papillae density, indicating that BMS is most prevalent among supertasters. Taken together, these data strongly suggest that BMS is an oral pain phantom generated by CT damage. Grushka has shown that agonists to the inhibitory neurotransmitter  $\gamma$ -aminobutyric acid (GABA) suppress BMS pain (Grushka et al., 1998), presumably by restoring lost inhibition from absent taste cues.

### ORAL ANESTHESIA IN CLINICAL EVALUATION

Laboratory and clinical data support the use of topical anesthesia in the mouth to determine the locus of oral sensory dysfunction. However, interpretations of topical anesthesia must be made carefully, as incomplete anesthesia will hamper differential diagnosis. In topical anesthesia, patients hold ~5 mL of 0.5% dyclone in the mouth for 60 seconds, rest for 60 seconds, rinse with water, and describe any oral sensations experienced for the duration of the sensory block (Bartoshuk et al., 1994b). Anesthesia should always be accompanied by a thorough medical history, physical examination, and careful evaluation of spatial and whole-mouth oral sensation.

If a taste or oral pain complaint becomes *more intense* as a result of oral anesthesia, then it does not arise from normal stimulation of oral sensory receptors. Venous taste sensations and other dysgeusias may be caused by intake of certain therapeutic agents (Bradley, 1973; Fetting et al., 1985; Stephen et al., 1980), so the patient's use of medications and supplements should be reviewed. Another possibility is that the nerve innervating the region of sensory disturbance has sustained physical damage. If damage is peripheral to ganglion cell bodies, the resulting neuroma may produce a nerve-stimulation phantom; topical anesthesia exacerbates nerve-stimulation phantoms via central disinhibition (Bartoshuk et al., 1994b). Conclusions involving nerve damage should be confirmed by further neurological examination.

When local anesthesia *abolishes* a taste or oral pain complaint, an actual stimulus may be present in the mouth. To test for the presence of such a stimulus, the patient should attempt to rinse it from the mouth; if the offending

sensation subsides at all, an actual stimulus should be considered. Alternatively, nerve damage unrelated to the altered sensation may have disinhibited input related to it, resulting in a central release-of-inhibition phantom; topical anesthesia further intensifies these phantoms (Bartoshuk et al., 1994b). Spatial testing should reveal localized taste loss at a site distant from the phantom.

### 34.3.4 Retronasal Olfaction

Odorants reach the nasal mucosa by two different routes: Orthonasal olfaction refers to odorants that enter the nostrils during sniffing, while retronasal olfaction refers to odors that are emitted by foods and forced behind the palate into the nasal cavity during mastication and swallowing (Rozin, 1982). This distinction is not merely conceptual, as orthonasal and retronasal olfaction are processed in different brain regions (e.g., Small et al., 2005; Small et al., 1997). Perceptually, retronasal odor cues fuse with taste and oral tactile sensations, culminating in a unitary sensation of flavor that is localized to the mouth. This process was long believed to involve oral touch alone (Hollingsworth and Poffenberger, 1917), but growing data indicate that taste input plays a significant role: Retronasal and taste cues enhance one another when mixed (e.g., Frank et al., 1989; Kuo et al., 1993; Murphy et al., 1977), PROP supertasters experience stronger retronasal sensations than do nontasters (Bartoshuk et al., 2002a; Snyder et al., 2007), and regional taste loss compromises retronasal olfaction and whole-mouth taste in parallel (Bartoshuk et al., 2012; Snyder, 2010). Clinical accounts of chemosensory disturbance often commence with complaints of flavor loss, and industrial applications of oral sensory testing typically involve flavor effects of altered food composition or manufacturing, so retronasal olfactory testing has emerged as a useful element of oral sensory evaluation.

Experimental vehicles for the presentation of retronasal olfactory stimuli vary considerably, including odors infused into water or tastant solution, vapor-phase odorants released into the mouth, and sampled food items. All of these models are confounded to varying degrees by enhancement or "dumping" effects arising from odor-taste integration (e.g., Frank and Byram, 1988; Stevenson et al., 1999), compromising the validity of retronasal intensity ratings. As such, consistent procedures for retronasal olfactory evaluation have not been established, although there is general agreement that an oral stimulus must be present to induce sufficient levels of retronasal sensation. One promising approach used recently involves the spatial and temporal dissection of flavor components: Foods are sniffed (orthonasal olfaction) and then sampled with the nose plugged (taste and oral somatosensation), and the nose is released to elicit a distinct retronasal cue (Snyder, 2010). Testing in this fashion permits evaluation of flavor

loss induced by oral sensory insult vs. other factors (e.g., olfactory deficits, nasal blockade).

The ability to evaluate distinct components of flavor experience holds promise for industrial efforts to enhance food palatability. For economic reasons, the food industry has long added taste stimuli to food to enhance its flavor, as commodities like sugar and salt are typically less expensive than flavor extracts (e.g., Noble, 1996). However, rising consumer awareness of health risks associated with added sugar and salt has raised interest in alternative strategies for flavor enhancement. Recent data from horticulture offer an intriguing possibility: Analysis of chemical and sensory measurements from tomatoes reveals that some flavor volatiles enhance sweetness independently of sugar (Tieman et al., 2012). In other words, some of the sweetness perceived in fruits and vegetables arises from sugars, and some of it arises from retronasal odor cues associated with sweetness. Thus, the addition of volatiles to food may represent a novel way to enhance sweetness, flavor, and palatability without adding sugar.

#### 34.4 ORAL SENSORY EVALUATION IN FOOD SCIENCE

In research and clinical settings, the goal of oral sensory evaluation is to measure the perceptual ability of chemosensory systems. Although within-subject comparisons are an important tool in this arena — as when sensation is compared before and after a manipulation, such as surgery or adaptation — group comparisons are especially prominent as a means of linking oral sensation to broader health-related themes. As such, much of the present chapter has focused on the use of psychophysics to make sensory or affective comparisons among people whose chemosensory experiences vary in some way: Does the taste of sucrose differ between males and females? Do PROP supertasters experience greater pleasure from sucrose than do others?

A different purpose guides industrial applications of chemosensation, as observed by Lawless and Heymann (2010: 5): “The primary concern of any sensory evaluation specialist is to insure that the test method is appropriate to answer the questions being asked about the product in the test.” Here, the focus is on the product rather than the individual, and healthy chemosensory function is either assumed or confirmed prior to testing. Consequently, differences among people are considered secondary to within-subject shifts following stimulus change: “From a practical point of food testing, the issue is not to uncover group differences, but rather to find differences among food products that will help workers in the food industry, food science or nutrition to provide food products with high acceptability to consumers” (Cardello et al., 2008:

474). In the future, this view may change with increasing use of sensory profiling in market segmentation to develop food products aimed at specific consumer groups.

Despite this fundamental difference, comparisons across foods and comparisons across consumers of food both require measurement of oral sensory experiences — for example, healthy chemosensory function must be confirmed in panelists, and manufacturers must identify optimal ingredient levels in their products. Relevant measures include threshold sensitivity, suprathreshold intensity across the dynamic range of a stimulus, and hedonic value. While the present chapter has outlined these methods, their specific use in food science is discussed at length in contemporary texts of sensory evaluation (e.g., Lawless and Heymann, 2010; Meilgaard et al., 2007).

#### 34.5 CONCLUSION

Human psychophysics is a powerful and necessary aspect of clinical, basic, and consumer science, offering a window onto neurobehavioral processes that are often inaccessible by other means. In the chemical senses, significant progress has been made in crafting measurement tools that render individual differences accurately and allow adaptive use in clinical, research, industrial, and field settings. Conservative approaches to this task emphasize threshold measures, but suprathreshold scaling has evolved into a sophisticated means of measuring and comparing biologically relevant experiences at real-world levels. When performed correctly, these methods have enabled the study of oral sensory variation in health and disease, and the systematic use of techniques from psychophysics, anatomy, neurology, and genetics has revealed complex relationships between oral sensation, affect, behavior, and pathology. In short, ongoing refinements in oral chemosensory assessment have strong clinical, food science, and basic research implications, as they yield highly predictive and highly comparable measures of sensory and hedonic experience.

## Mapping Brain Activity in Response to Taste Stimulation

DANA M. SMALL and ANNICK FAURION

### 35.1 INTRODUCTION

Before *functional* cerebral imaging was made accessible for human experimentation, the knowledge of neurophysiological pathways and the determination of the functions of the brain depended on animal electrophysiology. However, evolution across species modifies neural functions and anatomies. Clinical observations in patients constituted another source of information but lesions often affect multiple brain regions making definitive conclusions problematic. Positron Emission Tomography (PET), functional Magnetic Resonance Imaging (fMRI), and Magnetoencephalography (MEG) afforded, for the first time, the ability to non-invasively study the neurophysiological mechanisms of taste perception in humans. In this chapter, we review what we have learned about gustatory representation of the human brain from neuroimaging experiments. We also review relevant results from lesion studies in humans where appropriate and briefly describe important points of convergence and divergence with gustatory neurophysiology in rodents and primates.

### 35.2 LOCALIZING THE HUMAN GUSTATORY CORTEX

In non-human primates, single-cell recording (Ogawa et al., 1989; Yaxley et al., 1990; Scott and Plata-Salaman, 1999) and anatomical tract tracing (Pritchard et al., 1986, 2000) have identified the dorsal anterior insula and adjacent frontal operculum as the “primary” gustatory cortex (the cortical area where the taste message arrives first).

Gustatory information is subsequently conveyed to the ventral insula and to the caudomedial and caudolateral orbitofrontal cortex (OFC) (Baylis et al., 1995; Pritchard et al., 2005), which are generally considered secondary and higher-order gustatory cortical regions (Rolls et al., 1990; Rolls and Baylis, 1994). An obvious first step for human neuroimaging investigations was to determine whether there are homologous representations of gustatory information in the human brain.

Kinomura was the first to show brain activation in response to taste using PET, observing activation within the thalamus, anterior insular cortex, anterior cingulate gyrus, parahippocampal gyrus, lingual gyrus, caudate nucleus, and temporal gyrus (Kinomura et al., 1994). Subsequently, Cerf and collaborators developed a stimulating method using 100  $\mu$ l bolus repeatedly sent to the subject’s mouth every 3 sec which allowed them to exclude somatosensory stimulation and adaptation as potential confounds while minimizing head movements consecutive to swallowing. A linear potentiometer enabled the subject, in the magnet, to record his/her “Time-Intensity perception profile” (finger-span); this profile of perceived intensity, continuously recorded over time, was used as a template and correlated to the magnetic resonance signal of each voxel to retrieve activation (Cerf et al., 1996, 1998; Van de Moortele et al., 1997; Faurion et al., 1998, 1999). The waveform of the recorded intensity profiles confirmed a slow rate of rise of the taste perception in these conditions. Such quantitative psychophysical evaluation is an important factor for retrieving activated areas because the Time Intensity profile allows gustatory perception to be dissociated from the tactile stimulation inherent in the act

of tasting. At 3 Teslas, fMRI offers a spatial resolution of  $3 \times 3 \times 3$  mm projected on an anatomy resolution of 1 mm<sup>3</sup>. The slow rate of rise of the signal in the Blood Oxygenation Level Dependent (BOLD) method is of the same order as the psychophysical signal. Hence, the stimulation technique and the perception recording were coherent with the BOLD method. Using single subject analysis, taste areas were localized in various parts of the insula and in frontal, temporal, Rolandic opercula, including pre- and post-central gyri (Cerf et al., 1996; Cerf et al., 1998; Cerf-Ducastel et al., 2001), as was expected from electrophysiological recordings in the monkey (Ruch and Patton, 1946; Bagshaw and Pribram, 1953; Benjamin and Burton, 1968; Ogawa et al., 1985; Pritchard et al., 1986; Yaxley et al., 1990; Scott and Plata-Salaman, 1991; Kadohisa et al., 2005; Ogawa et al., 2005b) and clinical observations in humans (Bornstein, 1940; Lewey, 1943; Penfield and Faulk, 1955; Motta, 1959; Haussner-Hauw and Bancaud, 1987). Moreover, an unexpected activation was observed in the most inferior and anterior part of the insula in the dominant hemisphere of subjects which was in the direction of the orbitofrontal cortex (Faurion et al., 1999).

Simultaneously or soon after, other authors confirmed and extended these data with PET and MEG. Several studies reported activation of multiple insular, opercular, and caudal medial and lateral orbitofrontal regions during gustatory stimulation (Kobayakawa et al., 1996, 1999; Zald et al., 1998; Frey and Petrides, 1999). Small and colleagues (1997) elucidated a role for the right anterior temporal lobe in taste quality recognition and taste intensity perception coding (Small et al., 2001b; c). Zald and Pardo (2002) showed that water activated a similar region of the insula and operculum as taste. O'Doherty et al. (2001) reported activation in the insula and opercula, without chemotopical organization. O'Doherty et al. (2002) and De Araujo et al. (2003b) showed unimodal neuronal activity for taste in the anterior superior insula ( $Y = 3$  to 14) and frontal operculum, indicating that although most of the chemoreceptive neurons in these areas are polymodal neurons (taste and somatic, taste and olfactory etc.), a given neuronal activity can signal pure taste. These authors also confirmed activation of the caudolateral orbitofrontal cortex as well as a part of the rostral anterior cingulate cortex (De Araujo et al., 2003b).

Barry et al. (2001) with fMRI, and Yamamoto et al. (2003) with MEG, both used electrogustatory stimulation – or iontophoretic stimulation – to study cortical representation of taste. Small currents produced by a generator induce a movement of the cations in the subject's own saliva towards his/her receptors. With intensities below those eliciting tingling, these authors showed insular and opercular activation. For higher intensities, activation of the somatosensory cortex was also obtained, confirming

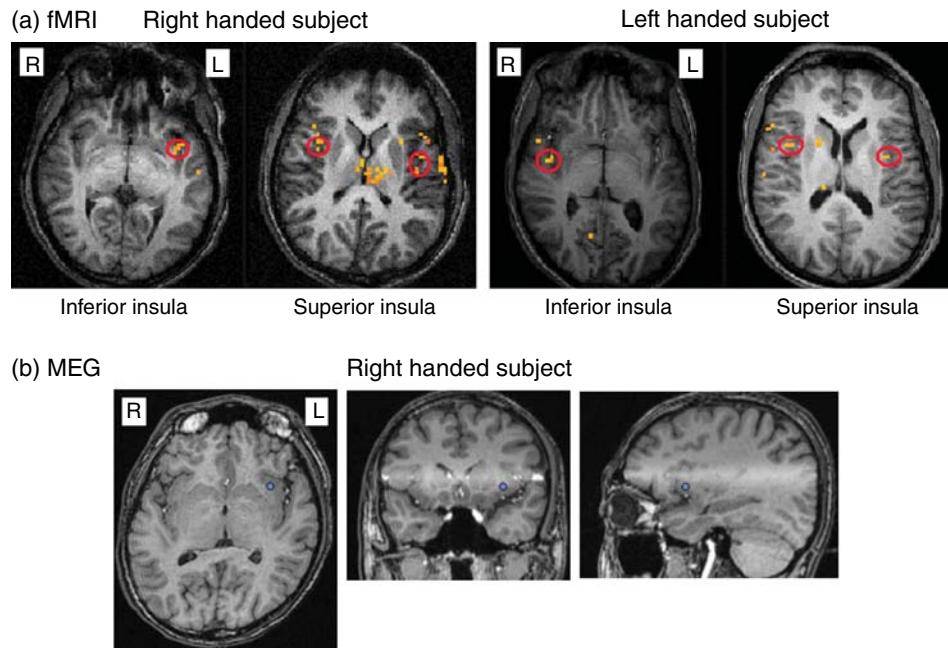

trigeminal stimulation. The electrogustatory stimulation (the same which is used in electrogustometry, EGM) furthermore confirmed that actual taste and not somatosensory responses were found in the postcentral gyrus at a more ventral location of the postcentral gyrus than where Pardo et al. (1997) found both taste and somatosensory senses.

Collectively, then, the early gustatory neuroimaging literature demonstrates that taste is represented, not only in the thalamus, anterior insula/frontal operculum, and caudal orbitofrontal cortex, but also in several other regions of the insula and overlying operculum, as well as in the anterior cingulate cortex and anterior medial temporal lobe.

### **35.2.1 Time Resolution: Magnetencephalography (MEG) Contributions to Describing Human Taste Pathways**

BOLD fMRI suffers from the long latency of the hemodynamic response (several seconds). Magnetoencephalography (MEG) records, in a series of SQUID (Superconducting QUantum Interference Device) sensors positioned on the scalp, the magnetic fields produced by the minute electrical currents elicited locally in the brain by any taste stimulation. Results are positioned on a MRI map of the subject's brain with a high spatial resolution. As MEG records the actual electrophysiological brain activity, its time resolution can easily be in the millisecond range. However, MEG suffers from a spatial drawback as the result depends on the solution of the inverse problem to localize the spatial origin of these local activities using first a "guess," then minimization algorithms. The strategy, which consists of associating both MEG and fMRI, guarantees, when finding the same areas activated, a good spatial resolution (1–3mm) without an *a priori* guess (with fMRI) and with an excellent time resolution (millisecond) in the same areas (with MEG).

To use MEG, Kobayakawa et al. (1996; 1999) developed a novel method so that stimulus delivery could be precisely time-locked to brain response. Tastants were delivered as boluses embedded in a stream of water that flowed through a Teflon tube. A small (3 x 9 mm) opening in the tube was created and placed across the tip of the subject's tongue so that the tastant could stimulate taste receptors on this region of the tongue. Importantly, the bolus was injected with a colored dye that could be detected by an optical sensor enabling stimulus onset to be time-locked to brain response. In addition, since the gustatory stimulus is embedded in a constant tactile stimulus (flow of liquid over the tongue) taste and tactile stimulation are dissociated. This offers the advantage of being able to detect brain response to pure taste signals. However, it is an artificial way to experience taste, which could also be taken as a disadvantage because during everyday tasting the gustatory and tactile signals co-occur. As such, similar flow

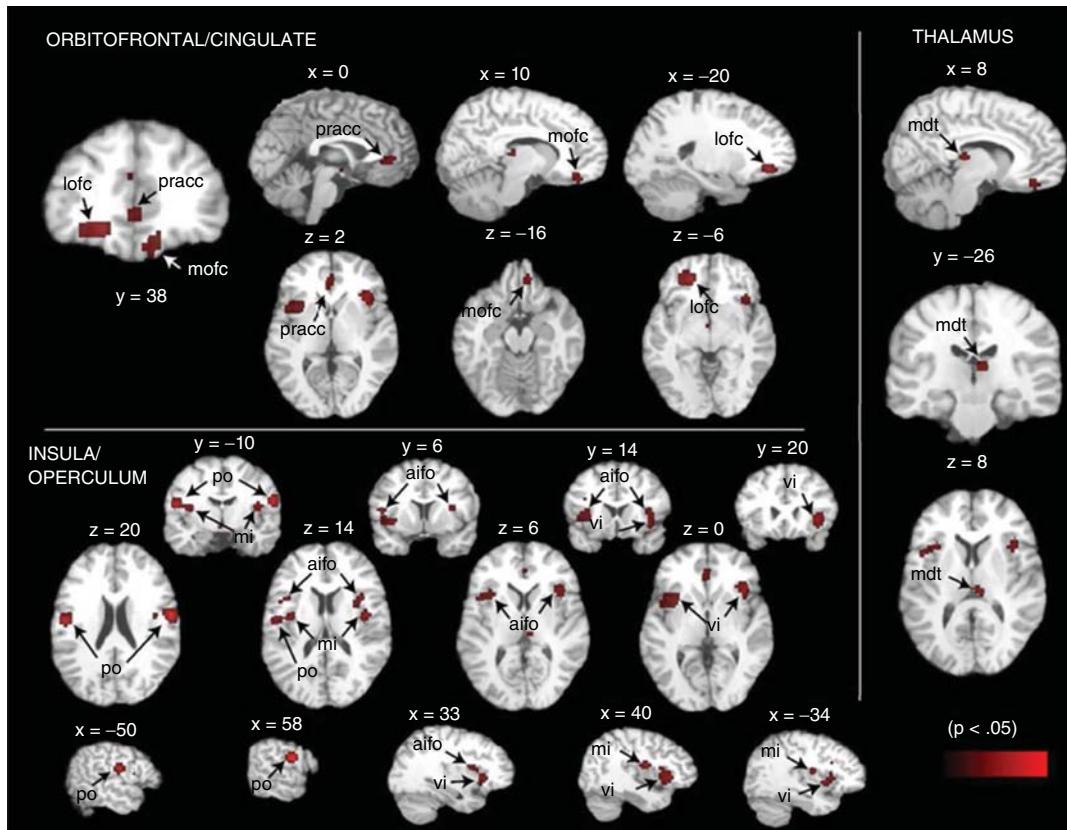

**Figure 35.1** Functional Magnetic Resonance Imaging (fMRI) showed activation in the left inferior anterior insula in right-handers (Oldenburg score 0) and in the right inferior anterior insula in the left-handers (Oldenburg score > 16) for taste stimulations. MagnetoEncephalography (MEG) showed activation in the left inferior anterior insula of right-handers at late latencies (800–1300ms). At this time, subjects begin to perceive the quality of the stimulus. This left inferior anterior insular area was also demonstrated, with fMRI, to be co-activated with the left angular gyrus in right-handers, a structure known to be involved in semantic treatments. NB: the right hemisphere appears in the left hand side of all images. (fMRI images from Faurion A, Cerf B et al. *Neuroscience Letters*, 1999, in collaboration with D. Le Bihan, SHFJ, CEA, DRM, Orsay, France, with permission from Elsevier; MEG images from Kobayakawa T and collaborators, Human Technology Research Institute, AIST, Tsukuba, Japan, by courtesy). (See plate section for color version.)

methods have been associated with reduced gustatory sensitivity in psychophysical assessments (Meiselman, 1971).

Using this method Kobayakawa and colleagues found that the area first activated by taste was located at the transition between the parietal operculum and the posterior superior insular cortex which they named area G for gustatory area, and in the Rolandic operculum, including the buried part of the central sulcus. The average onset latency was 93 ms for NaCl and 172 ms for saccharin (Kobayakawa et al., 1996), whereas no response was obtained for pure water used as a stimulus. The longer latency for the activation elicited by saccharin compared to NaCl was suggested to reflect the difference of events at the peripheral level, including the time for diffusion to receptors and transduction events for organic molecules compared to mere channel opening for  $\text{Na}^+$  cations (Kobayakawa et al., 1999). Kobayakawa and colleagues suggested “area G” represented the primary taste cortex since it was the first region to be activated. They also described other regions that were activated subsequently to area G in the frontal operculum and the anterior part of the insula, the hippocampus, the parahippocampal gyrus and the superior temporal sulcus.

Compared to electrophysiological results localizing the “primary” taste area in the anterior insula in monkeys or other neuroimaging results in human, this result from MEG and EEG recordings (Mizoguchi et al., 2002) seems contradictory at first. However, many fMRI studies do report activity in this region. For example, Ogawa et al. (2005a) reported activation in both the superior posterior insula (area G) and the buried part of the parietal operculum at right coordinates x;y;z: 46;−6;12 and left −38;−8;12, in the left frontal operculum at: −52;26;4 and Rolandic operculum at −60;−18;24 using fMRI. As such, the three meta-analyses of taste studies that have been conducted all conclude that there are multiple taste-responsive regions in the insula and overlying operculum (Small et al., 1999; Verhagen and Engelen, 2006; Veldhuizen et al., 2011a). For example, Veldhuizen and colleagues reviewed 15 studies in a meta analysis and observed the involvement of multiple cortical areas in gustatory processing constituting a taste evoked probability map including the bilateral anterior insula and frontal operculum, the bilateral mid dorsal insula and Rolandic operculum, the bilateral posterior insula/parietal operculum/postcentral gyrus, the left lateral orbitofrontal cortex (OFC), the right medial

**Figure 35.2** Localization of significant ALE values ( $p < 0.05$ ) of gustatory stimulation projected onto a standard template (colin1.1.nii) in Talairach space. Location of selected slice is denoted with stereotactic coordinates above each of them. Only clusters exceeding 100 cubic mm in size are labeled. Abbreviations of anatomical areas: mdt = mediodorsal thalamus, pracc = pregenual anterior cingulate cortex, mofc = medial orbitofrontal cortex, lofc = lateral orbitofrontal cortex, aifo = anterior insula and overlying frontal operculum, po = postcentral gyrus, posterior insula and overlying parietal operculum, mi = mid insula and overlying Rolandic operculum, and vi = ventral insula. OFC, the pregenual anterior cingulate cortex (prACC) and the right mediodorsal thalamus (Figure 35.2). Thus it is clear that the human neuroimaging literature supports the possibility that there is taste representation at the transition between the parietal operculum and the insular cortex. Also supporting this possibility is a clinical report of a patient with a gustatory disorder following a left posterior insular infarct (Cereda et al., 2002). However, Small has argued that designating this region as primary gustatory cortex in humans remains problematic because of the lack of anatomical evidence for a projection from the gustatory thalamus to this region in humans (Small, 2010). Neither histology studies on the primate gustatory organization (Pritchard et al., 1986), nor the studies of central connectivity (Mesulam and Mufson, 1982a; b; 1985) in the monkey or humans, have found connections of area G with other taste regions. As such, Small and colleagues have suggested that responses in this region of the posterior insula and parietal operculum likely reflect attentional

orienting to the mouth during tasting (Veldhuizen et al., 2007). It is also important to note that more recently, Ohla and colleagues using multiple EEG recordings noted pronounced activations of the bilateral anterior insula and adjacent frontal operculum as early as 70–160 ms (Ohla et al., 2010). This time frame is in line with the early activations noted by Kobayakawa and colleagues. There are possibilities that MEG, fMRI or multiple EEG alone may not detect all activation for technical reasons. MEG will detect activation in the sulci, which is the case for area G thanks to the specially efficient detection of orthogonal dipoles, but there are known limitations in dipole modeling that result in failure to detect two simultaneous signals. However, this early double information both in the anterior insula and frontal operculum (Ohla et al., 2010) and at the transition with the parietal operculum and the far posterior insula including the central sulcus (Kobayakawa et al., 1996) reminds one of the discovery of the bifurcating taste neurons projecting from the thalamus VPmpc to both

opercular insular area and the somatosensory area I with a 2–3 ms delay (Benjamin and Burton, 1968).

In any case, caution is called for in discounting area G, as interspecies differences clearly exist in the gustatory system. The most prominent example is the pontine parabrachial taste nucleus, which is of critical importance for rodent taste and ingestive behavior (Di Lorenzo, 1988; Di Lorenzo and Monroe, 1989; Di Lorenzo, 1990; Di Lorenzo and Monroe, 1992), and which is lacking in human (Topolovec et al., 2004) as in non-human primates (Pritchard et al., 1986; Scott and Small, 2009; Small and Scott, 2009). In addition, Craig (2009) has suggested the far anterior insular cortex may be a newly evolved area unique to humans. If true, this would mean that the anterior insula/opercular gustatory region is further caudal within the insular region in humans compared to monkeys. Consistent with this possibility, activations observed in human neuroimaging studies generally exclude the far anterior insular region (Small, 2010).

In summary, there has been, and continues to be debate over the precise location of the “primary” gustatory cortex in humans. This controversy exists for a number of reasons. First, tasting is inherently multi-modal. The primary taste cortex is not taste specific, most single neurons responding to taste and olfaction or to taste and somatic sensation. When we taste we also touch the food or drink in our mouths and sense its odor via retronasal olfaction (Giachetti and Mac Leod, 1975, 1977). Taste and touch are particularly intimately related with evidence for overlapping representation at virtually every level of the neuroaxis from the nucleus tractus solitarius (Boucher et al., 2003; review in (Small and Green, 2011). As such, the signals can be difficult to disentangle, or their successful disentanglement leads to issues with interpretation, since sensation is not ecological (cf. Gibson, 1979). Second, interspecies differences likely exist. In non-human primates, single-cell recording (Ogawa et al., 1989; Yaxley et al., 1990; Scott and Plata-Salaman, 1999), and anatomical tract tracing (Pritchard et al., 1986, 2000), have identified the dorsal anterior insula and adjacent frontal operculum as the primary gustatory cortex. The human neuroimaging studies reviewed in this chapter clearly demonstrate that taste is represented not only in this region, but also in several other regions of the insula and overlying operculum. However, there are limited anatomical studies in humans so it is difficult to rely on convergence between anatomy and electrophysiology to determine which of these regions reflect the first cortical representation. In addition, activations generally exclude the far anterior insular region, suggesting that gustatory information may be represented further caudally in the human compared to the monkey insular cortex. This is consistent with the evolutionary hypotheses developed by Craig (2009), which suggest that the taste area may appear to be moved further caudally compared

to monkeys because the far anterior insular cortex may be a newly evolved area unique to humans. Third, not only do conclusions about the primary gustatory cortex vary as a function of interpretation of data generated from different techniques (e.g., Kobayakawa et al., 1999 versus Veldhuizen et al., 2007), but the same gustatory stimuli can produce responses in the insula and overlying operculum at different locations depending upon the task a subject is asked to perform during stimulation (Bender et al., 2009).

### 35.2.2 Beyond the Primary Gustatory Cortex

One of the advantages afforded by the MEG sensitivity to temporal events is that it allows for viewing the spatio-temporal pattern of activation across brain areas. Each dipole can be followed during a few tens of milliseconds and new dipoles appear in various regions. As such, it is possible to gain insight into the flow of gustatory information from primary to higher-order regions (Kobayakawa et al., 1996, 1999, 2012). Four periods can be distinguished.

1. The first dipoles are observed in the superior posterior insula (area G), Rolandic operculum and pre-central gyrus. In a given example with NaCl, the earliest dipoles start bilaterally in the left post-central gyrus ( $-50; 15; 21$ ) at 76 ms for example and in the right post-central gyrus ( $44;-24;27$ ) at 80 ms, traveling respectively for 8 mm during 32 ms and 8.6 mm during 28 ms to reach both superior posterior insulae at 108 ms.
2. During a period between 200 ms and 500 ms, many areas are activated including various substructures in the insula, the frontal operculum, parietal operculum, middle temporal gyrus, cingulate gyrus, but also hippocampus and amygdala.
3. From 500 ms to 750 ms the activation decreases somehow even sooner for NaCl than for saccharin: signals disappear progressively in the post-central gyrus, the temporal transverse gyrus, the supramarginal gyrus, the superior temporal gyrus, and the inferior insula. During these periods, dipoles move within a given area, stop, and start flashing elsewhere and eventually come back.
4. Between 750 ms and 1500 ms, the nearly silent brain resumes a very late activation in the inferior far anterior insula (Figure 35.1) in the dominant left hemisphere of right-handers (Faurion et al., 1999), which was found to be co-activated with the left angular gyrus (Cerf-Ducastel et al., 2001) which is involved in semantic tasks. For comparison, in many behavioral experiments, a one second period is sufficient to consciously identify the taste stimulus and name it.

Hence, not only a spatial pattern is depicted for taste stimulation but also a dynamic spatio-temporal pattern is observed. Tracking dipoles from their appearance to their extinction exhibits numerous inter-talks between brain areas and within areas during the first second and a half period studied in MEG, with a climax between 200 and 500 ms (Faurion et al., 2008). Conspicuously absent from the spatio-temporal map produced by the MEG results is the orbitofrontal cortex. This is because the signals originating from this region lie in the radial direction relative to the SQUID sensors and thus escape detection (Kobayakawa et al., 1999).

### 35.2.3 Laterality of Taste Projections

For a long time, taste was thought to project contralaterally because researchers who used electrical stimulation of the tongue in rodents to activate taste nerves and localize their cortical projection elicited trigeminal evoked potentials instead of taste evoked potentials. Benjamin and Burton (1968) stimulated the chorda tympani and the lingual-tonsillar branch of the glossopharyngeal nerve in the squirrel monkey, producing exclusively ipsilateral evoked potentials in the anterior opercular-insular cortex. However, Norgren (1978) showed with histology tracing techniques that a few fibers cross from the NTS to the opposite parabrachial nucleus. But in cats and monkeys contrary to the rat, receptive fields for thalamic neurons are exclusively ipsilateral on the tongue (Norgren, 1995).

In the rat, the pontine taste or parabrachial nucleus (PBN) is a mandatory relay. In contrast, in primates neurons from the rostral NTS ascend directly to the thalamus (Beckstead et al., 1980), leading to the conclusion that primates lack the taste PBN relay. Consistent with this possibility, Norgen and colleagues were unable to identify monkey PBN neurons responding to the sapid stimulation of the anterior tongue (Norgren, 1981). However, he could obtain evoked potentials in the PBN with electrical stimulation of the glossopharyngeal nerve innervating circumvallate and foliate papillae, raising the possibility of a primate PBN taste relay for the posterior part of the tongue. In humans, Topolovec et al. (2004) used fMRI to study brain stem functions in healthy humans. They reported activation in the NTS to whole mouth stimulation with sucrose in all eight subjects (two bilateral, five right, and one left), but failed to isolate response in the PBN. Although taste deficits are occasionally reported following pontine lesions (Goto et al., 1983; Nakajima et al., 1983; Uesaka et al., 1998; Onoda and Ikeda, 1999), Small (Small, 2006) suggested that these disturbances likely reflected damage to fibers of passage rather than to cell bodies, which would imply the presence of a relay.

Information about laterality in humans either comes from observing unilateral neurological lesions with MRI and their functional consequences or from a few fMRI or MEG experiments in healthy subjects with hemi-lingual stimulation. So far, as described below, a wealth of clinical observations supports the hypothesis of an ipsilateral taste pathway.

Weidemann and Sparing (2002) reported the rare case of isolated hemiageusia due to a spontaneous hemorrhage in the ipsilateral solitary tract resulting from a cavernous haemangioma. Landis et al. (2006) also saw an ipsilateral transient hemiageusia after a thrombosis of the anterior inferior cerebellar artery. Uesaka et al. (1998) examined a patient with an ipsilateral ageusia and a small lesion localized with MRI around the brachium conjunctivum, involving a small area of the pontine tegmentum clearly dorsal to the right medial lemniscus (the medial lemniscus is the pathway for trigeminal sensitivity). Sato and Nitta (2000) reported a woman with ageusia on the right half of the tongue and a small lesion revealed by MRI in the right dorsolateral tegmentum of the middle pons, lateral to the medial lemniscus. These cases suggest that the central gustatory pathway (central tegmental pathway) projecting from the nucleus of the solitary tract to the thalamus is ipsilateral. Ipsilateral loss of taste is also observed following pontine (e.g., (Nakajima et al., 1983; Takeuchi et al., 2006) lesions?. Such clinical observations are not rare but, as indicated above, it is difficult to know whether they affect fibers rather than neuronal cells. Hence, they definitely argue for an ipsilateral projection of taste from the periphery to the PBN but they cannot be taken as evidence of a taste relay in the human pons on its way to the cortex.

As far as higher brain pathways are concerned, Berlucchi et al. (2004), studying patients with right brain damage compared to patients with left brain damage, suggested a predominantly ipsilateral cortical projection for taste and a predominantly contralateral projection for lingual tactile information. At the thalamic level, the laterality of the gustatory representation remains unresolved for Sánchez-Juan and Combarros (2001) because taste is preserved in patients with a corpus callosum section and strokes or tumors involving the insula. The authors collected arguments in support of the hypothesis of a gustatory representation of both hemi-tongues in the left cerebral hemisphere, and of only the right hemi-tongue in the right hemisphere. Similarly, Cereda et al. (2002) show taste disorders after insular infarct in the left side only. In Sánchez-Juan and Combarros (2001), the loss of taste after surgery for trigeminal neuralgia suggests an accessory gustatory pathway might exist through the trigeminal sensory root. But, Boucher et al. (2003) have shown the convergence of trigeminal afferents on second order taste responding neurons in the NTS. The mere suppression

of these afferents drastically reduces taste sensitivity, as shown in subjects with dental de-afferentation (Boucher et al., 2006). Both trigeminal sensitivity and taste are in neurophysiological intimate interaction (Cerf-Ducastel et al., 2001; Lugaz et al., 2005; Faurion, 2006).

Among studies supporting a partially bilateral taste projection, Barry et al. (2001), using fMRI and electro-gustometric stimulation at low current intensities which excludes tingling sensation, in right-handed subjects, could not show a simple relationship between the side of the applied stimulus and the side where the activation was found in insular and opercular areas at the level of the individual. However, in the group analysis, they found a predominant right activation in the frontal opercular area. Finally, in this study taste appears to project more to the right hemisphere than lingual touch. They also divided the insula into nine parts divided the insula into nine parts (i.e. anterior, middle, posterior x superior, central, inferior) and concluded, in right handers, that taste-evoked activation in the superior part seems to predominate in the right hand side, activation in the central part appears bilateral, and activation in the inferior part is in the dominant left hemisphere. An alternated right-left prevalence, depending on anteriority, was observed with equal left and right projection in the anterior insula/opercular area at  $20 < y < 30$  (Talairach coordinates) and a more pronounced right insular activation at  $0 < y < 10$  (less anterior) which may also look subject-dependent (Cerf-Ducastel et al., 2001). Faurion et al. (1999) showed bilateral activation in middle insula and unilateral activation in the far inferior anterior insula. These results do not prove, however, the existence of initial contralateral projection.

Onoda et al. (2005) observed more frequent bilateral than ipsilateral or contralateral responses at the transitional cortex between the insula and the parietal operculum (area G) in patients whose chorda tympani nerve had been severed unilaterally. Averaged activation latencies were not significantly different in both hemispheres. These results suggest that unilateral gustatory stimulation activates the transitional cortex between the insula and the parietal operculum bilaterally in humans. A temporary conclusion of this development was brought by Onoda et al. (2012) who observed more ipsilateral cases for lesions located from the medulla to the pons versus ipsilateral, contralateral, and bilateral cases for lesions located above the midbrain. Bilateral cases were more frequently detected, suggesting the taste pathway branches and ascends bilaterally from midbrain to cortex in humans.

Conversely, in more recent fMRI studies by Iannilli et al. (2012), the unilateral stimulation with supra-threshold concentrations showed a high predominance of ipsilateral activation at the thalamus and insular levels, and also in the frontal operculum and the lateral prefrontal cortex. Convergently, Stephani et al. (2011) presented patients

with implanted electrodes in the insula, which produced often unpleasant phenomena ("bad," "nasty" taste ( $n = 7$ ) or "metallic" or "like aluminium," with all effects of lateralized electrodes found ipsilateral to the side of stimulation.

What can be concluded about the laterality of the taste system given these contradictory findings? We argue that one critical consideration is that many of the tests used for evaluating deficits in cases of brain lesions are not conclusive because they cannot rule out higher-order contributions that confound the findings. For example, a bilateral deficit evaluated by the failure to recognize a tastant in response to a stimulus applied on either side of the tongue, associated to a unilateral lesion in the insula, is no proof of bilateral primary projection because taste "recognition" involves integrative functions such as learning, semantics, memorization and retrieval, processes far beyond the core of the primary gustatory projections. Moreover, methods of evaluation of taste disorders could be improved at the clinical level, considering quantitative evaluations are closer to peripheral chemoreceptive events and practically devoid of cognitive integration, hence being better adapted to track the "primary taste projection". Secondly, there is no doubt that the gustatory neuroaxis ascends ipsilaterally, but the converging-diverging transfer of information to a series of subcortical regions may prevent a clear-cut picture with the experimental tools and observations so far in use.

### 35.3 FUNCTION

The sense of taste contributes to ingestive behavior by enabling organisms to detect, quantify, and identify critical nutrients or toxins in foods and drinks. In this section, we focus on reviewing the neurophysiology of taste intensity, quality, familiarity, and pleasantness coding. We also consider the role of top-down influences, such as expectation and beliefs, on brain representation of the perceptual dimensions of taste. However, taste sensations rarely occur in isolation. Rather, taste co-occurs with other oral sensations to produce unitary flavor perceptions (Prescott, 1999). In addition, sensory information must be integrated with the nutritional state of the organism to appropriately guide behavior. As such, neural coding of taste is not simply a reflection of peripheral input but also a multimodal integration where gustation is processed among sensory and visceral inputs from other modalities to inform feeding behavior relevant to survival (de Araujo et al., 2012). We refer the reader to the following recent reviews for further details the integration of taste with flavor and homeostatic processing (Stevenson and Tomiczek, 2007; de Araujo et al., 2012; Small, 2012).

### 35.3.1 Intensity Coding of Taste

Responses to tastants increase with stimulus concentration at all levels of the neuroaxis (Zotterman, 1935; Scott et al., 1986a,b; Spector, 1995; Smith and Scott, 2003). However, the *perception* of taste intensity likely emerges from neural circuits within the insula and amygdala. Response magnitude functions generated from taste-responsive cells in the anterior insula and frontal operculum in monkeys conform best to the slopes reported in human psychophysical experiments of perceived intensity (Smith-Swintosky et al., 1991). Changes in suprathreshold taste intensity perception have also been observed following lesions to the insula in humans. Pritchard and colleagues (1999) asked subjects with insular lesions to rate the intensity of tastes applied to either the right or the left side of the tongue. Patients with right insular damage showed decreased sensitivity to tastes applied to the right side of the tongue and patients with left insular damage showed decreased sensitivity to tastes applied to the left side of the tongue. Mak and colleagues also reported decreased taste intensity perception on the side of the tongue ipsilateral to an insular lesion (Mak et al., 2005). However, when they compared their data to matched controls they noted that the change was not due to an ipsilateral decrease but rather to a contralateral increase in taste intensity perception. One possible explanation for this result is that a release from interhemispheric reciprocal inhibition occurred. Similar observations have been reported following damage of the CT in humans (Kveton and Bartoshuk, 1994), suggesting that inhibition may be a general property of the gustatory system. For example, Yanagisawa reported that anesthetizing the CT nerve in humans resulted in increased intensity perception of bitter following application of quinine to the regions of the oral cavity innervated by IX (Yanagisawa et al., 1998), providing evidence for inhibition between these cranial nerves. Also Berteretche et al. (2008) showed patients whose chorda tympani had been slightly injured during stapedectomy surgery complained of painful sensations on the tongue, suggesting a disinhibition of the lingual (trigeminal) nerve.

Clinical studies also implicate the amygdala in taste intensity coding. Small and colleagues reported that patients with resection of the right anterior temporal lobe showed decreased taste intensity ratings (Small et al., 2001b, c). Patients tested with solutions applied to discrete loci of the tongue gave more intense ratings than did the control group, with the exception of sucrose ratings. The authors argued that their pattern of findings might reflect differential intensity coding of appetitive vs. aversive tastes, as suggested by the dual affective architecture model of affect proposed by Cacioppo and Bernston (1999). In this model, the appetitive system has a weak positive output, whereas the activation function

for the aversive system has a lower offset and rises more quickly. They referred to this as a “negativity bias.” Such a model conforms well to early gustatory psychophysical experiments. For example, Wundt (1897) noted, “that for equal intensities, sour, and more especially bitter, produce much stronger feelings than sweet.” With this in mind Small and colleagues developed an fMRI study in which the intensity of a pleasant sweet taste and an unpleasant bitter taste were carefully matched for perceived intensity (Small et al., 2003). This matching procedure is important because it ensures that the difference in intensity perception between the strong and weak solutions is similar for the appetitive and the aversive taste. Under these carefully controlled perceptual conditions, amygdala activation was observed following the comparison of the strong sweet vs. the weak sweet, as well as the comparison of the strong bitter vs. the weak bitter. Similar effects can also be observed with olfactory stimuli (Anderson et al., 2003) that are either positive or negative, but not neutral in valence (Winston et al., 2005). Thus we concluded that the processing in the amygdala reflects an interaction between valence and intensity, and as such, that encoding here may underlie the negativity bias for unpleasant tastes.

Neuroimaging studies of taste intensity perception also implicate the insula and overlying operculum (Small et al., 2003; Nitschke et al., 2006; Grabenhorst et al., 2008; Spetter et al., 2010; Cerf-Ducastel et al., 2012; Kobayakawa et al., 2012). In addition to amygdala responses to intensity, Small and colleagues reported preferential responses in the cerebellum, pons, middle insula, operculum, and posterior insula to bitter and sweet tastes that were rated strong compared to weak (Small et al., 2003). In all cases these responses reflected intensity perception irrespective of hedonic valence. In contrast, valence-specific responses were observed in the anterior inferior insula (xyz: 36;12;-3 and -27;12;-15. MNI) which extends to the OFC. Notably, the OFC responses were independent of intensity, suggesting that coding in the OFC is concerned with other dimensions of taste than intensity. Grabenhorst and Rolls (2008) asked subjects to rate intensity or pleasantness of 0.1M monosodium glutamate with 0.005 M inosine monophosphate on separate trials. Individual differences in rated perceived pleasantness were associated with responses in the medial OFC but not in the insula, while individual differences in perceived intensity were associated with responses in the middle and anterior insula but not in the medial OFC. Corresponding differential responses were also observed in these regions as a function of attention to pleasantness vs. intensity. When subjects attended to the intensity of the stimulus, greater activation was produced in the insula. When they attended to the pleasantness of the stimulus, greater activation was produced in the medial OFC. More recently,

Spetter and colleagues reported increased activation in the middle insula associated with increasing concentrations for both NaCl and sucrose which were independent of the tastant (Spetter et al., 2010). The right putamen and the precentral gyrus also represented intensity, but the right amygdala was modulated only by salt, which may again reflect the role of the amygdala in maintaining a negativity bias. Finally, Ge et al. (2012), have also reported intensity-dependent responses in the right anterior insula (42;18;-14) and right middle insula (40;-2;4) where the activation can be top-down modulated from anterior lateral prefrontal areas.

Responses to taste stimulus concentration (Kobayakawa et al., 2008) and intensity perception (Kobayakawa et al., 2012) have also been investigated with MEG. In these studies, concentration or intensity parametrically modulates responses in area G rather than in more anterior insular regions. However, in keeping with the fMRI reports, intensity perception modulated responses in the hippocampus, anterior cingulate cortex, and prefrontal sulcus. Amygdala responses were not observed, likely because this nucleus does not have layered structure and therefore does not generate signals that can be detected with MEG.

Thus, neuroimaging investigations of taste intensity perception in humans clearly implicate the insula, but the exact region again appears dependent upon the methodology employed. Studies also indicate that there is a larger network of regions involved in intensity variations, including the amygdala and hippocampus of the anterior medial temporal lobe, the cerebellum, the anterior cingulate cortex, and the prefrontal sulcus.

### 35.3.2 Quality Coding of Taste

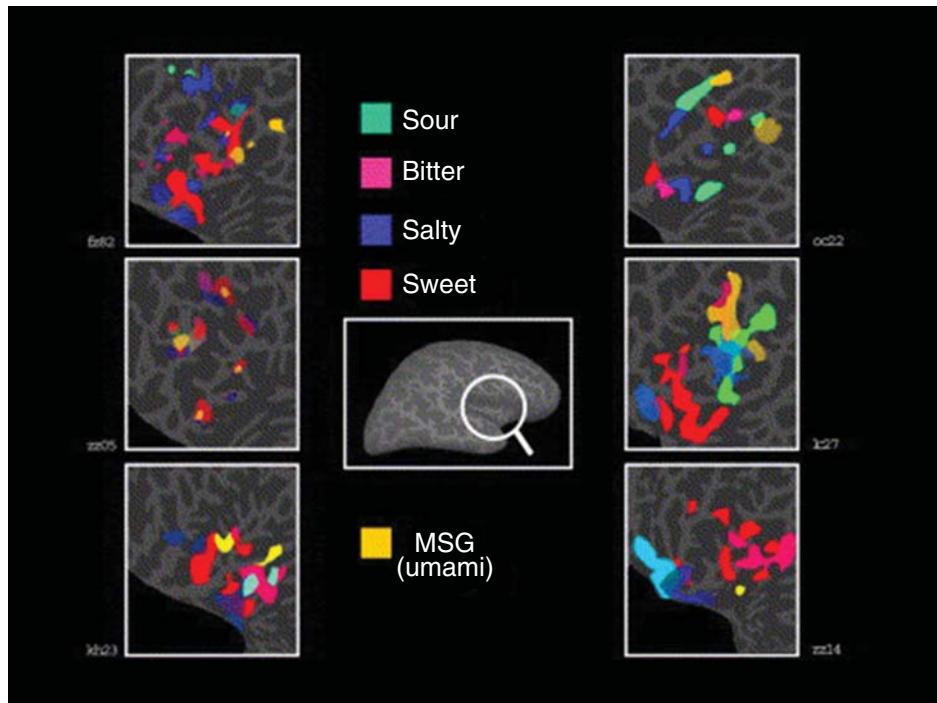

As in rodents (Katz et al., 2002a; Katz et al., 2002b) and primates (Smith-Swintosky et al., 1991), the coding of taste quality perceptions in humans appears dependent upon insular circuits (Prescott, 1999; Schoenfeld et al., 2004; Adolphs et al., 2005). However, whether chemotopy exists, and the extent to which other regions contribute to the quality code, remain uncertain. Several clinical studies found that resection of the anterior medial temporal lobe resulted in elevated recognition thresholds for a sour taste (Henkin et al., 1977; Small et al., 1997) and that a patient with bilateral damage to this region displayed gustatory agnosia (Small et al., 2005), which is the complete inability to identify taste quality despite intact ability to discriminate stimuli based on intensity or affective differences. These reports are reminiscent of the “Kluver-Bucy syndrome” in which monkeys with bilateral amygdala lesions have been observed to indiscriminately place objects (edible and inedible) in their mouths (Kluver and Bucy, 1938). Patients with insular lesions similarly show deficits in taste quality

identification (Pritchard et al., 1999), with one case of agnosia reported where the individual was able to indicate preferences for taste stimuli without being able to report the taste quality (Adolphs et al., 2005). Thus, the clinical literature highlights involvement of the anterior medial temporal lobe and insula in taste quality coding.

Whereas many studies report tastant-specific activations in the insula, overlying operculum, and anterior medial temporal lobe, there is a lack of obvious chemotopy, and most studies have attributed segregated responses to differences in stimulus valence or physiological significance rather than quality (Zald et al., 1998, 2002; O’Doherty et al., 2001; Small et al., 2003; Haase et al., 2009). For example, O’Doherty et al. (2001) looked for a topographic representation of sweet and salty sensations and concluded that the patterns of activation showed considerable overlap. Nevertheless, they were able to map distinct localizations for glucose and salt in accordance with valence in the OFC. Small and colleagues reported distinct responses for quinine and sucrose in the insula, operculum, and OFC, but also attributed these differential responses to valence rather than quality. Also congruent with these findings are studies reporting overlapping responses to different taste qualities in the insula, OFC, amygdala, and anterior cingulate cortex (de Araujo et al., 2003a; Small et al., 2003; Rudenga et al., 2010).

After de Araujo et al. (2003) had shown that monosodium L-glutamate (MSG), which elicits the so-called “umami” taste, activates the insular/opercular cortex, researchers showed that isomolar solutions of MSG and sodium chloride (NaCl), two compounds having the sodium cation in common, induce fMRI activation in various ROIs in the insula, some of them being common to both stimuli (Nakamura et al., 2011; Iannilli et al., 2012). In the middle insular cortex, peaks of activation for MSG were very close to the activation produced by NaCl. Moreover, using a personalized mouth piece to ensure stimulating a wide tongue area, Nakamura et al. (2011) showed that MSG and NaCl induced different but reproducible coordinates of activation patterns in each individual. Hence, the “response” to a chemical seems to be constituted by several dispersed activated areas with reproducibility possibly observed at individual level.

Schoenfeld et al. (2004) have argued that individual differences in quality specific responses might account for failure to observe chemotopy (Figure 35.3). In their study, they used a cortical flattening technique to rule out uncertainties due to the high degree of cortical folding in insula/operculum taste regions and focused analyses on the patterns of responses within subjects. They found that taste specific patterns of activated ROIs were stable over time in each subject and hence, reproducible. Moreover they noted a high inter-individual topographical variability versus

**Figure 35.3** The figure shows the individual activity maps for all investigated taste stimuli on the flattened cortical surfaces of the insular/opercular cortex of the right hemisphere of six subjects. In the center of the figure the picture shows the location of the patches on an unfolded brain. Note the high inter-individual variability of the activations. Reprinted from Schoenfeld et al. (2004) with permission from Elsevier. (See plate section for color version.)

individual reproducibility. Two groups of researchers (James et al., 2009; Ge et al., 2012) further confirmed inter-individual differences of topographical activity for a given tastant in the brain. Thus, it is likely that individual data treatment leads to better-refined information. This result matches well with (i) the great inter-individual differences of quantitative sensitivity profiles which are reproducible in individuals (Faurion, 1980; 2008), with (ii) different neuronal sensitivity profiles also reproducible in non inbred hamster chorda tympani (Faurion and Vayssettes-Courchay, 1990; Faurion, 2008) and with (ii) differences in quality perceptions among numerous tastants (Schiffman, 1979).

In summary, activation is overlapping for different tastants; however, a pattern of such ROIs may be specific for each tastant. Although this information may differ from subject to subject, it is individually reproducible and the various ROIs can be collected as probability maps of activation for a given compound. These features are relevant to a wealth of electrophysiological data in monkeys showing that cells which respond to a given stimulus are intermingled among cells responding to other stimuli (e.g., Baylis and Rolls, 1991), or even other modalities. Neurons also respond to several stimuli and the parameter evaluating the breadth of tuning of single taste neurons does not show increased specificity at the insular cortex level. No chemotopic organization is observed (e.g., Yaxley et al., 1990; Smith-Swintosky et al., 1991; Scott and Plata-Salamon, 1999). Similarly, Accolla et al. (2007), using *in vivo* optical imaging in the rat taste cortex, showed

taste modalities were represented by distinctive patterns but that no region was specific to a single modality.

It is also worth noting, however, that there are several complicating factors in considering the taste quality code – especially in humans. First, the spatial resolution of neuroimaging methods may not be sufficient to resolve tastant-specific neural responses. For example, Chen and colleagues have described segregated responses to taste qualities at the cellular level in rodents using biphoton microscopy and a  $540 \times 540 \mu\text{m}$  frame window in each animal (Chen et al., 2011). The spatial resolution of human fMRI imaging studies of taste are generally on the order of 6–10 mm, with the average voxel containing on the order of hundreds of thousands of neurons. Second, quality specific responses can be identified across large ensembles of spatially segregated neurons (Katz et al., 2002a,b) and these ensembles are very possibly modulated by the temporal patterns arising from earlier gustatory relays in the brainstem (Di Lorenzo and Victor, 2003). Thus, a quality-specific neural signature for taste may escape detection because it is represented as a distributed spatial pattern or temporal profile across this network. Finally, one important confound for all studies attempting to isolate quality-specific responses is that there is a very tight coupling between quality and physiological significance. As such, it is often impossible to designate a BOLD, electrical, optical, or psychophysical response as reflecting quality separately from physiological significance. This point is elegantly demonstrated in the classic rodent study by Chang and Scott (1984) in which they

show that the representation of sweet quality, portrayed by multi-dimensional scaling, shifts following pairing of the sweet taste with nausea to resemble the pattern produced by bitter taste. It is also echoed in the more recent work using *in vivo* optical imaging in rodents to show that the spatial distinction between insular responses to saccharin and quinine fade considerably after an aversion is conditioned for the saccharin (Accolla and Carleton, 2008). Thus, caution is warranted in interpreting spatially segregated insular responses as evidence for the existence of chemotopy (Chen et al., 2011). To conclude, in our opinion the existence of chemotopy in gustation is still unresolved.

### 35.3.3 Familiarity Coding of Taste

Other factors than intensity coding and quality coding are clearly represented in the insula. Testing novel stimuli repeatedly induces an increase in perceived intensity in humans and an increase of chorda tympani response amplitude – both of which stabilize after these repeated exposures to the stimulus. Furthermore, this effect is stimulus-specific, suggesting peripheral events such as receptor expression (Berteretche et al., 2005). These authors looked at plasticity on repetitive imaging in subjects who underwent a protocol designed to familiarize them to novel tastes. They found that the number of activated pixels significantly changed in the insular/opercular area between the first fMRI session, in which the subject tasted the novel stimuli for the first time, and the second fMRI session, which occurred after the subjects had been repeatedly exposed to the stimuli for hundreds of trials. No change occurred between the second and third fMRI sessions, even though repeated exposures to the stimuli had again been made. The results pointed to a relationship between the evolution (increase versus decrease) of the number of activated pixels in the insular/opercular area and the orientation of the evolution of the hedonic assessment (increase versus decrease) during the process of familiarization to the novel tastants. For a group of experiments (an experiment = “one subject and one stimulus”), the hedonic assessments shifted from positive to less positive and this was interpreted as a diminution of interest for the repeated stimulus, although palatable. Simultaneously, the number of activated pixels diminished. Conversely, for the other group of experiments, the hedonic assessments shifted from negative to less negative or even to positive values and this was interpreted as extinction of neophobia. Simultaneously, the number of activated pixels increased. What was impressive, albeit unexpected, was the exact parallel between the evolution of hedonics and of the number of activated voxels at the individual level (Faurion et al., 1998, 2002).

### 35.3.4 Affective Coding of Taste

The affective value of a taste depends upon numerous factors, including its perceived intensity, quality, and familiarity, and the subject’s internal state, beliefs, expectations, and prior experience (Veldhuizen et al., 2008). As such, computation of the perceived pleasantness of a taste requires sensory, homeostatic, reward, cognitive, and learning circuits. Viewed in this light, perceived pleasantness must be an emergent property of the interaction, not only of particular brain regions, but also of whole brain networks. Indeed there is clear evidence that the value of taste and flavor relies upon contributions from many different systems, including systems involved in beliefs about brand or price (McClure et al., 2004; Passamonti et al., 2009), intensity (Nitschke et al., 2006), and uncertainty (Bjørns et al., 2001), as well as gut hormones (Malik et al., 2008). However, studies examining these disparate factors converge in indicating that the perceived pleasantness of taste and flavor emerges from OFC circuits and that OFC responses can be a good indicator of subsequent behavior (Hare et al., 2009, 2011; Spetter et al., 2012). That said, it is important to keep in mind that reward is multifaceted. How one defines these facets is often debated (Berridge and Robinson, 2003; Veldhuizen et al., 2008; de Araujo, 2011; Salamone and Correa, 2012), but what is agreed upon is that they are distinct processes. For example, different regions may code anticipation vs. receipt of a pleasant taste (O’Doherty et al., 2002). Also relevant is the fact that there are numerous individual factors that influence responses in classic reward regions during taste and flavor stimulation such as obesity (Stice et al., 2008a; Stice et al., 2008b; Green et al., 2011), genotype (Felsted et al., 2010; Stice and Dagher, 2012), smoking status (Geha et al., 2012), dietary composition (Rudenga and Small, 2011; Burger and Stice, 2012; Green and Murphy, 2012), a history of chronic stress (Rudenga et al., 2012), or a history or presence of an eating disorder (Wagner et al., 2008; Frank et al., 2012). Here we focus on the role of the OFC as the site of convergence of the relevant signals and its role in representing taste pleasantness and unpleasantness.

Zald and Pardo were the first to investigate brain responses to aversive vs. pleasant tastes and flavors (Zald et al., 1998). A concentrated saline solution represented the aversive stimulus and a 3 g piece of Hershey’s Symphony Chocolate (Hershey’s, Hershey, PA., USA) represented the pleasant stimulus. Greater responses were observed to saline vs. chocolate in the pregenual cingulate cortex, motor cortex, insula, OFC, and amygdala, prompting the authors to conclude that these regions were particularly sensitive to aversive stimuli. However, a subsequent study comparing brain responses to saline vs. glucose solutions observed similar responses when subjects tasted unpleasant saline and pleasant glucose in the OFC, insula, operculum,

amygdala, anterior cingulate cortex, anterior temporal lobe cortex, and inferior prefrontal cortex (O'Doherty et al., 2001). The only region showing valence-specific responses was the OFC, where overlapping as well as distinct responses to the two tastants were observed. The authors concluded that pleasant and aversive tastes were represented in the amygdala and OFC.

In support of this conclusion are the results of Small and colleagues who designed a study to dissociate brain response to intensity and pleasantness perception of taste (Small et al., 2003). Subjects first rated the perceived intensity and pleasantness of a series of sucrose and quinine solutions. Only those individuals who gave ratings in a pre-defined target range were included in the neuroimaging experiment that assessed brain response to four stimuli: weak sucrose, strong sucrose, weak quinine and strong quinine. Critically, the affective intensity of the stimuli was matched so that the sweet tastes were rated as pleasant as the bitter tastes were rated unpleasant. In addition, the strong solutions were rated as similarly strong in intensity, and the weak solutions as similarly weak. Response to the weak and strong pleasant sucrose vs. a tasteless control stimulus was observed in the putamen, claustrum, hypothalamus, thalamus OFC, subcallosal cingulate cortex, anterior cingulate cortex and anterior ventral insula. Response to the weak and strong unpleasant quinine was observed in the midbrain, hypothalamus, claustrum, insula/operculum, anterior OFC, medial prefrontal cortex, subcallosal cingulate cortex and ventral lateral prefrontal cortex. Directly contrasting the pleasant vs. unpleasant tastes resulted in valence-specific responses in the OFC, with the left anterior OFC responding preferentially to the unpleasant taste and the right caudolateral OFC responding preferentially to the pleasant taste (Figure 35.4). As mentioned in the section on intensity coding, both effects were independent of intensity. In contrast, response in the amygdala was observed to the strong stimuli compared to the weak stimuli. The authors therefore proposed that responses in the amygdala may reflect stimulus saliency, which could be determined by affective value, intensity or familiarity, whereas responses in the OFC reflected affective value. Consistent with this possibility, in the Zald and Pardo (1998) study, the saline was rated as highly intense, whereas the chocolate was rated as only moderately intense, raising the possibility that differences in intensity or saliency rather than perceived pleasantness drove differential brain responses.

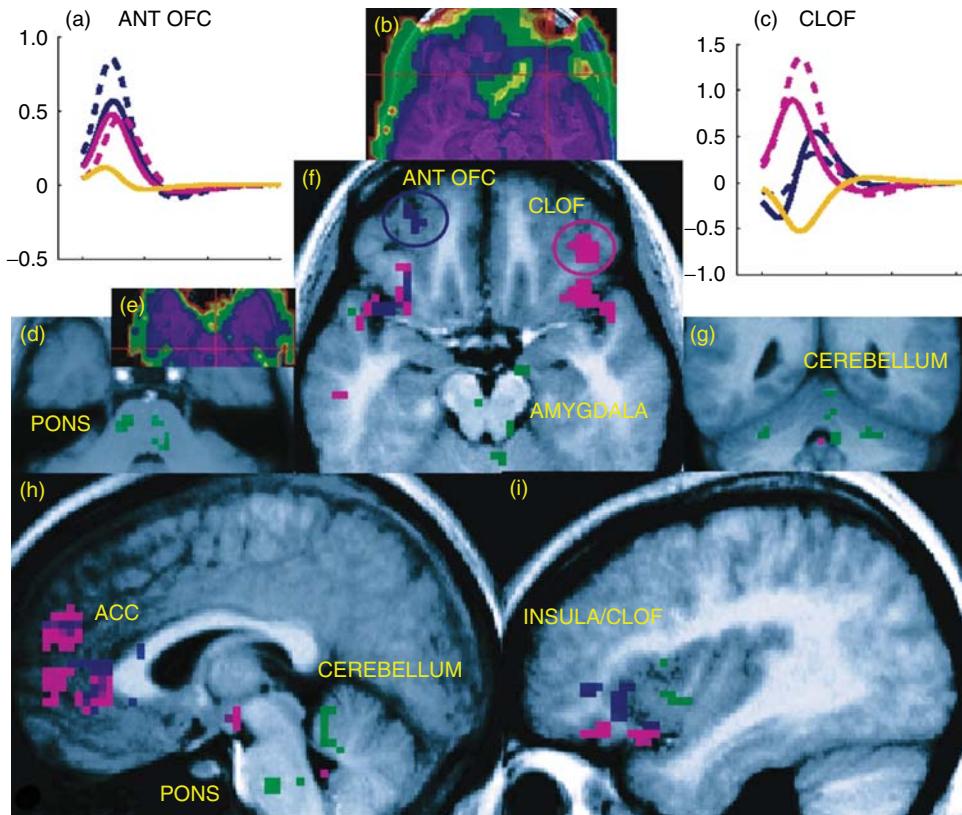

The perceived pleasantness of a taste can also be modulated by changes in internal state, a phenomenon termed alliesthesia (Cabanac, 1971). Consistent with reports in primates (Critchley and Rolls, 1996), response in the OFC to the consumption of pure taste (Haase et al., 2009), and flavors (Small et al., 2001a; Kringlebach et al., 2003; Smeets et al., 2006) is attenuated by feeding to satiety and positive correlations are observed between changes in

rated pleasantness produced by feeding and responses in the OFC. These studies also report associations between pleasantness ratings and/or internal state manipulations in other regions including the insula, hypothalamus, thalamus, hippocampus, parahippocampus, amygdala and midbrain, consistent with the idea that signals from reward and homeostatic circuits contribute to orbital computation of pleasantness. Finally, it is clear that OFC attenuation by feeding is not just a generalized effect of internal state, but relates specifically to the devaluation of the sensory properties of taste, since response is modulated significantly more if subjects are sated on food related to the taste or flavor (Kringlebach et al., 2003), a phenomenon termed sensory specific satiety (Rolls et al., 1981).

There is also evidence that simply evaluating pleasantness, as opposed to other dimensions of taste, can engage orbital circuits (Bender et al., 2009; Grabenhorst and Rolls, 2010). As mentioned above, tasting MSG while attending to pleasantness produces greater medial OFC responses than does tasting MSG while attending to intensity. It may also be the case that a taste stimulus is not required for this engagement. Bender and colleagues reported that the caudolateral OFC responds to taste (sucrose, citric acid and NaCl) and tasteless solutions preferentially when subjects evaluate tastant pleasantness compared to stimulus presence or quality. However, greater connectivity between the caudolateral OFC and earlier gustatory relays (caudomedial OFC and anterior insula) was observed when subjects judged pleasantness and sampled tastants as opposed to the tasteless solution. It was therefore suggested that the lateral OFC organizes the retrieval of gustatory information from earlier relays in the service of computing perceived pleasantness or unpleasantness (Bender et al., 2009).

Also of note, is the potent influence of beliefs and expectations on the perceived pleasantness and brain encoding of taste and flavor. For example, when subjects are inaccurately lead to believe that a taste is the weaker of two bitter solutions they rate it as less unpleasant and show reduced responses in the insula and operculum compared to when they sample the same bitter stimulus and are accurately told that it is the stronger bitter taste (Nitschke et al., 2006) (Figure 35.5). Moreover, activation in the rostral anterior cingulate cortex, the OFC, and dorsal prefrontal cortex to the misleading cue predicts decreased response in the insula and amygdala to the aversive taste (Sarinopoulos et al., 2006). These data suggest that these regions can modulate insular coding of taste based on expectation to alter perceptual experiences of intensity and aversion.

In addition, a region of anterior ventral insula has been identified where overlapping responses to pleasant and unpleasant oral stimulation occur but preferential connectivity with the hypothalamus and ventral striatum occurs when the oral stimulus is potentially nutritive (sweet or salty) compared to potentially harmful (bitter or burn)

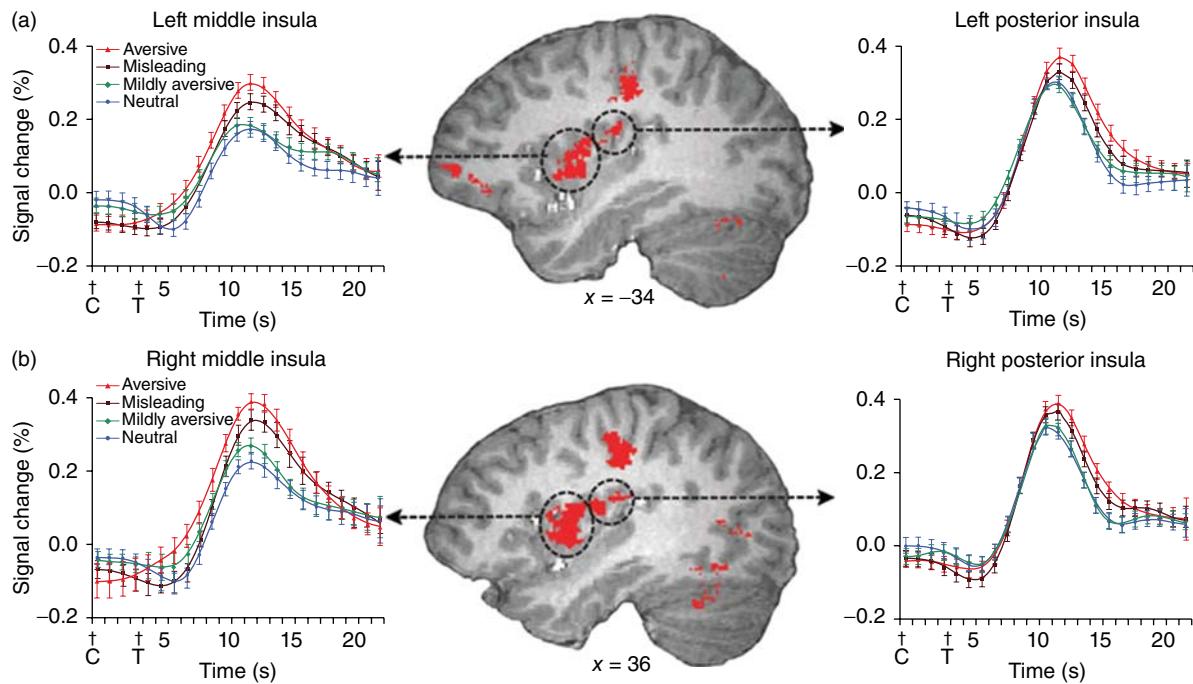

**Figure 35.4** Dissociation of taste intensity and affect. Results from the three main random effects analyses color coded and superimposed on the group mean image (d, f, g, h, and i) (green, intensity  $[(IP + IUP) - (WP + WUP)]$ ; magenta, pleasant  $[(IP + WP) - \text{tasteless}]$ ; blue, unpleasant  $[(IUP + WUP) - \text{tasteless}]$ ). The activations highlight the dissociation between areas responsive to both concentrations of pleasant (magenta) or unpleasant (blue) taste versus those areas responsive to intensity irrespective of valence (green). Note the lack of intensity activation (green) throughout the orbitfrontal cortex (f) and anterior cingulate cortex (ACC) (h). Activation related to either pleasant (pink) or unpleasant (blue) taste is seen extending from the orbitfrontal cortex into the anterior ventral insula (i). In contrast, only activation related to intensity is observed in the middle insula (i), amygdala, pons (d), and cerebellum (g). The right graph (a) displays the fitted hrf extracted from the anterior orbitfrontal cortex region (ANT OFC) corresponding to the circled blue activation in the same representative subject (y axis, response; x axis, peristimulus time with each line indicating a 5 s interval). As per Figure 35.3, blue solid line, IUP; blue dotted line, WUP; magenta solid line, IP; magenta dotted line, WP; and yellow line, tasteless. Note that the response is greatest for WUP, illustrating that valence and not intensity drives the response in this region. The right graph (c) displays the fitted hemodynamic response function (hrf) extracted from the caudolateral orbitfrontal corresponding to the circled magenta activation in a representative subject (y axis, response; x-axis, peristimulus time with each line indicating a 5 s interval). In (b), the BOLD detectability map for the orbitfrontal cortex is presented (Parrish et al., 2000), indicating that we are able to detect a 0.5%–1% signal change throughout a large portion of orbitfrontal cortex, although signal dropout is still evident within the caudomedial region. Purple indicates ability to detect a 0.5% signal change; blue, 1%; green, 2%; and yellow, 4%. The crosshatch is centered on the right caudolateral orbitfrontal cortex corresponding to the peak identified in  $[(IP + WP) - \text{tasteless}]$ , which is activated to pleasant compared to unpleasant taste irrespective of valence. In (e), the BOLD detectability map is displayed for the brainstem, showing that we are able to detect greater than 0.5% signal change throughout this region. Reprinted from Small et al. (2003) with permission from Elsevier. (See plate section for color version.)

(Rudenga et al., 2010). This suggests that interactions between the anterior ventral insula and the hypothalamus and striatum are important for integrating sensory signals with homeostatic and affective circuits to guide feeding.

Misleading subjects about the identification of a taste can also alter responses, not only in the insula and operculum but also the thalamus, ventral striatum, OFC, anterior cingulate cortex, inferior frontal gyrus and intraparietal sulcus (Veldhuizen et al., 2011b). In all of these regions

response to sucrose and tasteless solutions are greater if individuals believe they will receive a sweet solution but instead receive a tasteless solution, or if they believe they will receive a tasteless solution but instead receive a sweet solution compared to when they receive the solution they are expecting. This suggests that unexpected oral stimulation results in an up-regulation of sensory, attention and reward regions to support the orientation, identification and learning about salient stimuli. Unfortunately, perceived

**Figure 35.5** (a,b) The left and right insula and operculum clusters shown here were also more strongly activated by the highly aversive taste following the highly aversive cue than by the same taste following the misleading (mildly aversive) cue. Time courses illustrate mean percent signal change across all time points of the trials in each of the four conditions: highly aversive taste following aversive cue (red), highly aversive taste following misleading mildly aversive cue (brown), mildly aversive taste following mildly aversive cue (green) and neutral taste following neutral cue (blue). The onset of the 2-s cue (C) preceded delivery of the tastant (T) by 2–5 s. Error bars are for confidence intervals (95%) around the mean after adjusting for between-subject variance. Reprinted from Nitschke et al. (2006) with permission from the Nature Publishing Group. (See plate section for color version.)

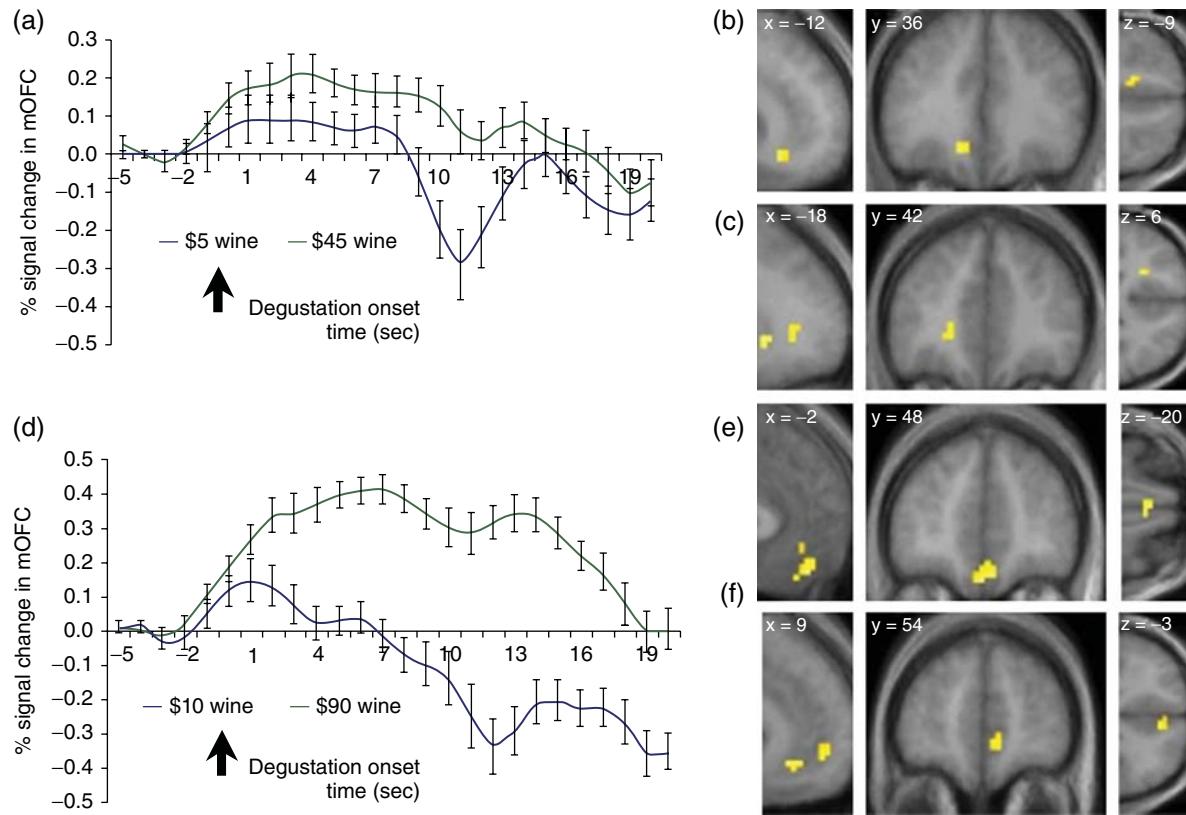

pleasantness was not evaluated so it is unclear how these modulations are related to affective value.

More complex cognitive manipulations can also dramatically alter perceived pleasantness and brain responses. McClure and colleagues delivered Coke and Pepsi to subjects in behavioral taste tests and during fMRI (McClure et al., 2004). When the brand was anonymous they found a positive correlation between response in the ventromedial prefrontal cortex and subjects' behavioral preferences. In contrast, when the brand was revealed, preferences changed to reflect the preferred brand and associations with preference were observed in the hippocampus, dorsolateral prefrontal cortex, and midbrain, rather than in the ventromedial prefrontal cortex. In another study, brain responses and the perceived pleasantness of wine were manipulated by providing accurate and fictitious information about price. Subjects sampled three Cabernet Sauvignon wines and a tasteless solution. The wines were administered in random order with the appearance of a price identifier. Unbeknownst to the subjects, two of the wines were administered twice, once identified by their actual retail price and once by a 900% mark-up (\$5 retail vs. 45\$ fictitious) or 900% mark-down (\$90 retail, \$10 fictitious). Greater responses were observed to the same

wine when sampled at the high vs. low price in a large network of regions that included (among others) the medial OFC, ventromedial prefrontal cortex, and dorsolateral prefrontal cortex. Strikingly, in the medial OFC the magnitude of the BOLD responses reflected the magnitude of the price differential; there were larger differences for \$90 vs. \$10 than for \$45 vs. \$5 (Figure 35.6). Moreover, price similarly influenced perceived pleasantness, which also correlated with medial OFC response (Plassmann et al., 2008).

Finally, activation in the anterior inferior insula (mostly left) and the adjacent frontal operculum was shown for disgust resulting from tasting a bitter tastant or from looking at someone tasting and experiencing disgust or by imagining being disgusted. This shared region was connected to distinct and diverging functional circuits allowing different emotional reactions to these different situations (Jabbi et al., 2008).

Collectively these studies indicate that beliefs and expectations exert powerful influences upon gustatory and flavor information processing and resulting perceptions of affective value. They also converge in highlighting a role for the OFC and insular cortex in computing perceptions of the pleasantness and unpleasantness of gustatory stimuli.

**Figure 35.6** The effect of price on each wine. (a) Wine 1: averaged time courses in the medial OFC voxels shown in b (error bars denote standard errors). (b) Wine 1: activity in the mOFC was higher for the high- (\$45) than the low-price condition (\$5). Activation maps are shown at a threshold of  $P < 0.001$  uncorrected and with an extent threshold of five voxels. (c) Wine 1: activity in the vmPFC was also selected by the same contrast. (d) Wine 2: averaged time courses in the medial OFC voxels shown in e. (e) Wine 2: activity in the mOFC was higher for the high- (\$90) than for the low-price condition (\$10). (f) Wine 2: activity in the vmPFC was higher for the same contrast. Reprinted from Plassmann et al. (2008) with permission. (See plate section for color version.)

## 35.4 CONCLUSION

In humans, taste information travels from receptors in the oral cavity to the cortex in a predominantly ipsilateral projection. The human gustatory neuroaxis appears to closely parallel the monkey pathway, with the bulk of evidence suggesting that primate evolution has favored the omission of the PBN relay. However, such a profound divergence in mammalian evolution is surprising and this question has not received the intensive interrogation it deserves given its potential importance. Although functional neuroimaging techniques are not without their weakness, one distinct advantage is the ability to examine whole brain responses to savoring stimulation. It is this advantage that has enabled human imaging studies to determine that a far larger region of insula and overlying operculum is devoted to gustatory functions than previously suspected based upon electrophysiological work. The possibility of functional specialization within the distinct sub-regions of the insula and operculum is still under investigation. Also elusive,

due in part to the spatial and temporal limitations of human neuroimaging techniques, and in part to the difficulty of dissociating quality and physiological significance, are the neural correlates of taste quality in humans. However, clinical work suggests that interactions between amygdala and insula may be important. What is clear is that many of the insular/opercular taste regions are sensitive to experience, stimulus concentration, and to top-down modulation with some indication that these factors can interact to influence perceived pleasantness. Also established is the interaction between insular sensory coding and homeostatic and affective circuits. This is particularly evident in the anterior ventral insula, which is likely where flavor perceptions begin to emerge (Small, 2012). Key nodes of the gustatory network beyond the insula and operculum are the amygdala, the caudomedial and caudolateral OFC, and the subcallosal and anterior cingulate cortex. These regions play a role in establishing the value and saliency of gustatory sensations based upon stimulus features, internal state, beliefs and expectations.

## The Ontogeny of Taste Perception and Preference Throughout Childhood

CATHERINE A. FORESTELL and JULIE A. MENNELLA

### 36.1 INTRODUCTION

The study of the ontogeny of human taste perception has been the focus of scientific investigations for more than a century (as summarized in Table 36.1). From this knowledge base, we now know that humans are born with a well-developed peripheral taste system—a taste system that, by the last trimester of pregnancy, is capable of conveying information to the central nervous system. This information is made available to brain structures critical for organizing a variety of consummatory (e.g., intake) and reflex-like (e.g., facial expressions) behaviors; (see Ganchrow and Mennella, 2003, for an earlier review). Clearly, taste plays an important role in determining whether a foreign substance should be accepted or rejected, and informs the gastrointestinal system about the quality and quantity of the impending rush of nutrients (Egan and Margolskee, 2008; Sclafani, 2007). Although the taste system involves innate responses, these responses change and mature throughout childhood, as will be described in this chapter (e.g., Cowart, 1981; Mennella et al., 2010b; Stein et al., 1994).

The sense of taste has taken on great interest in recent years because it is a major determinant of the food acceptance patterns of children (Birch 1998). Thus, our accumulating knowledge about taste plays an important role in understanding the basis for food choices in children. Although the modernization and industrialization of the

food supply have produced many benefits, diets rich in sugars and salt and low in fruits and vegetables have become increasingly commonplace, thereby producing unanticipated consequences. For example, excessive intake of foods containing high amounts of salt or sugars (and, consequently, foods that taste salty and sweet) causes or exacerbates a number of illnesses, including hypertension, diabetes, and metabolic syndrome (Mokdad et al., 2004). Reduced intake of fruits and vegetables increases the risk of a number of chronic diseases, including cardiovascular diseases and certain cancers (Knai et al. 2006). Because eating vegetables as part of an overall healthy diet can aid in weight management for children and adults (Blanck et al., 2008; Lakkakula et al., 2008; McCrory et al., 1999), their reduced intake likely contributes to the obesity epidemic.

In this chapter, we focus on the approaches and discoveries that have contributed to our current knowledge of human development of the five “basic” tastes of sweet, sour, salty, bitter, and umami (savory) and the impact they have had on our understanding of the sensory world of children. This review is not meant to be representative of all research conducted to date; rather, it highlights the breadth of methodologies employed, the convergence of findings, and extant gaps in knowledge. Although a detailed treatment of taste anatomy is beyond the scope of this chapter, we begin by providing an overview of the mechanisms underlying taste sensations and when they emerge during development.

## 36.2 THE ONTOGENY OF TASTE PERCEPTION

*Taste*, or *gustation*, refers to the sensation that occurs when chemicals stimulate taste receptors located on a large portion of the tongue's dorsum and other parts of the oropharynx, such as the larynx, pharynx, and epiglottis. *Flavor*, in contrast, is elicited by a combination of tastes and odors experienced orthonasally and retronasally while consuming substances. Taste is initiated at taste receptors, which are localized in taste buds and are innervated by branches of three cranial nerves: the facial (VIIth), glossopharyngeal (IXth), and vagal (Xth) nerves. The taste stimuli that interact with these receptors are often separated into a small number of "primary" taste qualities: sweet, salty, bitter, sour, and umami.

Contemporary knowledge about the development of the five basic taste qualities stems from research that has examined receptor morphogenesis and functional maturity (for review, see Bradley and Mistretta, 1975; Cowart et al., 2004; Ganchrow and Mennella, 2003). Early research conducted in this area revealed that taste buds begin to emerge throughout the oral cavity, including the dorsal surface of the tongue, palatoglossal arches, palate, posterior surface of the epiglottis, and posterior wall of the oropharynx, just 8 weeks after conception. By 13 weeks, taste buds begin to resemble those of the adult and are found throughout the oral cavity (Bradley and Mistretta, 1975; Bradley and Stern, 1967; Hersch and Ganchrow, 1980; Witt and Reutter, 1996; 1998). Taste pores, which provide access for tastants to interact with taste bud receptor cells, are generally considered as markers of functional maturity (Mistretta, 1972). Such pores have been identified in fetal fungiform papillae before the end of the fourth month (Witt and Reutter, 1996; 1998). At birth, the newborn infant is endowed with a rich population of gustatory receptors associated with such pores.

It is probably not a coincidence that the timing of these developmental changes corresponds to the emergence of fetal sucking and swallowing behavior. Ultrasound studies have revealed early development of swallowing and oral sensorimotor function at approximately 15 weeks gestational age (Miller et al., 2003; Ross and Nijland, 1997). By term, infants are actively swallowing between 500 and 1000 ml/day of amniotic fluid (Pritchard, 1965; Ross and Nijland, 1997). This not only represents a major route of amniotic fluid absorption but also serves to stimulate the taste buds and influence their synaptic connections. The chemosensory composition of the amniotic fluid is in constant flux throughout pregnancy, especially once the fetus begins to urinate, exposing the newly developed taste buds to varying concentrations of a variety of chemicals, including sugars, sodium and potassium salts, various acids

(Liley, 1972), and flavors from the mother's diet (Mennella et al., 1995; Mennella et al., 2001).

## 36.3 RESEARCH APPROACHES AND METHODOLOGIES

Table 36.1 presents an extensive summary of studies of taste sensitivity and preference during development, organized by taste quality, age group, and methodology. A variety of psychophysical methodologies have been employed to assess taste perception and preference throughout infancy, childhood, and adolescence. The method chosen depends on the objective of the study as well as the age (and, in turn, cognitive and language abilities) of the participants under study. These psychophysical studies on taste provide data relevant to two separate aspects of sensation: (1) the *sensitivity* of the system to chemical stimuli and (2) the *hedonic valence*, or pleasantness, of the sensation (Cowart, 1981; Cowart et al., 2004).

For preverbal children, the tools used often focus on reflex-like responses (e.g., salivation, sucking, heart rate, or orofacial responses) or consummatory responses. Interestingly, many of the experimental paradigms for this age group are similar to those used in animal studies (Berridge and Kringelbach, 2008; Boughter and Bachmanov, 2007; Glendinning et al., 2002; Grill and Norgren, 1978; Spector et al., 1981; Steiner et al., 2001). Because virtually all of these measures can be associated with acceptance or rejection, they presumably involve a hedonic component. As a result, sensitivity and hedonics are difficult to distinguish in animals and in nonverbal infants (Cowart et al., 2004).

For older children, a variety of methodological tools have been used, which vary according to their language and cognitive development. Measures of sensitivity include threshold detection and suprathreshold scaling procedures, while hedonic measurements include ratings or ranking of stimuli. Several of these sensory methodological tools have been published in standard guides (ASTM International, 2003) and review articles (Popper and Kroll, 2005) and often are modifications of methods used in adult populations. However, the validity and reproducibility of many of these procedures have not been assessed for children.

Findings from this expanding collection of methodological tools are remarkably consistent across studies and laboratories throughout the world. In the sections that follow, we review the methodologies used with children of different ages and highlight findings that support the hypothesis that behaviors associated with gustatory function are robust during early development and contribute significantly to adaptation and survival of the developing infant and child.

## 36.4 TASTE SENSITIVITY IN THE FETUS

A key question in the ontogeny of taste perception is whether function is present prior to birth. As summarized in Table 36.1, two approaches have been used to answer this important question: (1) indirect observations of the fetus and (2) direct observations of premature infants. Although the response of human fetuses to taste has never been directly investigated, indirect evidence from studies in fetuses together with findings from studies in premature infants, suggests that prenatal monitoring of some taste stimuli is possible during late gestation. Moreover, as alluded to earlier in the chapter, the fetus is exposed to a unique chemosensory environment prior to birth (for review, see (Mennella, 2007).

There are two reports of increased fetal swallowing following the injection of sweet stimuli such as saccharin into the amniotic fluid of pregnant women (DeSnoo, 1937; Liley, 1972). Decreased swallowing has been noted following analogous injection of bitter-tasting poppy seed oil (Liley, 1972). Such findings provide indirect evidence that the fetus is capable of tasting and differentially responding to bitter- and sweet-tasting substances.

Stronger evidence that the fetus can respond to taste stimuli comes from research on premature infants. To overcome methodological limitations caused by premature infants' immature suck-swallow coordination, innovative methods have been developed that avoid the risk of fluid aspiration. These include brief, intermittent presentations of small quantities of tastants (sometimes on absorbent cotton) directly into the oral cavity (Eckstein, 1927; Tatzer et al., 1985) and embedding tastants in a nipple-shaped gelatin media that release small amounts of tastants during mouthing or sucking (Maone et al., 1990). By measuring the strength, length, and latency of nonnutritive sucking to these tastants relative to a control, such as water, researchers have been able to infer sensitivity to, and preferences for, various tastants. This body of research revealed that newborns delivered preterm and tested postnatally produced stronger and more frequent sucking responses when offered a sucrose-sweetened nipple compared to an unsweetened gelatin-based nipple (Maone, Mattes et al., 1990), or to drops of sweetened solution compared to water (Tatzer, Schubert et al., 1985).

When small amounts of bitter or sour tastants were placed directly on the tongue of preterm infants, differential responding has been observed. Eckstein (1927) found, for example, that various concentrations of bitter-tasting quinine retarded sucking in most of the infants he studied, whereas a drop of pure lemon juice increased reflex salivation that was accompanied by increases in sucking vigor and, in some cases, retching. Taken together, this body of research suggests that by the last trimester, humans

have a well-developed taste system capable of detecting and hedonically responding to sweet, bitter, and sour tastants.

## 36.5 TASTE SENSITIVITY AND PREFERENCE DURING INFANCY

### 36.5.1 Sucking and Consummatory Responses

Sucking and ingestive responses have been successfully used to study patterns of responses that occur as a function of individual and age-related differences in taste perception and preferences throughout infancy (summarized in Table 36.1). Methods include delivering small quantities of taste solutions (1–2 ml) applied directly to the tongue (Crook and Lipsitt, 1976; Crook, 1978), embedding tastants in a gelatin-based nipple (Maone et al., 1990), or providing brief (30–180 s) access to multiple bottles in succession which contain various taste or diluent solutions (Beauchamp et al., 1994; Beauchamp et al., 1986; Beauchamp and Moran, 1982; Beauchamp and Pearson, 1991; Kajuira et al., 1992). One can infer that the infant can detect the tastes, and to some extent that they prefer the taste solution (e.g., sweetened water) more than the diluent (e.g., water), if they consume more from the bottles that contain the taste solution than from those that contain the diluent solution (Beauchamp et al., 1986; Desor et al., 1973). Consistent with the findings for premature infants, research has repeatedly demonstrated strong acceptance of sweet-tasting sugars by the newborn. Within days after birth, they can not only detect dilute sweet solutions, but can also differentiate varying degrees of sweetness and different kinds of sugars (Desor et al., 1973). These findings converge with physiological findings that sweet tasting stimuli administered to newborn infants produced greater relative left-sided activation in both frontal and parietal regions of the brain, which is considered to be a reliable indicator of positive emotion (Fox and Davidson, 1986).
