The early studies of Desor, Maller, and colleagues (Desor et al., 1975b; Maller and Desor, 1973) found that newborns did not differentially consume bitter and sour solutions relative to water. Thus, it was not clear whether newborns failed to detect the taste solution or were indifferent to it. This conundrum was overcome by adding sugar to the diluent making it slightly sweet (0.07 M), raising its baseline ingestion above that of water, which is typically aversive to newborns. When citric acid was added to this weak sweet diluent, consumption of the solution was reduced, indicating that the citric acid could be detected and was aversive (Desor, Maller et al., 1975). However, they did not differentially consume a urea solution, which has a bitter taste. According to a later study, differential

consumption of urea does not occur until infants are approximately 2 weeks of age, at which point they began to reduce their consumption of urea in a sweetened solution relative to the sweet diluent alone (Kajurira et al., 1992).

Another example of the importance of employing an appropriate diluent for taste testing in infants can be found in the research on umami taste. The early work of Steiner (1987) revealed that babies reject umami taste (e.g., amino acid L-glutamate, 5'-ribonucleotides) in water, presumably because the addition of glutamate decreases the palatability of water solutions. However, because glutamate tends to increase the palatability of food, more recent research with infants used the same method as for older children and adults, by providing the umami taste in a soup broth (Beauchamp and Pearson, 1991; Steiner, 1987; Vazquez et al., 1982) or an infant cereal base (Mennella et al., 2009). When the umami taste was presented in these food bases, infants exhibited differential preference for umami by consuming more when glutamate was added to the diluent.

A further methodological consideration for consummatory studies is that failure to control for basic stimuli (e.g., concentration, temperature, volume, and type of diluent) and methodological parameters (e.g., degree of satiation, experience, and age of the participants) may produce data that are variable and inconsistent. Many of these issues can be resolved by using a within-subject design. Mennella et al., (2009) fed, on different days, a familiar cereal that was adulterated with D-lactose (sweet), sodium chloride (salty), urea (bitter), citric acid (sour), or monosodium glutamate (umami). The presentation order of the cereal preparations was counterbalanced across days. During each test session, which occurred at approximately the same time of day and 30–60 minutes before the next scheduled feeding, mothers fed their infants while wearing a mask and refrained from talking, thereby eliminating potential influences of their facial or verbal responses on the infants' behaviors. Infants determined the pacing and duration of the feeding, and the experimenter, who was out of view of the mother–infant dyad, ended the feeding when the infant rejected the food on at least three consecutive occasions. Results indicated that infants' consumption of the different cereals was determined to some extent by their early feeding experiences: infants who had been fed protein hydrolysate formula (a formula that tastes bitter, savory and sour due to high levels of free amino acids) ate significantly more savory, bitter, sour, and plain cereals than did those who had been breastfed or formula-fed, and in formula-fed infants who were eating table foods, intake of the cereals with each of the basic tastes reflected the types of foods they had been fed. Thus, when grouping participants for data analyses, it is important to consider their early feeding history so that differences in taste preferences will not be masked by experience-related factors.

To what extent do early experiences alter or modulate the development of sweet preferences later in life? Early feeding patterns have been shown to modulate infants' innate preference for sweet tastes. Longitudinal studies have found that babies who were routinely fed sweetened water during the first months of life exhibited a greater preference for sweetened water during brief-access tests when tested at 6 months and then again at 2 years of age (Beauchamp and Moran, 1984; 1982) compared to those who had little or no experience with sweetened water. A more recent cross-sectional study of 6- to 10-year-old children supported these findings and revealed that such feeding practices may have longer term effects on the preference for sweetened water than previously realized (Pepino and Mennella, 2005b).

For salt, the story is more complex. Unlike innate responses to the other basic tastes, differential responses to salt are not exhibited by newborns. Rather, responsibility matures postnatally. While infants younger than 4 months of age consumed moderate concentrations of salt solution (0.10–0.20 M) and water in equal amounts, those between 4 and 24 months of age consumed more of the salt solutions relative to water (Beauchamp et al., 1986; Desor et al., 1975b). Beauchamp and colleagues have argued that postnatal experience with salty tastes probably does not play a major role in this shift from apparent indifference to salt at birth to acceptance at 4 months of age. This instead may reflect postnatal maturation of central or peripheral mechanisms that underlie salt taste perception (Beauchamp and Cowart, 1985; Cowart and Beauchamp, 1990). Later research has demonstrated that infants younger than 4 months of age may not be completely indifferent to salt taste. When presented with moderate (0.17 M) and strong (0.34 M) concentrations of a salted solution relative to water at 2 months of age, they consumed significantly less of the strong salt solution relative to water, and their acceptance of both concentrations of salt was negatively associated with their birth weight (Stein, Cowart and Beauchamp, 2006).

Infants' acceptance of salty taste is also affected by prenatal experiences. Infants born to women who reported suffering from moderate to severe symptoms of morning sickness had significantly higher relative intake of salt solutions at 4 months of age than did those whose mothers reported having no more than mild morning sickness (Crystal and Bernstein, 1998). That these effects last beyond infancy is suggested by the finding that adolescents and young adults preferred higher concentrations of salt in a soup base in the laboratory, and reported significantly higher daily salt use, if either they had suffered from infantile vomiting or diarrhea themselves or their mothers had suffered from morning sickness while pregnant with them (Lesham, 1998).

Like experience with sweet, experiences with salt provide the infant with opportunities to learn about the level of

saltiness to be expected in foods. As has been observed with sweet taste, 6-month-old infants' consumption of moderate (0.17 M) and strong (0.34 M) salt solutions (Stein et al., 2012) or salted cereals (Harris, Thomas et al., 1990) can be modified by their dietary patterns once they start eating table foods. Relative to those who did not eat starchy foods, which are a significant source of sodium in infants' diets, those who ate these foods at home consumed significantly more of a solution or cereal when salt was added. Thus, it appears that although infants' hedonic responses to basic stimuli are innate, early experiences, some of which occur before birth, are important modulators of responses to these stimuli.

### 36.5.2 Orofacial Expressions

Reflexive orofacial changes of both humans and animals to tastes and flavors have also been widely studied (see Table 36.1) (Berridge and Kringelbach, 2008; Forestell and Mennella, 2012; Grill and Norgren, 1978; Mennella et al., 2009; Spector et al., 1981; Spector and Travers, 2005). Similarities between species in their facial responses to taste stimuli (as reviewed in Berridge, 1996) suggest that such behavioral responsiveness has evolved in a range of mammals and is clearly adaptive. It has been hypothesized that the small number of taste qualities evolved because of the functional importance of the perception of basic taste qualities in nutrient selection. Preference for salty, sweet, and savory tastes is thought to have evolved to attract us to that which is beneficial: salty-tasting minerals, energy-producing sugars, and vitamin- and protein-rich foods; in contrast, rejection of bitter-tasting substances may have evolved to protect mammals and other organisms from poisons, many of which are bitter (Glendinning, 1994; Jacobs, 1978).

Steiner (1973) was among the first to examine facial reactivity in detail to tastants in human infants. Evidence supporting the concept that these orofacial responses were innate and unlearned came from observations that they were present in both normal and anencephalic infants whose brainstems were intact within hours of birth and before their first postnatal feeding. In these pioneering studies, a drop of solution representing one of the basic taste qualities (i.e., sweet, sour, salty, bitter) was placed on the infant's tongue. Responses of normal and anencephalic infants were strikingly similar: when tasting sweet, their faces relaxed and they began suckling and smiling; in contrast, bitter tastes elicited gaping responses, while sour elicited squinting and lip pursing (Steiner, 1973, 1977, 1979). No facial response was evident to salt before the age of 4 months, which is consistent with findings from the consumption studies discussed above e.g., (Beauchamp et al., 1986). That normal as well as anencephalic infants demonstrated similar orofacial responses suggests that

these responses are mediated in the region of the hindbrain and not in the cerebral cortex, where voluntary movement is controlled (Steiner, 1973, 1977).

Subsequently, Rosenstein and Oster (1988) employed a more precise method of describing orofacial responses with Ekman and Friesen's anatomically based Facial Action Coding System (FACS; Ekman and Friesen, 1978). With this system, virtually any facial expression can be dissected into its constituent action units (AUs). In Rosenstein and Oster's study, the percentages of infants who emitted particular reactions, or AUs, to sweet, sour, bitter, and salt solutions were measured. When initially tasting a sweet substance, infants transiently showed negative mid-face actions, such as cheek raising (AU 6) or nose wrinkling (AU 9). This was followed by more positive and sustained responses such as facial relaxation and sucking. In contrast to the observations of Steiner and colleagues (e.g., Ganchrow et al., 1983; Steiner, 1973), this study did not find marked smile-like facial responses to the presentation of sweet tasting stimuli (AU12). In response to sour and bitter tastants, infants reacted more negatively, as demonstrated mainly by their lower-face actions. For example, while both sour and bitter solutions elicited similar upper and midface AUs (which included cheek raises (AU 6)), sour solutions elicited lip pursing (AU 18), and bitter solutions elicited gaping (AU 26 and AU 27). Although no such FACS analysis has been conducted on the newborn's response to umami taste, Steiner (1987) has reported that the presentation of umami-tasting stimuli results in facial relaxation, sucking, and smiling in infants.

In more recent studies, slow-motion video analysis (Berridge, 1996) has been used to quantify the actual number of affective reactions infants express to a taste stimulus as a measure of the valence and intensity of an affective reaction (Mennella et al., 2009). A necessary requirement of this method is the need for trained individuals (preferably certified in FACS) to analyze the video images and establish reliability between their scores, which can be time-consuming and costly. In one study, the number of AUs each infant expressed in response to sweet, sour, bitter, savory, salty, and plain cereal over the first two minutes of each feeding session was recorded (Mennella et al., 2009). Because of marked individual differences in the display of faces, the analyses focused on the total number of facial expressions of distaste made for each spoonful offered, as well as the incidence of specific facial responses such as gapes and smiles. In general, infants made more facial responses related to distaste while eating the bitter cereal than while eating the other cereals. Moreover, those who had been fed protein hydrolysate formula or breast milk, both of which are higher in glutamate content than are formulas based on cow's milk, smiled more when fed the savory cereal than did those fed milk-based formulas. The effects of early exposure to flavors appear to be particularly

persistent, lasting for several years. That is, children who were fed hydrolysate formulas as infants appear to be programmed to like not only the taste of protein hydrolysates but also the taste of foods that are more savory (e.g., chicken), sour (e.g., lemon), and bitter (e.g., broccoli) compared with children who were fed milk-based formulas (Liem and Mennella, 2002; Mennella and Beauchamp, 2002; Mennella et al., 2006; Schuett et al., 1985). These findings provide further evidence of the plasticity of the taste system such that the early diet can determine later preferences and dietary habits.

In summary, studies on orofacial responsivity to taste demonstrate that, like adults, infants can control the muscles required to express primary emotions and are thus well equipped to convey a wide range of emotional states and reactivity to tastes (Ekman and Oster, 1979). Moreover, the ability to discriminate all but one of the basic tastes (salt) is evident early in life, and infants can respond with characteristic facial responses that correspond to the hedonic valence of the taste stimulus. Thus, infants' facial expressions can provide caregivers with important information about whether they like or reject a food (Forestell and Mennella, 2007, 2012). Visually striking facial displays of gaping are readily identified by caregivers and thus provide preverbal infants with an efficient means to communicate their dislike of the taste of what they are eating.

### 36.5.3 Analgesic Responses

Sucrose acts as an opioid-receptor-dependent calming agent; thus, its ability to act as an analgesic has been the subject of extensive investigations in preterm and term infants, beginning with the early work of Blass and Hoffmeyer (1991). As demonstrated in a recently updated systematic review (Harrison et al., 2010), studies performed over the past 20 years have shown that sweet tastants can be effective in reducing spontaneous crying and pain in preterm and term infants during an array of painful procedures such as a heel lance, venipuncture, or intramuscular injections, with minimal to no side effects. In these studies, crying, and in some cases heart rate/vagal tone, sucking, and facial grimacing, was evaluated before, during, and immediately after infants received a sweetened pacifier or drops (i.e., 0.05–0.5 ml) of nutritive (e.g., sucrose, glucose, or fructose) (for review, see Stevens et al., 2010) or nonnutritive (aspartame; Barr et al., 1999) sweeteners in solutions and compared to responses of infants given unsweetened pacifiers or drops of water, respectively.

This body of research, as summarized in Table 36.1, has revealed that, in general, when a small amount of a sweet substance is placed on the tongue of a crying infant, a rapid, calming effect ensues that persists for several minutes, whereas no such response is observed when water

or an unsweetened pacifier is administered. This reduction in crying is concordant with changes in measures of other physiological reflexes, such as heart rate and orofacial responses. Sucrose has also been shown to attenuate a negative electroencephalographic (EEG) response to a painful procedure (Fernandez et al., 2003), suggesting that sucrose blocks pain afferents, which in turn diminishes stress and cardiac changes. Because noncaloric sweet substances such as aspartame mimic the calming effects of sucrose (Barr et al., 1999), and the administration of sucrose by direct stomach loading is ineffective (Ramenghi et al., 1999), it is generally accepted that afferent signals from the mouth, rather than gastric or metabolic changes, are responsible for the analgesic properties of sweet tastes. Interestingly, such effects may be also induced by some non-sweet tasting stimuli. One study found that quinine transiently decreased crying (Graillon et al., 1997), implying that in addition to positive hedonic valence, taste salience may account for initial crying reduction. It is presently unknown whether other tastes, such as salty or sour tasting agents, would produce similar analgesic effects.

## 36.6 TASTE SENSITIVITY AND PREFERENCE IN CHILDREN

The ability to reliably measure changes in the taste system throughout childhood requires a thorough understanding of developmental abilities of children at various ages so that developmentally appropriate tasks may be chosen after careful consideration of the objectives of the study and the methodological issues. There is a need for more experimental investigations of children's taste sensitivity and preference; however, a major challenge in studying children's behavioral responsivity is to identify developmentally appropriate tasks that are fun for children and that produce reliable and valid results (Mennella and Beauchamp 2008). Below we discuss some of the methodological issues to consider when designing experiments to measure taste sensitivity and preference in 2- to 16-year-old children.

When testing children, care should be taken to create a friendly and inviting atmosphere and to employ an age-appropriate experimental protocol to ensure that both the child and the parent are comfortable with the setting. Upon arrival, initial interactions with the child and parent should be devoted to developing rapport and allowing them to habituate to the testing environment. To encourage the child to engage in the testing procedure, test sessions should not begin with an unpleasant taste. It is also important to remember that children are sensitive to demand characteristics and will often alter their behavior to conform to the experimenter's expectations.

For example, children will often answer questions in the affirmative. This can be avoided by using a forced-choice categorization procedure, which requires that they choose which solution they like better (or is more concentrated), rather than indicating whether they like (or can detect) the taste of a solution. In general, experimental tasks should be embedded in the context of games that are fun for the child and minimize the impact of language and cognitive development.

Relative to older children and adults, young children have difficulties with concept formation (e.g., sweetness) and classification (e.g., like/dislike), and because of their limited linguistic skills, they may have difficulty understanding directions or the abstract nature of symbols and pictures. Therefore, prior to actual testing and after a period of acclimation, the experimenter should ascertain whether or not the child comprehends the task. Even when children understand the task, they are more prone to attention lapses and limited memory spans, which may limit their performance. For example, 3-year-old children can understand a standardized sorting task, but only about half have the attention span to successfully complete the task. Any method relying on sustained attention that places demands on memory could yield spurious findings. For this reason, it is important to establish the reproducibility of measures over time. Unfortunately, few peer-reviewed research studies have systematically determined the validity of their methods among children of varying ages (Chambers, 2005). Moreover, only a handful of studies reviewed herein include methods to assess how reproducible and stable the child's response is over time.

In the following sections, we describe the methodologies used to measure 2- to 16-year-old children's reflex-like behaviors to tastants and the behavioral tasks performed to measure their taste sensitivities and preferences. A summary of this research is provided in Table 36.1.

### 36.6.1 Reflex-like Behaviors

**36.6.1.1 Orofacial Responses.** Although studies with infants have used orofacial responses to measure differential responses to the basic tastes (Rosenstein and Oster, 1988; Steiner, 1973, 1977), fewer studies have used this approach to measure hedonic responses in older children. As children mature they learn to control and manage their facial expressions to satisfy display rules that are consistent with societal norms (Ekman and Freisen, 2003; Larochette et al., 2006). Because of such emotional masking, children's attempts to conceal or exaggerate their actual responses to particular tastes may lead to biased or inaccurate data. According to Ekman and Freisen (Ekman and Freisen, 2003), although individuals attempt to manage their facial responses, micro-expressions that reflect their true emotions often "leak" into their overall expression for

a fraction of a second. Although these microexpressions are difficult to measure, subtle changes in facial responses can be detected using facial electromyography, which measures the electrical activity of facial muscles and can detect movements that are too discrete for the eye. This procedure has been used to measure hedonic, emotional, and cognitive responses to tastes (Hu, Luo et al., 2000; Armstrong, Hutchinson et al., 2007; Armstrong et al., 2007; Epstein and Paluch, 1997; Hu et al., 1999, 2000). The three most commonly used muscles for detecting changes with EMG are the levator labii, contraction of which results in lifting of the upper lip (AU10) and wrinkling of the nose (AU9), and the corrugator supercilii, which furrows the brows (AU4). Both of these muscles respond strongly to unpleasant stimuli and poorly to pleasant stimuli. The third muscle is the zygomatic major muscle, which pulls up the corners of the lips (AU12) and responds strongly to hedonically positive and negative taste stimuli (Armstrong et al., 2007). Future research that incorporates the monitoring of facial expressions will provide important insights into children's sensitivity and liking of basic tastes.

**36.6.1.2 Analgesic Responses.** Only a few published studies have investigated whether the analgesic effect of sweet tastes extends from infancy into later childhood (Miller, Barr et al., 1994; Lewkowski et al., 2003; Pepino and Mennella, 2005b; Mennella, et al., 2010b). In order to induce pain in 8- to 11-year-old children in an ethical manner, these studies have used the cold pressor test in which participants submerge a forearm in a cold water bath (10 degrees Celsius) while holding equal volumes (15–20 ml) of water during one session or 24% sucrose solution in the mouth during another session.

Such studies have demonstrated that the pain threshold (the time in seconds at which discomfort was first indicated by raising the non-immersed hand) and pain tolerance (the number of seconds the hand was kept in the cold water) are both increased when children hold sucrose, but not water, in the oral cavity (Mennella et al., 2010b; Miller et al., 1994; Pepino and Mennella, 2005b). Interestingly, sucrose's efficacy in reducing pain threshold and tolerance was related to the hedonic value of sweet taste for the child: the more a child liked sucrose, the more tolerant the child was of the pain of the cold water while tasting sucrose (Mennella et al., 2010b; Pepino and Mennella, 2005b). Further work has demonstrated that children who have depressive symptomatology report eating more sweet-tasting foods than do those who are not depressed; however, they had similar pain thresholds regardless of whether they held sucrose or water in the mouth during the cold pressor task, demonstrating that sucrose is an ineffective analgesic for these children (Mennella et al., 2010b). Thus, it appears that depression antagonizes the analgesic properties of sucrose.

### 36.6.2 Behavioral Methodologies for Measuring Taste Sensitivity and Preference

#### 36.6.2.1 Paired-Comparison and/or Forced-Choice Procedures.

In older children, it is possible to use methods that do not confound sensitivity and hedonics. Often these methods involve forced choice, a procedure that requires respondents to compare two or more options and choose one. In taste studies with children, forced-choice procedures often involve the presentation of a series of trials that present solutions that vary in concentration of a particular tastant. Each of the solutions in the series may be presented alone, in which case the children are asked to indicate whether they can detect or like the tastant in each sample. Alternatively, each solution may be paired with another solution (e.g., the diluent, or another concentration of the tastant). In these studies children are asked to compare the solutions on each trial and to choose which they like best (preference), or which contains the tastant under study (sensitivity). In some cases, especially when the subject population consists of children younger than 5 years, this forced-choice task is embedded in the context of a game (Mennella et al., 2005; Schmidt and Beauchamp, 1988) or story (Visser et al., 2000). In general, forced-choice, paired-comparison procedures, unlike tests where the subject is required to remember sequentially presented stimuli to make relative judgments, are especially useful for young children because memory requirements are minimized. Below we highlight some examples of procedures that have utilized these methods.

Using a forced-choice procedure that was presented in the context of a game, Mennella et al. (2010a) determined children's sensitivity thresholds to 6-n-propylthiouracil (PROP). Based on the procedures of Anliker et al. (1991), children were presented, in succession, with a sample of water and then three increasing concentrations of PROP (56, 180, and 560  $\mu\text{M}$ ) and asked to taste the sample without swallowing. If the solution tasted like "water" or "nothing," then they were asked to give the sample to Big Bird, a popular television character. If the sample tasted "bad," "yucky," or "bitter," children were asked to give it to Oscar the Grouch so he could throw it in his trash can. Children were classified into groups based on the concentration of the first sample, if any, that was given to Oscar the Grouch. This research has shown that children who are heterozygous at the TASR38 gene locus are more sensitive to taste of PROP than were heterozygous adults, with the thresholds of heterozygous adolescents being intermediate (Mennella et al., 2010b), whereas homozygous children and adults did not differ in threshold. This task is one of the few that has been shown to be reliable (>85%; (Mennella et al., 2005) and valid, with 76% concordance between genotype and phenotype (Keller et al., 2010),

and is effective for children as young as 3 years of age (Mennella et al., 2010a).

In other studies, children were presented with a series of pairs of solutions, with one member of the pair being water and the other containing an aqueous tastant (i.e., paired comparisons). In some cases the aqueous tastants increased in concentration with each pair presented, and the child was required to indicate which sample of the pair contained the tastant, or tasted stronger. The lowest concentration that was detected successfully in one or two consecutive trials was recorded as the detection threshold (James et al., 1997). In other cases, the concentration of the tastant in each pair was determined by the child's ability to detect the tastant in the previous pair of samples. For example, in the staircase procedure, if the child incorrectly indicated which sample contained the tastant, in the next trial the next stronger tastant solution was presented; if the child was correct, a second presentation with the same concentration was given (Anliker et al., 1991).

A similar procedure, called the forced-choice tracking procedure, has been adapted to assess suprathreshold concentrations of tastants. In these studies, participants are instructed to taste, without swallowing, each solution and then to point to which of the pair they like better (or tastes stronger). For example, Mennella et al. (2011b) presented children with pairs of sucrose solutions that differed in concentration (3–36%). They were first presented with a pair of samples chosen from the middle range (6% vs. 24%) and were asked to taste each without swallowing and then to point to which of the pair they liked better. Like the staircase procedure described above, each subsequent pair was then determined by the subject's preceding preference choice. The procedure continued until the subject either had chosen a given concentration of sucrose when it was paired with both a higher and lower concentration or had chosen the highest (36% w/v) or lowest (3% w/v) sucrose solution two consecutive times. The entire task was then repeated with stimulus pairs presented in reverse order (e.g., weaker stimulus presented first in series 1; stronger stimulus first in series 2), thus preventing children from reaching criterion response based on bias toward first or second position. The geometric mean of the two sucrose concentrations chosen in series 1 and 2 estimated the participant's preferred level of sucrose.

By comparing the solution chosen in the first and second (reverse-order) task, one can achieve reliable results within each participant. As reviewed in Table 36.1, this procedure has been shown to be sensitive enough to examine individual differences (e.g., race, age, genetic) in sweet and salt taste preferences in children as young as 5 years of age and how differences in preferences relate to a variety of factors, including analgesia, obesity, dietary habits, and depression (Cowart and Beauchamp 1990; Mennella et al.,

2010b, 2011b, 2005; Pepino and Mennella 2005a; Coldwell et al., 2013).

**36.6.2.2 Scaling Techniques.** Various types of scaling methods, that is, methods in which sensations to varying concentrations of suprathreshold stimuli are quantified, have been used to determine children's preferences and sensitivity to tastes. Depending on the child's age, these procedures involve presenting the child with a line or other type of scale that contains pictorial or verbal descriptors in a graded order. Although there has been no systematic determination of what scaling test is most appropriate for children at what age, some researchers have concluded that use of scales in children younger than 5 years can be problematic because they have not mastered the ability to rank things in order of magnitude (Guinard, 2001).

For children as young as 3 years of age, researchers typically use hedonic rating scales. Depending on the age of the child, these scales can consist of two to nine faces where one of the anchors is a happy face and the other is a frowning face. While the increase in the number of faces potentially allows for finer-grain analyses of children's hedonic responses, preschool children do not appear to be able to reliably use scales that contain more than five faces (Chen and Resurreccion, 1996). However, little is known about the validity and reliability of these scales and at what age children begin using the entire scale rather than the anchors only.

Due to this gap in our knowledge about the use of hedonic face scales with children, researchers typically use them in combination with other measures. For example, when de Graaf and Zandstra (1999) tested the pleasantness of sucrose (0.03–0.88 M) in water and in orangeade in 9- to 10-year-old children, adolescents, and adults with a 5-point hedonic face scale, they found ratings of pleasantness correlated moderately with intake, and the strength of these correlations increased with age. The authors suggest that the increasing reliability observed with increasing age could be related to the development of cognitive capacity, which allowed older children to more consistently process and code the sensory information.

In addition to hedonic face scales, researchers have used other scales that include verbal descriptors (ranging from "no taste" to "very strong taste" (Anliker et al., 1991), and in some cases these verbal descriptors have been used with the Labeled Magnitude Scale (Coldwell et al., 2009). Here, children are shown a visual analog scale labeled with "barely detectable," "weak," "moderate," "strong," "very strong," and "strongest imaginable" and are asked to compare the intensity of each taste to oral sensations of any kind. Typically participants are trained on this scale by asking them to rate examples, including the sweetness

of cotton candy, the bitterness of celery, or biting into a raw lemon or chili pepper. Although the use of verbal descriptors appears to be effective for measuring sensitivity in 9- to 10-year-old children (Coldwell et al., 2009; Graaf and Zandstra, 1999), younger children may require a more concrete activity to visualize these descriptors. This has been done by asking children to place a ball into buckets that are placed at different heights to exemplify increasing taste intensities (Anliker et al., 1991; Turnbull and Matisoo-Smith, 2002). Despite gaps in knowledge about the reliability and validity of scaling techniques, there is some evidence that reliable results can be obtained from children if care is taken to use developmentally appropriate scales.

**36.6.2.3 Rank Order.** In rank-order methods, the goal is either to determine the child's most preferred concentration from a series of solutions, or to place all of the solutions in order of preference or stimulus intensity. In some cases children may be asked to taste all of the solutions in random order, after which they are asked to point to the one they like best (sweet preference inventory). This procedure has been used to determine whether children who chose higher concentrations of sucrose in tea have more dental caries (Jamel et al., 1997; Maciel et al., 2001a,b; Tomita et al., 1999). Their results suggest that socioeconomic status mediates the relationship between taste preference and number of dental caries in 4- to 6-year-old children (Tomita et al., 1999). However, one weakness of this methodology, which may limit the sensitivity of their results, is that children are required to remember and track a series of solutions in order to indicate their preferences, which may be difficult for preschool children.

Other approaches that are less cognitively demanding employ paired-comparison techniques in which all possible pairs of samples are presented and children are asked to choose which they prefer or which tastes stronger in each pair (e.g., Liem and Mennella, 2003). In a similar paradigm called rank by elimination, the sample that is selected from a pair in a trial is removed from the set, and children are asked to taste the remaining samples again and to point to the sample they like best or that tastes strongest. This procedure continues until a rank-order preference or intensity is established. Liem and Mennella (2003) used this procedure to determine sour preferences and sensitivity. A series of four citric acid (0.00–0.25 M) samples prepared in a gelatin base were tasted without swallowing by 5- to 9-year-old children and their mothers. They pointed to the sample that they liked best during trials of one session, and the sample that tasted most sour during trials of another session. This study demonstrated that children who showed preferences for higher sour concentrations were more likely to report that they had tried and liked sour candies compared

to those who preferred lower concentrations of citric acid in gelatin. These findings are consistent with other research that has shown that preference for sour taste is correlated with intake of fruits in infants (Blossfeld et al., 2007) and with previous consumption of protein hydrolysate formulas (Liem and Mennella, 2002) in 4- to 5-year-old children.

Other studies have used a bifurcated approach in which children are first asked to place the sample into either a “good/like” or a “bad/dislike” category. The degree to which they like the stimuli is determined using forced-choice methods, in which the children are presented with pairs of stimuli from each of the categories and asked to indicate which sample in the pair they prefer. This methodology has been used with children as young as 4 years of age to rank preferences to various foods with added sugar or salt (Sullivan and Birch, 1990), including sweetened beverages (De Graaf and Zandstra, 1999; Liem and de Graaf, 2004; Liem et al., 2004). It is important to note, however, that like the procedures previously discussed, little work has been done to validate ranking procedures with children.

#### **36.6.2.4 Stimulus Presentation Methods.**

When testing children, it is important to consider the method of presentation of the taste stimuli to the tongue. Studies in which evaluation of taste solutions were directly applied to small portions of the tongue versus the whole mouth have revealed inconsistencies in sucrose sensitivity in children relative to adults. Whereas children demonstrated high sucrose sensitivity relative to adults in local anterior regions (Temple et al., 2002b), this pattern of results was not observed when a whole-mouth procedure was used (James et al., 1997). These findings suggest that taste information may not be integrated as efficiently peripherally and/or centrally in children relative to adults. Moreover, research has shown that different regions of the tongue follow different patterns of growth throughout development: growth of the posterior region continues until approximately 15 years, whereas the fungiform-papilla-rich anterior region of the tongue attains adult size by the time children are 8–10 years of age (Temple et al., 2002a). Cessation of growth of the anterior region of the tongue by mid-childhood, however, does not mean that the anatomy and functionality of this region have reached adult levels of functioning. In a series of studies using videomicroscopy, Laing and colleagues have shown that in 8- to 9-year-old children, fungiform papillae and taste pores are smaller, papillae are rounder and more homogeneous in shape (Segovia et al., 2002), and the densities of fungiform papillae and taste buds are significantly higher compared to adults (Stein et al., 1994). As a result of the uneven pattern of growth of the tongue, care must be taken not to generalize evaluation of taste solutions directly

applied to small portions of the tongue to other regions, which may be at a different stage of anatomical growth and function. This could lead to misperceptions regarding children’s taste sensitivity.

## **36.7 IMPLICATIONS**

### **36.7.1 Children’s Different Sensory Worlds**

Findings from experimental research during the past century, and especially in the past 20 years, have revealed that age is a particularly good predictor of individual differences in taste preferences. The convergence of findings from basic research reviewed herein reveals that children live in different sensory worlds than adults, preferring sweeter and saltier (and in some cases more sour) tastes than do adults and more intensely disliking bitter tastes. There is a striking paucity of research on umami taste in children; whether there are age-related changes, as observed for the other four basic tastes, remains unknown.

Further support for the concept that such hedonic responses are innate is suggested by research that has observed neonates within a couple hours of birth before their first feeding (Rosenstein and Oster 1988; Steiner, 1987). Such responses persist throughout childhood and influence dietary behaviors. For example, children generally dislike bitter-tasting foods such as leafy green vegetables, and as a result fewer than 15% of children between the ages of 4 and 8 years consume the recommended levels of vegetables (Guenther et al., 2006). Such responses are due in part to their genotype, which is related to their acceptance of a variety of foods (e.g., broccoli, brussels sprouts, cabbage) that contain bitter-tasting moieties such as glucosinolates. However, regardless of their genotype, just as children’s responses to salt and sweet are influenced by early experiences, so are children’s responses to bitter-tasting foods. Through repeated exposure to bitter-tasting foods, and to a variety of other foods from an early age, they can learn to like the taste of these once disliked foods. This has been demonstrated in infants who have been exposed to bitter-tasting protein hydrolysate formulas throughout infancy. Relative to those infants who had been fed milk-based formulas, these infants consumed more of and showed fewer orofacial responses of distaste to a bitter-tasting food (Mennella et al., 2009). This inherent plasticity of the chemical senses, which serves to mediate the effects of genetics through maturation and experience, ensures that we are not restricted to a narrow range of foodstuffs by virtue of a few preferences for or strong aversions to foods.

Although children are also born with an innate distaste for sour tastes, for some children this initial negative

**Table 36.1** Summary of research findings on the five basic tastes during stages of development.

SWEET	Development Stage/Methodology	Outcomes	References
<b>Fetuses</b>			
<b>Consummatory responses</b>	Volume of amniotic fluid determined before and after injection of saccharin in amniotic sac.	↓ volume of amniotic fluid postinjection compared to pre-injection, suggesting ↑ intake of amniotic fluid after saccharin injections.	DeSnoo 1937; Liley 1972
<b>Reflex-like responses</b>	Sucking responses measured for 1 min after drops of sweetened solution (33% glucose) or water were placed on tongue of newborns (30–36 weeks gestational age) over 5 trials.	↑ strength and frequency of sucking to sweetened solutions relative to water. ↑ strength and frequency of sucking to sweetened solutions as trials progressed. No such increase was observed with water.	Tatzer et al., 1985
	Sucking responses measured when sweetened (30% sucrose + corn syrup) gelatin nipples and unsweetened nipples were placed in oral cavity of newborns (25–36 weeks gestational age).	↑ strength and frequency of sucking to sweetened relative to unsweetened nipple.	Maone et al., 1990
	Spontaneous crying measured relative to baseline crying when 0.1 ml/min of aqueous 10% glucose, or water was placed in oral cavity of newborns (24–36 weeks gestational age) over 5 min.	↓ crying relative to baseline in newborns that received glucose but not those who received water.	Smith and Blass 1996
	Variety of pain responses measured during and after painful procedures (e.g., heel lance, subcutaneous injection, or venipuncture) when a sweetened substance (glucose- or sucrose-sweetened water and/or pacifier), or unsweetened substance (water and/or pacifier), or no substance was present in oral cavity of newborns (24–37 weeks gestational age).	↓ pain response (e.g., crying, facial grimacing, limb movements) to sweetened relative to unsweetened or mildly sweetened pacifier or solution, or no solution.	Abad et al., 1996; Acharya et al., 2004; Bucher et al., 1995; Carbajal et al., 2002; Deshmukh and Uddani 2002; Gibbins et al., 2002; Okan et al., 2007; Stevens et al., 2005

Development Stage/Methodology	Outcomes	References
<b>Infants (newborn to 2 years)</b>		
<b>Reflex-like responses</b>		
Sucking responses measured when a sweetened gelatin nipple, drops of aqueous sucrose (2–20%), an unsweetened nipple, or drops of water were placed in oral cavity of newborn infants (24–72 h old).	↑ sucking burst length to 15% aqueous sucrose relative to 5% sucrose or water. ↓ sucking latency to all sucrose concentrations relative to water. ↑ strength and frequency of sucking to sweetened relative to unsweetened nipples.	Crook 1978; Crook and Lipsitt 1976
Sucking responses measured when two quantities of response-contingent aqueous sucrose (5%) were delivered in consecutive 4-min periods to newborns (48–72 h old). One group of infants received the larger amount (0.03 ml/suck) whereas another received smaller amounts (0.01 ml/suck) during both periods.	↑ sucking bursts and inter-burst pausing for infants feeding larger versus smaller amounts.	Crook 1976
EEG was recorded from the frontal and parietal scalp regions in newborns (2–3 days old) who were presented with water followed by a sucrose solution.	↑ left-side activation relative to right-side activation in frontal and parietal regions to aqueous sucrose compared with water.	Fox and Davidson 1986
A variety of pain responses, movement, EEG, and heart rate measured during heel lance, circumcision, or subcutaneous injection when a sweetened substance (nutritive or nonnutritive), unsweetened substance, or no substance was present in oral cavity in newborns ranging from < 1 day to 30 days old.	↓ crying, facial grimacing, heart rate, recovery time, vagal tone, and limb movements to sweetened substance than to unsweetened substance, or no substance. Effects of nonnutritive sweeteners were similar to those of nutritive sweeteners. ↑ left frontal and parietal EEG activation to sweetened substance (indicating positive emotion) relative to water.	Abad et al., 1996; Bellieni et al., 2002; Blass and Hoffmeyer 1991; Blass and Watt 1999; Bucher et al., 2000; Carabajal et al., 1999; Fernandez et al., 2003; Fox and Davidson 1986; Gradin et al., 2002; Greenberg 2002; Ramenghi et al., 1996
Orofacial responses measured when a sweet solution or water was placed on the tongue in normal and anencephalic newborn infants who were 2–96 h old.	↑ sucking-like and mouthng responses, licking, facial relaxation, smiling, and hand-mouth contact to sweet solutions but not to water in normal and anencephalic infants. (Rosenstein and Oster 1988) report that fewer infants demonstrated raised cheeks (AU 6), narrowed or tightly closed eyes (AU 43 or AU 7 + 43), nose wrinkles (AU 9), or brows raised (AU 1 + 2) and/or lowered (AU 4) to sweet solutions than to nonsweet solutions.) ↑ amplitude of mouthing responses as concentration of sweet solution increased.	Barr et al., 1999; Ganchrow et al., 1983; Graillon et al., 1997; Nowlis and Kessen 1976; Peterson and Rainey 1910; Rosenstein and Oster 1988; Steiner 1973, 1977, 1979; Steiner et al., 2001

Table 36.1 (Continued)

Development Stage/Methodology	Outcomes	References
Spontaneous crying measured relative to baseline crying when a sweet nutritive (i.e., 6%–24% sucrose, 10% glucose, 9% fructose, 17.5% lactose) or nonnutritive (e.g., 0.12% aspartame) solution or water was placed in oral cavity of infants who ranges from 1 day to 12 weeks old.	↓ crying relative to baseline for some sweet nutritive (sucrose, glucose, and fructose) or nonnutritive solutions but not for water. No change in crying relative to baseline for lactose relative to water	Barr et al., 1999; Bllass and Camp 2003; Bllass and Smith 1992; Smith and Bllass 1996; Zeitman et al., 1996
Heart rate measured when drops of aqueous sucrose (5% or 15%) or water were placed on the tongue of newborns (48–72 h old) in calm state.	↑ heart rate to 15% sucrose solution relative to 5% or water.	Crook 1976; Crook and Lipsitt 1976
<b>Consummatory responses</b>  Intake measured in newborns (1–3 days old) during brief-access (3 min) tests; bottles contained aqueous glucose, fructose, lactose, or sucrose (each ranging from 0.05 to 0.30 M) or water.	↑ intake of all sugar solutions relative to water. ↑ intake of sucrose and fructose than of lactose and glucose solutions. ↑ intake of 0.20 and 0.30 M solutions than of 0.05 and 0.10 M solutions	Desor, Maller et al., 1973
A longitudinal study measured intake in infants soon after birth (1–9 days old) and again at 6 months of age during brief-access (180 s) tests; bottles contained 0.2 or 0.6 M sucrose solution or water. Beauchamp and Moran (1984) tested a subset of these children again at 2 years of age using cups in brief-access (30 sec) tests. Cups contained 0.2 or 0.6 M sucrose or diluent (water or unsweetened Kool-Aid). Seven-day dietary records were also obtained from mothers at 6 months and 2 years.	↑ intake of sucrose relative to water in 6-month-olds and 2-year-olds who were regularly fed sugar water compared to those who were not regularly fed sugar water. Compared to intake at birth, ↓ intake of sucrose relative to water in 6-month-old infants who were not regularly fed sugar water. At 2 years of age, intake of sweetened Kool-Aid was higher than for unsweetened Kool-Aid regardless of whether they had been regularly fed sugar water.	Beauchamp and Moran 1982; Beauchamp and Moran 1984
<b>Children (2–19 years)</b> <b>Reflex-like responses</b>	↑ pain threshold to sucrose relative to water.	Mcennella et al., 2010b; Miller et al., 1994; Pepino and Mcennella 2005b
Facial EMG recorded in children (6–9 years) after placing drops of one of 8 concentrations of sucrose (0.05–1.34 M), 8 concentrations of quinine hydrochloride (0.08–2.31 M), NaCl (0.18 M), or citric acid (0.01 M) solutions or water on the posterior portion of the tongue.	↑ increased EMG activity in the zygomaticus and levator labii for sucrose relative to water. No difference in EMG responses in the zygomaticus to the four tastants, but for the levator labii, the difference in EMG activity was significantly lower for sucrose than for the other three tastants.	Armstrong et al., 2007

Table 36.1 (Continued)

Development Stage/Methodology	Outcomes	References
<b>“Add to taste” preference procedure</b> Adolescents (11–19 years) were presented two cups of tea, one sweetened with 30% sucrose and one unsweetened. After tasting the solutions in each cup, they were provided with a third cup and asked to pour one-half the unsweetened tea into this cup and then to add sweetened and unsweetened tea until the mixture was “tasty.” At the end of the session the cups were weighed to determine the sugar concentration of the final mixture. Mothers were queried about health history during focal pregnancy and the child’s history of infantile vomiting and diarrhea.	↓ concentrations of sweetened tea preferred by adolescents who experienced infantile vomiting and diarrhea, or whose mothers reported experiencing morning sickness during their pregnancy with them.	Lesham 1998
<b>Five-point hedonic face rating scale</b> Children (11–15 years) rated liking for six concentrations of aqueous sucrose (0.056–1.000 M) using a <i>five-point hedonic face rating scale</i> , ranging from smiling (extreme like), to neutral (just ok), to frowning (extreme dislike). Ratings for the two lowest concentration solutions were subtracted from those of the two highest concentration solutions. Positive difference scores were designated “high preference”; negative difference scores were designated “low preference.”	↑ levels of biomarkers for bone growth in the high-sugar preference group compared to low-sugar preference group.	Coldwell et al., 2009
<b>Sweet preference inventory</b> Children (4–15 years) tasted five sweetened aqueous solutions in random order and pointed to the solution they liked best.	Children generally preferred the higher concentrations of sucrose. Children who preferred ↑ sucrose were from lower socioeconomic backgrounds, which in turn was associated with dental caries.	Jamel et al., 1997; Maciel et al., 2001a; Maciel et al., 2001b; Tomita et al., 1999
<b>Ranking procedure</b> A cross-sectional comparison of children (9–15 years, a subset of whom were twins) and adults who sipped without swallowing concentrations of sucrose (0.075–0.60 M) or lactose (0.30–0.40 M) and then ranked them from most to least preferred.	Most-preferred level of sweetness ↑ in male than in female children. Most-preferred level of sweetness ↑ in black than in white children. Most-preferred level of sweetness ↑ in children than in adults. No significant differences between the monozygotic and dizygotic twin groups in level of sweetness most preferred.	Desor and Beauchamp 1987; Desor et al., 1975a; Greene et al., 1975

(continued)

Table 36.1 (Continued)

Development Stage/Methodology	Outcomes	References
A longitudinal study tested participants during adolescence (11–15 years) and adulthood, who sipped without swallowing four concentrations of aqueous sucrose (0.075–0.60 M) and then ranked them from most to least preferred.	↓ sucrose concentration rated highest as age increased; 50% of the children and adolescents, but only 25% of the adults, ranked the strongest sucrose concentration (0.60 M) highest.	Desor and Beauchamp 1987
<b>Two-step, forced-choice ranking procedure</b> Children (4–10 years), adolescents (14–16 years), and adults were presented five to seven concentrations of sucrose (0.03–0.88M) in water or orangeade (or six sweetened, salted, and plain foods in Sullivan and Birch (1990)). Stimuli were presented in random order, and participants were asked to categorize each using a hedonic face scale ranging from a smiling face for tastes they liked to a frowning face for tastes they did not like. After all stimuli were categorized, participants were asked to rank the beverages or foods from most preferred to least preferred within each category.	Most-preferred level of sweetness ↑ in children than in adolescents and ↑ in adolescents than in adults. Most-preferred level of sweetness ↑ in children who were repeatedly exposed to sweet foods at home. Children preferred sweetened ricotta cheese to salted or plain ricotta cheese. Preference for a sweetened novel food increased after it was repeatedly exposed at home.	De Graaf and Zandstra 1999; Liem et al., 2004; Sullivan and Birch 1990
Children (8–11 years) and adults were presented with sweetened (0.42 M added sucrose) orangeade with six concentrations of citric acid (0–0.065 M citric acid) or a sweetened (0.42 M added sucrose) yogurt with six concentrations of citric acid (0–0.17 M) in random order. Participants categorized each into categories using hedonic face scales ranging from smiling (most preferred), to neutral (just ok), to frowning (least preferred). Next, participants ranked their liking of the foods within each category. They then received repeated exposure to orangeade that contained 0.42 M sucrose and 0.02 M added citric acid over 8 days. The posttest was conducted in the same manner as the pretest.	↑ ranking for the sweetened orangeade with no added citric acid in both children and adults after the 8-day exposure period. Preferences for the sweetened yoghurt with no added citric acid did not reach significance.	Liem and de Graaf, 2004
<b>Paired-comparison, forced-choice ranking procedure</b> Children (4–7 years) and adults indicated the level of sweetness they “liked best” in pairs of five or six concentrations (0–0.93M) sucrose-sweetened beverages (apple juice or orangeade). Parents completed questionnaires that asked about their children’s consumption of sweet foods. In Liem et al., (2004) participants’ responses in this test were compared to responses in the two-step, forced choice ranking procedure as described above.	Most-preferred level of sweetness ↑ in children than in adults. Most-preferred level of sweetness ↑ in those who were exposed to sweet foods at home. In Liem et al., (2004) 5-year-olds’ and adults’ responses were consistent between procedures (76% and 87%), whereas 4-year-olds showed 61.2% consistency.	Liem et al., 2004; Liem and Mennella 2002

(continued)

Table 36.1 (Continued)

Development Stage/Methodology	Outcomes	References
<b>Paired-comparison, forced-choice tracking procedure</b> Children (5–12 years) and adults tasted pairs of aqueous sucrose solutions (3–36%) or pudding samples that varied in sweetness (13.4–36.2%) and chose the solution or pudding they liked better. Each subsequent pair contained the participant's preceding preferred concentration paired with an adjacent stimulus concentration, until the participant chose either the same sucrose concentration paired with a higher and lower concentration, or the highest or lowest concentration on two consecutive trials.	Most-preferred level of sweetness in water and in pudding ↑ in children and adolescents compared to adults. Most-preferred level of sweetness differed among children by genotypes at the TAS2R38 locus. Most-preferred level of sweetness ↑ in black children than in white children. Most preferred level of sweetness was associated with genetic variation within the TAS1R3 gene in adults but not children.	Mennella et al., 2005; 2010b; 2011b; 2012; Pepino and Mennella 2005b
<b>Forced-choice sensitivity procedure</b> Tested ability of children (8–9 years) and to detect sweet taste in binary mixtures of sucrose and salt solutions was measured. Samples were randomly ordered and consisted of sucrose concentrations (0–0.224 M) that were presented in water on eight trials and with 0.125M salt on eight trials.	Children identified both components (sweet and salty) in binary mixtures, except those containing the two lowest concentrations of sucrose. Fewer correct responses occurred with the mixtures than with sucrose alone. Similar results were found for adults.	Watson et al., 2001
<b>Two-step, forced-choice discrimination procedure</b> Children (4–5 years), were presented five concentrations of sucrose (0.22–0.29M) in orangeade in random order, and participants were asked to categorize each using a scale that visualized “most sugar” and “least sugar” by means of different numbers of sugar cubes. After all stimuli were categorized, participants were asked to order the stimuli within each category according to sweetness intensity.	While 5-year-old children were able to identify differences in sweetness across the five different sugar concentrations, 4-year-olds were not able to identify differences in sweetness across the five different sugar concentrations.	Liem et al., 2004
<b>Paired-comparison, forced-choice sensitivity procedure</b> Children (8–9 years) and adults assessed a series of 12 concentrations of aqueous sucrose solutions ( $1.17 \times 10^{-4}$ to $7.5 \times 10^{-2}$ M) paired with water, presented in ascending order, with left-right sample position randomized. Participants were instructed to indicate which of the solutions tasted stronger.	↑ sucrose detection threshold for boys than for girls. ↑ sucrose detection threshold for boys than for men and women.	James et al., 1997

(continued)

Table 36.1 (Continued)

Development Stage/Methodology	Outcomes	References
<b>Labeled Magnitude Scale (LMS)</b> Children (11–15 years) rated the intensity of six concentrations of aqueous sucrose (0.056–1.000 M) along a visual analog scale labeled with “barely detectable”, “weak”, “moderate”, “strong”, “very strong”, and “strongest imaginable”. Subjects were asked to compare the intensity of each taste to oral sensations of any kind and were given examples including the sweetness of cotton candy, biting into a raw lemon, the bitterness of celery, and biting into a chili pepper.	Children who had previously indicated that they liked lower concentrations of sucrose more than the higher concentrations (classified as low preference) using the five-point hedonic face rating scale (described above) perceived the intensity of sucrose to be higher than children who were classified as high preference. This difference was significant for three of the six sucrose solutions tested (0.056 M, 0.1 M, and 0.32 M)	Coldwell et al., 2009
<b>Time-intensity scale</b> Children (8–9 years) and adults rated the intensity and duration of sweetness over 90 s while holding sweetened water, orange drink, or sweetened custard in the oral cavity.	Children rated sweetness intensity higher and recorded shorter sweetness durations compared to adults.	Temple et al., 2002b
<b>BITTER</b>		
<b>Fetuses</b> <b>Consummatory responses</b> Volume of amniotic fluid determined before and after injection of Lipiodol (iodized poppy seed oil, a radiocontrast agent).	↑ volume of amniotic fluid post- versus preinjection, suggesting ↓ intake of amniotic fluid after Lipiodol injections.	DeSnoo 1937; Liley 1972
<b>Premterm infants (24–37 weeks of gestational age)</b> Sucking responses measured when drops of a quinine or water were placed on the tongue of newborns.	↓ sucking frequency in all but one infant.	Eckstein 1927
<b>Infants (newborn to 9 months)</b> <b>Reflex-like responses</b> Orofacial responses measured when drops of quinine or urea solutions, gentian tincture, or water were placed on the tongue of normal and anencephalic newborn infants who were 2–96 h old.	↑ Facial grimacing and gaping (AU 26 or AU 27) to bitter solutions relative to water in normal and anencephalic infants. Transient ↑ in mouthng to quinine in crying infants.	Ganchrow et al., 1983; Graillón et al., 1997; Peterson and Raney 1910; Rosenstein and Oster 1988; Steiner 1973, 1977, 1979; Steiner et al., 2001
<b>Consummatory responses</b> Intake measured in newborn to 24-week-old infants during brief-access (30–180 s) tests; bottles contained aqueous solutions of urea (0.12–0.48 M) or diluent (e.g., water, or weak (0.07 M) sucrose solution).	No differential consumption of aqueous urea relative to water, or urea in sucrose relative to sucrose alone in newborns. ↓ intake of urea relative to diluent alone in 2- to 24-week-olds.	Desor et al., 1975b; Kajura et al., 1992; Maller and Desor 1973; Schwartz et al., 2009

(continued)

Table 36.1 (Continued)

Development Stage/Methodology	Outcomes	References
Intake and facial responses measured while infants (4–9 months old) were fed urea-flavored (0.24 M) and plain cereal by their mothers in a laboratory setting.	↑ intake of bitter-tasting cereals and ↓ facial expressions of distaste in infants routinely fed hydrolyzed casein formula than among those fed breast milk or milk-based formula.	Mennella et al., 2009
<b>Children (3–19 years)</b>		
<b>Five-point hedonic face rating scale</b>	Children classified as PROP tasters gave ↓ ratings to raw broccoli and American cheese than did PROP nontasters.	Keller et al., 2002
<b>Paired-comparison, forced-choice ranking procedure</b>	Addition of a sodium gluconate significantly ↓ the perceived bitterness and ↑ the acceptance of urea and caffeine. Addition of sodium gluconate significantly ↑ the perceived bitterness and ↓ acceptance of tetralone.	Mennella et al., 2003
After a session in which children (7–10 years) were trained to understand differences in basic tastes, they were presented three bitter agents (urea (0.5 M), caffeine (0.08 M), tetralone ( $1.37 \times 10^{-4}$ M)), one pair at a time, in all possible pairs of four solutions (bitter alone, sodium gluconate (0.03 M), bitter + sodium gluconate, water) and asked to indicate which of the pair tasted more bitter during one test session and which tasted better during another.		
<b>Forced-choice sensitivity procedure</b>	Children who were heterozygous <i>TAS2R38</i> /PROP tasters perceived ↓ PROP concentrations than did heterozygous adults, and homozygous adolescents were intermediate. ↑ BMI in boys who were homozygous <i>TAS2R38</i> AA genotype/PROP non-taster relative to homozygous females. In 76% of children, <i>TAS2R38</i> genotype predicted PROP phenotype.	Keller et al., 2010; Mennella et al., 2010a, 2005
Children (3–10 years), adolescents (11–19 years), and adults (mostly mothers) were asked to taste solutions of PROP (56, 180, and 560 $\mu$ M). If the solution tasted like “water” or “nothing,” children were asked to give it to Big Bird. If the drink tasted “bad,” “yucky,” or “bitter,” children were asked to give the drink to Oscar the Grouch so he could throw it in his trash can. Participants were classified into four groups based on which was the first sample, if any, given to Oscar the Grouch. The A49P alleles of the <i>TAS2R38</i> gene were also genotyped. (In Keller et al. (2010), children were classified as tasters according whether they gave 560 $\mu$ M PROP to Big Bird or Oscar the Grouch.)	Mennella et al. (2010a) conducted PROP testing a second time on a random sample of children all of whom were sensitive to PROP; reliability was 85.7%.)	

(continued)

Table 36.1 (Continued)

Development Stage/Methodology	Outcomes	References
<b>Staircase threshold procedure</b> Sensitivity of children (3–6 and 10–11 years old) to PROP was measured with 15 samples (0.0051–3.2 mM), offered to the child with a sample of distilled water. With the <i>staircase procedure</i> , if the child incorrectly indicated which sample contained PROP, the next stronger PROP solution was presented; if the child was correct, a second presentation with the same PROP concentration was given. If two correct choices were made at this concentration, testing continued at the next weaker PROP concentration. Four to five reversals were required to complete the test. PROP threshold was defined as the mean of the last four reversals. Children's liking of seven or eight foods was also assessed. (In Anliker et al. (1991), liking for foods in those classified as PROP tasters (i.e., those with thresholds < 0.05 mmol/L) was compared with non-tasters, whereas in Turnbull and Matisoo-Smith (2002), ratings for foods were correlated with PROP thresholds.)	Children classified as PROP nontasters had ↓ thresholds for PROP than did adult nontasters. Children classified as tasters provided ↓ ratings for cheese. Children sensitive to the bitter taste of PROP were more likely to dislike the taste of raw spinach.	Anliker, Bartoshuk et al., 1991; Turnbull and Matisoo-Smith 2002
Sensitivity of children (3–6 years) to urea (3.75–3000 mM) was measured using the staircase procedure described above. The children were told a story about a goblin that makes drinks for baby goblins. A little goblin, who wanted to help make the drinks, put water in some of the bottles instead of “goblin drinks.” Children were asked to help find the goblin drink in each of the pairs. A moderate concentration of urea was presented first. To shorten the procedure for younger children, concentrations were lowered by two steps until the first incorrect response, and then always increased or decreased one concentration step. The test stopped when two incorrect responses were given on the same concentration; detection threshold was defined as the first level above this concentration.	There were no age or gender differences in sensitivity to urea. The mean detection threshold for urea was 59.4 mmol/L.	Visser, Kroeze et al., 2000

(continued)

**Table 36.1 (Continued)**

Development Stage/Methodology	Outcomes	References
<b>Suprathreshold rating tests</b> Children (5–7 years) who had already been identified as PROP tasters using the staircase procedure described above were presented 15 PROP samples (56–1800 µM) one at a time in random order and asked to rate the intensity of the solutions on a scale from 1 (no taste) to 5 (very strong taste).	Children identified as PROP tasters provided ↑ intensity ratings to the PROP solutions (i.e., perceived them to be stronger) than did PROP nontasters.	Ahliker et al., 1991
Children (3–6 years) tasted four PROP solutions (0.056 to 1.8 mM) and two samples of distilled water. After tasting each solution they were instructed to place a ball into one of three buckets that were placed at different heights to exemplify increasing taste intensities: mild, quite strong, and very strong. Intensity ratings for the strongest PROP solution (1.8 mM) and ratings for a variety of foods and beverages were analyzed.	Children more sensitive to PROP were more likely to dislike the taste of raw spinach.	Turnbull and Matisoo-Smith 2002
<b>Labeled Magnitude Scaling</b> Paper impregnated with PROP was placed on children's (10–11 years) tongues for 10 s, after which they rated its bitterness on a 10-cm scale: 0 = no sensation to 10 = most intense sensation they had ever experienced (e.g., the loudest sound they had ever heard). Those who scored > 4.2 were classified as PROP tasters.	PROP tasters were more likely to be described by their mothers as fussy eaters than were PROP nontasters.	Golding et al., 2009
<b>SALT</b> <i>Preterm infants (24–37 weeks of gestational age)</i> Orofacial responses measured when drops of salty solutions or water were placed on the tongue.	Indifference in two-thirds of the infants and rejection in one-third.	Eckstein 1927
<i>Infants (newborns to 24 months)</i> <b>Reflex-like responses</b> Orofacial responses measured when drops of salt solutions or water were placed on the tongue of newborn infants within hours of birth.	Indifference to salty solutions relative to water. Peterson & Rainey (1910) report that results were mixed; while some neonates grimaced, others exhibited contented sucking.	Peterson and Rainey, 1910; Rosenstein and Oster 1988; Steiner 1979

Table 36.1 (Continued)

Development Stage/Methodology	Outcomes	References
Sucking responses measured when drops of NaCl (0.1–0.6 M) or water were placed in oral cavity of newborn infants (46–78 h old).	↓ burst length as the concentration of salt increased.	Crook, 1978
A cross-sectional comparison of newborns' and 4- to 8-month-olds' sucking responses during brief-access (30 s) multiple-bottle tests with aqueous salt solution (0.2 or 0.4 M) or water.	↓ number of sucks to 0.2 M salt solutions than to water in newborns. ↓ number of sucks to 0.4 M salt solution than to water in newborns and 4- to 8-month-olds.	Beauchamp, Cowart et al., 1994
A longitudinal study measured sucking responses monthly in 2- to 8-month-olds during brief-access (60 s) multiple-bottle tests of salted (0.15 M) or unsalted formula.	Indifference to salted versus unsalted formula in 2- to 3-month-olds. ↓ number of sucks to salted relative to unsalted formula in 6- to 7-month-olds (presumably from sweet suppression by salt). ↑ number of sucking bursts that were shorter in duration to salted relative to unsalted formulas in 4- to 7-month-olds.	Beauchamp, Cowart et al., 1994
<b>Consummatory responses</b>		
Cross-sectional comparisons of intake of varying aqueous solutions of salt (0.10–0.40 M) or diluent (water or weak (0.07 M) sucrose solutions) in infants (newborn to 8 months) during multiple-bottle brief-access (30–180 s) tests. (Mothers in Crystal and Bernstein (1998) study were also asked to report experiences of nausea or vomiting during their focal pregnancy.)	No differential consumption of 0.1 M and 0.2 M salt solutions relative to diluent (water or weak sucrose solution) in infants < 4 months. Infants between 4 and 7 months consumed ↑ 0.1 M and 0.2 M salt solutions relative to water. Infants < 8 months of age consume less 0.4 M salt than water Infants of women who reported moderate or severe vomiting during early pregnancy showed ↑ preferences for moderate concentrations of salt solutions over water compared to infants of women who reported no symptoms.	Beauchamp et al., 1986, 1994; Crystal and Bernstein 1998; Desor et al., 1975b
Longitudinal studies measured intake of salted solutions (0.17 M and 0.34 M) or water in 2- and 6-month-olds during multiple-bottle brief-access (60–120 s) tests. Mothers reported their infants' birth weight and whether they had been exposed to starchy table foods.	Negative correlation between birth weight and acceptance of 0.017 M and 0.34 M salt solutions relative to water at 2 months but not at 6 months. ↑ intake of 0.17 M and 0.34 M salt solutions relative to water in 6-month-olds whose mothers reported that they fed their infants starchy table food.	Stein, Cowart et al., 2006, 2012
Intake measured when infants (16–25 weeks) were fed salted or plain cereal by their mothers on four separate days.	↑ intake of salted relative to plain cereal at 16 weeks. ↑ consumption of salted than unsalted cereal in younger infants than in older children.	Harris et al., 1990

Table 36.1 (Continued)

Development Stage/Methodology	Outcomes	References
Intake and facial responses measured while infants (4- to 9-months) were fed salted (0.1 M) or unsalted cereal by their mothers in a laboratory setting. Mothers reported whether their children had been exposed to table foods, and if so, which foods.	↑ intake of salted relative to unsalted cereals in infants who were eating cheese at home versus those who were not.	Mennella et al., 2009
<b>Children (7 months to 19 years)</b>		
<b>Consummatory responses</b>		
A cross-sectional study measured intake in children (7-72 months) during brief (30 s) access to multiple cups containing 0.17 or 0.34 M salt solutions or diluent (i.e., water or soup).	↑ intake of 0.17 M salt solution relative to water, but intake of 0.34 M did not differ from that of water in 7- to 24-month-olds. ↓ intake of 0.17 M and 0.34 M salt solutions relative to water in 31- to 72-month-olds. ↑ intake of 0.34 M salted soup relative to 0.17 M salted and the unsalted soup in 36- to 72-month-olds.	Beauchamp et al., 1986; Cowart and Beauchamp 1986
<b>“Add to taste” preference procedure</b>		
Adolescents (11-19 years) were presented two cups of tomato soup, one salted (3.3% w/w) and one unsalted. After tasting the soups in each cup, they were provided with a third cup and asked to pour one-half the unsalted soup into this cup and then to add salted and unsalted soup until the mixture was “tasty.” At the end of the session the cups were weighed to determine the salt concentration of the final mixture. Mothers were queried about health history during the focal pregnancy and the child’s history of infantile vomiting and diarrhea.	↑ concentrations of salted soup preferred by adolescents who had experienced infantile vomiting and diarrhea or whose mothers reported experiencing morning sickness during their pregnancy with them. Adolescents preferred ↑ concentration of salt in soup if they reported adding more salt to food.	Lesham 1998
<b>Ranking procedure</b>		
Children (9-15 years, a subset of whom were twins) and adults tasted four or five concentrations of salt in water (0.05-0.4 M) or in soup (0.025-0.10 M) and either indicated which was their favorite or ranked them from most to least preferred.	Most-preferred salt concentration ↑ for children than for adults. Most-preferred salt concentration ↑ in black than in white children. No significant differences in preference for salt solutions between monozygotic and dizygotic twin groups. Most-preferred level of salt in soup in Korean adolescents was ↑ if they frequently ate at fast food restaurants.	Desor and Beauchamp 1987; Desor et al., 1975a; Greene et al., 1975; Kim and Lee 2009

Table 36.1 (Continued)

Development Stage/Methodology	Outcomes	References
<b>Two-step forced-choice ranking procedure</b> Children (4–5 years) were presented salted, sweetened, and plain tofu and ricotta cheese in random order and asked to categorize each into hedonic categories (e.g., like, dislike) using face scales and then to rank the foods from most preferred to least preferred within each category. Children were then exposed to salted, sweetened, or plain tofu 15 times over 9 weeks. The ranking procedure was conducted two additional times throughout the exposure phase and at the end of 9 weeks.	Children initially ranked salted ricotta cheese ↑ than plain ricotta. Children exposed to salted tofu showed ↑ preference for salted tofu and ↓ preference for plain tofu. Children exposed to plain tofu showed ↑ preference for plain tofu and ↓ preference for salted tofu.	Sullivan and Birch 1990
<b>Paired-comparison, forced-choice ranking procedure</b> Children (3–7.5 years) ranked the level of saltiness they preferred in all possible pairs of samples chosen from three or four concentrations (0–0.56 M) of salt solutions or soup.	Most children preferred plain water more than salt water solutions. Most children preferred salted to unsalted soup. Most-preferred concentration of salt in soup was ↑ than typically observed with adults.	Beauchamp and Cowart 1990; Cowart and Beauchamp 1986
<b>Paired-comparison, forced-choice tracking procedure</b> Children (3–11 years) and adults tasted pairs of salted soups (0.01 M–1.00 M) and chose the sample they liked better. Each subsequent pair contained the participant's preceding preferred concentration paired with an adjacent stimulus concentration, until the participant chose either the same concentration of salt paired with a higher and lower concentration, or the highest or lowest concentration on two consecutive trials. The task was then repeated with the members of the stimulus pairs presented in reverse order. The geometric mean of the salt concentrations chosen in the two trial series provided the estimate of the child's most preferred level of salt.	Children preferred ↑ concentrations of aqueous salt than did adults. No racial differences between children were evident, nor did degree of salt exposure affect preferences.	Beauchamp and Cowart 1990
<b>Forced-choice sensitivity procedure</b> Children (8–9 years) and adults were presented 16 test trials in random order presenting sucrose solutions (0.056–0.224 M), and binary mixtures of NaCl (0.032–0.125 M) mixed with each of the concentrations of sucrose, or water, to determine if they could detect salt taste in aqueous binary mixtures of sucrose and salt.	Children identified both components (sweet and salty) in all binary mixtures except the two lowest concentrations of sucrose. Fewer correct responses occurred with the mixtures than with the single tastant. Similar results were found for adults.	Watson et al., 2001

Development Stage/Methodology	Outcomes	References
<b>Paired-comparison, forced-choice sensitivity procedure</b> Adolescents (12–13 years) were presented a three-alternative, paired-comparison, forced-choice sensitivity procedure in which each of seven aqueous salt solutions (0.86–25.6 mM) was presented in ascending order with two additional cups containing water. The participants were informed that only one cup of each triad contained a very dilute salt solution, and that the others contained just water. The lowest salt concentration that was detected successfully in one or two consecutive trials was recorded as the detection threshold.	↑ salt detection threshold in adolescents who reported liking soup.	Kim and Lee 2009
<b>Suprathreshold rating test</b> After identifying a threshold for salt using the paired-comparison, forced-choice sensitivity procedure described above, children (5–16 years) with cystic fibrosis and matched controls were presented four cups that contained the threshold concentration and four cups containing water. If the subject succeeded in accurately distinguishing the threshold solutions from the water, the procedure was repeated with the next lower salt concentration. This was continued until the participant was no longer able to distinguish the salt concentration from water, at which point the next higher concentration was deemed to be the salt concentration threshold.	Threshold concentrations of salt did not differ between children with cystic fibrosis of the pancreas and age-matched controls.	Wotman et al., 1964
	Children liked popcorn with ↑ concentrations of salt than did adults.	Verma et al., 2007

<b>Preterm infants (24–37 weeks of gestational age)</b>			
Sucking responses measured when drops of pure lemon juice or water were placed on the tongue of newborn infants.	↑ reflex salivation accompanied by apparent increases in sucking vigor and sometimes retching.	Eckstein 1927	Ganchrow et al., 1983; Peterson and Rainey 1910; Rosenstein and Oster 1988; Steiner 1973; Steiner 1977, 1979; Steiner et al., 2001
<b>Infants (newborns to 24 months)</b>			
<b>Reflex-like responses</b>	Orofacial responses measured when drops of citric acid or water were placed on the tongue of normal and anencephalic newborn infants within hours after birth.	↑ facial squinting (AU 6 + 7) and pursing (AU 18) responses to sour solutions relative to water.	Blossfeld et al., 2007; Desor et al., 1975b
<b>Consummatory responses</b>	Intake in infants (newborn and 15–20 months) was measured during brief-access tests with bottles or cups contained aqueous solutions of citric acid (0.013–0.065 M) or diluents (water, weak 0.07 M sucrose). The older infants were grouped according to their intake of these solutions. Those who consumed more of the 0.029 M or the 0.065 M solutions relative to either water or the 0.013 M solution were grouped in the high-sour group. Infants' food intake was assessed with 3-d food diaries.	No differential consumption of aqueous citric acid relative to water, but addition of citric acid to a sucrose diluent ↓ consumption relative to aqueous sucrose alone. ↑ fruit intake in infants with high sour preferences relative to those with low sour preferences.	Mennella et al., 2009
	Intake and facial responses in infants (4–9 months) measured while their mother fed plain cereal during one session and sour-flavored cereal (0.006 M citric acid added) during another. Infants' milk feeding history was recorded.	↑ intake of sour-tasting cereals in infants fed hydrolyzed casein formula compared to those fed breast milk or milk-based formula.	(continued)

**Table 36.1** (Continued)

Development Stage/Methodology	Outcomes	References
<b>Children (3–12 years)</b>		
<b>Rank-by-elimination procedure</b>		
Children (5–9 years) and their mothers were presented four concentrations of citric acid (0.00–0.25 M) in a gelatin base. They tasted without swallowing each gelatin and pointed to the one that they liked best during one session or the one that tasted most sour during another; that gelatin was then removed, and children were asked to taste the remaining three gelatins again and indicate which of the three was most preferred or tasted most sour. This procedure continued until a rank-order preference and sour intensity were established.	More than one-third of the children, but virtually none of the adults, ranked the highest concentration of citric acid in gelatin as one of their most preferred. Those children who preferred the highest concentration of citric acid in gelatin were more likely to report that they had tried and liked sour candies compared to those who preferred lower concentrations of citric acid in gelatin.	Liem and Mennella 2003
<b>Paired-comparison, forced-choice ranking procedure</b>		
Children (4–7 years) were presented six concentrations of citric acid (0–0.07 M) in apple juice and ranked the concentration of citric acid most preferred in all possible pairs of solutions. Mothers were queried about the type of formula children had been fed as infants.	Children 4–5 years old who were fed protein hydrolysate formulas preferred ↑ concentrations of citric acid in juice than did 6- to 7-year-old children fed similar formulas.	Liem and Mennella 2002
<b>Two-step forced-choice ranking procedure</b>		
Children (8–11 years) and adults were presented with six concentrations of citric acid dissolved in either orangeade (0–0.065 M citric acid) or a yogurt base (0–0.17 M) in random order and asked to categorize each into hedonic categories using hedonic face scales ranging from smiling (most preferred), to neutral (just ok), to frowning (least preferred). Next, participants ranked their liking of the foods within each category. They then received repeated exposure to orangeade that contained 0.42 M sucrose and 0.02 M added citric acid over 8 days, and posttests were conducted in the same manner as the pretest.	Children's most-preferred orangeade during pretest was similar to that observed during the posttest. Similar results were obtained for yogurt.	Liem and de Graaf 2004

<b>UMAMI</b>		
<b>Reflex-like responses</b>		
<b>Infants (newborns to 24 months)</b>		
Orofacial responses measured when drops of MSG solutions or diluent (i.e., water or soup) were placed on the tongue of normal newborn infants within hours of birth.	↑ sucking-like and mouthng responses, licking facial relaxation, smiling, hand-mouth contact to soup with MSG relative to soup alone. MSG in water did not elicit positive facial expressions relative to water alone.	Steiner 1987
<b>Consummatory responses</b>		
Measured intake of MSG solutions (0.05–0.40%) or diluent (i.e., soup, water) in 2- to 24-month-old, well-nourished and/or malnourished infants during multiple-bottle brief-access (60 s) tests.	Malnourished and well-nourished infants consumed ↑ soup containing MSG relative to soup containing no MSG. Well-nourished infants consumed ↓ aqueous MSG relative to water.	Beauchamp and Pearson 1991; Vazquez et al., 1982
Intake and facial responses were measured while infants (4–9 months) were fed glutamate-flavored (0.02 M) and plain cereal or broth by their mothers in an infant-led feeding paradigm. Infants had been routinely fed hydrolyzed casein formula or cow's milk for varying amounts of time.	↑ intake of savory-tasting cereals in infants routinely fed hydrolyzed casein formula than in those fed milk-based formula or breast milk. ↑ smiling during feeding savory-tasting cereals in breastfed infants and those routinely fed hydrolyzed casein formula than in those fed milk-based formula. ↑ acceptance of savory-tasting broth relative to plain broth in infants fed hydrolyzed casein formula for 3 or 8 months but not for 1 month.	Mennella et al., 2009; Mennella and Castor, 2012

Abbreviations: AU, action units (from Ekman and Friesen 1978) Facial Action Coding System); EEG, electroencephalogram; EMG, electromyography; PROP, 6-*n*-propylthiouracil; TAS2R38, taste receptor, type 2, member 38 (a bitter-receptor gene); TAS1R3, taste receptor, type 1, member 3 (a sweet-receptor gene); MSG, monosodium glutamate; M, molarity or moles per liter of solute.

response to sour transforms into preference by 18 months of age (Blossfeld et al., 2007). By the time children have reached middle childhood, approximately one-third display a strong preference for concentrated sour tastes (e.g., 0.25 M citric acid; (Liem and Mennella 2003). These sour preferences have been shown to be related to intake of sour-tasting foods such as fruit throughout infancy (Blossfeld et al., 2007) and childhood (Liem and Mennella 2003), as well as personality characteristics, such as sensation seeking (Urbick 2000).

### 36.7.2 Preferences Counter-adaptive to Our Modern World

Why is it that children reject the very tastes that are associated with so many healthful foods, and prefer those that are associated with high-calorie, fatty foods? From an evolutionary perspective, it has been argued that children's responses to tastes enhance survival by attracting them to foods that contain energy, minerals, and vitamins (e.g., mother's milk, fruits) during periods of maximal growth and inhibiting ingestion of potentially toxic substances, many of which are bitter. Children's innate taste preferences, which reflect their biological needs, help to explain why they like to eat the foods and beverages they do. For example, Coldwell et al., (2009) have shown that preferences for sweet-tasting foods are correlated with periods of high growth. In our modern society, this once adaptive link between sweet preference and biological need may leave children especially vulnerable to negative long-term consequences, including obesity and dental caries.

Although children's hedonic responses to the basic tastes may have once enhanced their survival, today children's predisposition to prefer sugar and salt and to avoid bitter-tasting foods, such as green vegetables, is no longer adaptive in an obesogenic environment that contains an overabundance of processed carbohydrate-rich and salty foods. Approximately a third of children more than 2 years of age are overweight (Ogden et al., 2010); this excess weight is associated with a number of serious health complications that were previously considered rare in children, such as type 2 diabetes and high blood pressure (Lee et al., 2006; Maynard et al., 2003). Given that unhealthy dietary patterns established in childhood track into adulthood (Mikkila et al., 2004), it is necessary to develop a thorough understanding of the basic biology of taste and the mechanisms involved in the development of taste and flavor preferences throughout childhood.

The innate rejection of bitter-tasting substances in children, in addition to reducing consumption of green vegetables, also plays a central role in children's hesitance to take oral medications (for review, see Mennella and Beauchamp 2008). Although many solid oral dosage forms

(e.g., pills, tablets) have the advantage of masking or encapsulating the bitter tastes of active compounds, such methods are ineffective for many children because they often cannot or will not swallow pills or tablets. Most children, at some point in their lives, are required to take medicine, which often tastes bitter, and some will refuse to take it. When children refuse to take a single dose—let alone a full course of medication—because it tastes bad to them, that bitter taste thwarts the benefits of even the most powerful drug. Thus, the main challenge of administering medicine to children is a matter of taste because drugs, by their very nature, often taste unpleasant and bitter. The unpleasant taste of a medicine is a sensory expression of its pharmacological activity—the more potent the drug, the more bitter-tasting and/or irritating it will be. And the more bitter-tasting and irritating its flavor, the more likely the drug will be rejected by children.

A recent study explored the relationship between genotype of only one of the 25 bitter receptor genes (*TAS2R38*) and medication history (Lipchock et al., 2012) and found that children younger than 10 years with at least one bitter-sensitive allele (PP or AP genotype) were more likely to have taken medicine in solid formulation than were bitter-insensitive (AA genotype) children. It was hypothesized that the resistance to taking bitter liquid formulations may be related to compliance and that bitter-sensitive children may be resistant to taking bitter liquid formulations and are more motivated to try medicine in pill form as an alternative. These findings open up another important area for taste psychophysics and genetics, suggesting that taste genetics and individual differences in bitter sensitivity could be an important factor in formulation choice and compliance in the pediatric population.

## 36.8 CONCLUSIONS

Although this area of research has enjoyed more than a century of basic research, we have many gaps in knowledge that have important implications for the health of our children. Although many developmentally appropriate methodologies and approaches have been created to test taste sensitivity and preference throughout childhood, more work needs to be done to validate and standardize these procedures across taste modalities. In some cases, the question may need to be asked several ways and the convergence of findings from different methodologies is required to give confidence to the conclusions.

While each measure has its limitations, the convergence of research findings supports the conclusion that the ability to detect sweets is evident very early in human development and that its hedonic tone changes throughout childhood. With respect to bitter, newborns respond with

highly negative facial expressions to concentrated quinine and urea, but they do not reject moderate concentrations of urea. The reason for this difference remains unclear. Newborns also reject the sour taste of strong citric acid solutions; however, at least for some children, this initial rejection transforms into a preference before two years of age. Because only a handful of studies on sour tastes have been conducted, it is not known whether there are developmental changes in sensitivity or preference for sour-tasting foods and beverages. Conclusions regarding the response to savory and salty tastes are more problematic, and further research is needed. With regard to salt taste, studies measuring intake and facial expressions suggest that the newborn infant is indifferent to and may not detect salt. However, in tests where salt has been presented within an appropriate context (i.e., soup), children younger than two years of age have shown preferences for this taste.

The bottom line is that unhealthful behaviors, such as the overconsumption of sweet and salty foods and the rejection of bitter green vegetables or unpalatable medications, are a reflection of the child's basic biology. From an evolutionary perspective, the senses that evaluate what is put into the mouth have likely evolved to reject that which is harmful and seek out that which is beneficial. In particular, rejection of bitter-tasting and irritating substances is thought to have evolved to protect the animal from being poisoned and the plant producing these chemicals from being eaten.

That being said, our biology is not our destiny; children learn through repeated experiences with various types of foods. A case in point is sweet taste. Research has shown that children learn in which contexts sugar is typically found through experience (Beauchamp and Cowart 1985; Beauchamp and Moran 1982). That is, the sensation of sweetness may be context dependent and can acquire meaning through learning. In a recent studies, children who were exposed to a sweetened orange-flavored beverage (Liem and de Graaf 2004) or a sweetened food (Sullivan and Birch 1990) over the course of eight to fifteen days exhibited a stronger preference for the sweetened beverage or food at the end of the exposure period, but not a significant preference for the sweet taste in another context (e.g. yogurt or ricotta cheese), suggesting that this learning may be context-dependent (Liem and de Graaf 2004). That is, through familiarization, children develop a sense of what should, and what should not, taste sweet (Beauchamp and Cowart 1985; Pepino and Mennella 2005a).

Such learning is not confined to sweet taste, as evidenced by studies of salt taste perception (Beauchamp, Cowart et al., 1986; Cowart and Beauchamp 1986), as well as by studies examining more complex food media such as extensively hydrolyzed protein infant formulas (ePHF), which taste bitter, sour, and savory and have unpleasant aromas (Mennella and Beauchamp 2005). In a series of randomized clinical trials, we have shown that there is

a sensitive period before 4 months of age during which experience can shift the hedonic tone to the flavor of the formula (Mennella et al., 2004; Mennella et al., 2011a). Evidence that such flavor programming lasts beyond childhood is suggested by the finding that children who were fed ePHF as infants are programmed to like the taste of not only ePHF when they are older, but also the taste of foods that are more savory (e.g., chicken), sour (e.g., lemon), and bitter (e.g., broccoli) (Liem and Mennella 2002; Mennella 1998; Mennella and Beauchamp 2002; Mennella et al., 2009; Mennella et al., 2006).

In conclusion, it is a public health priority to develop standardized psychophysical methods that are appropriate for children of all ages. More insight into the "taste world" of children will initiate new perspectives that will aid in the development of evidence-based strategies for improving children's food preferences and eating behaviors and help ameliorate bitter taste, which is the primary culprit for children's refusal to accept liquid formulations.

## Nutritional Implications of Taste and Smell Dysfunction

JANICE LEE, ROBIN M. TUCKER, SZE YEN TAN, CORDELIA A. RUNNING,  
JOSHUA B. JONES and RICHARD D. MATTES

### 37.1 INTRODUCTION

The chemical senses are intimately tied to nutrition. These senses have high metabolic demands due to the high turnover rates of their receptive elements and, as a consequence, require a regular supply of nutrients (Nawroth et al., 2007; Niven and Laughlin, 2008). At the same time, the chemical senses aid in the detection and ingestion of nutrients and avoidance of toxins. Eating, while essential, is a dangerous behavior in omnivores like humans as each eating event entails exposure to a different array of chemicals. Decisions must be made about when, what, how, and how much to consume. Such choices are largely guided by sensory input (Woods, 1991).

There are inherently unpleasant sensations mediated by each sensory system. Examples include bitter taste, rancid odors, and irritancy that can signal potentially dangerous food ingredients. The functionality of such aversive signals is intuitive but also limited. Many toxic compounds still pose a threat to health because they evade chemosensory detection systems (e.g., botulinum toxin). These undetected chemicals cause millions of cases of food poisoning and thousands of deaths annually (CDC, 2011). Additionally, sensory warning signals may be purposefully ignored as culturally determined safe feeding practices are learned. This can expand the available food supply, but can also lead to complications (alcohol intoxication, caffeine insomnia).

Food-borne chemicals also promote ingestive behaviors by multiple mechanisms. Flavor chemicals guide food choice. A fundamental tenet of the food industry is that in

any attempt to alter food attributes such as price, nutritional value, or convenience, sensory properties must be optimized or the product will fail (i.e., not promote repeated purchases and ingestion) (IFICF, 2011). In the United States, less than 10% of discretionary income is devoted to food (USDA, 2011), and food is accessible, abundant, diverse, and convenient, so ingestion of unpalatable foods is easily avoided.

In addition to influencing food selection, the sensory properties of foods modulate their own digestion, nutrient absorptive efficiency, and peripheral metabolism. Until recently, the prevailing view held that the receptors mediating pre-ingestive chemical detection were unique and limited to the oropharyngeal region. However, the discovery of these same receptors and transduction systems in other areas of the body has prompted a more holistic perspective of an integrated, common chemical communication system playing both protective (Green, 2012) and probably nutritive (Kokrashvili et al., 2009a) roles. This raises intriguing new questions about the interaction between the chemical senses and nutrition. With the advent of food ingredients (e.g. high intensity sweeteners, fat replacers) that uncouple their sensory properties from typically associated metabolic challenges, the functionality of the system is uncertain. Animal studies (Swithers et al., 2009) and human imaging studies (Smeets et al., 2011) suggest corruption of the veracity of the signal may hold implications for food choice and nutritional status. With diet underlying the etiology, manifestation, and management of most chronic diseases, the importance of better characterization of the interaction between the chemical senses and nutrition has never been greater. The present

chapter summarizes the current understanding of the field though much change is anticipated in knowledge and practice in the near future.

## 37.2 HUNGER AND SENSORY FUNCTION

Appetitive and flavor sensations are components of multiple inter-related mechanisms that influence energy and nutrient balance. Hunger promotes the initiation of feeding, satiation influences its termination, and satiety affects the inter-meal interval whereas sensory factors guide food choice. Electrophysiological studies in primates (Scott, 1992; Rolls, 1997) and common experience indicate these four factors are interactive. Often it is assumed that a common factor (e.g., blood glucose, fatty acids, or amino acids) influences all of these sensations, but strong support for any such driver is lacking. Several hormones linked to energy metabolism have significant effects on taste responses. For example, in mouse models, plasma leptin binds to receptors on taste cells and inhibits responses to sweet stimuli (Sanematsu et al., 2009). Conversely, glucagon-like peptide-1 (GLP-1) (Jyotaki et al., 2010) and glucagon (Elson et al., 2010) increase sensitivity to sweet stimuli. How this relates to appetitive sensations and ingestive behavior is not straightforward.

### 37.2.1 The Chemical Senses and Appetite

Appetite is a multidimensional sensation, reflecting both metabolic hunger as well as just the desire to eat for sensory gratification (often referred to as desire to eat). While both sensations are related to the motivation to eat, they can vary independently. A good example is the desire to indulge in a palatable dessert after having eaten a satiating meal when metabolic hunger is low.

Evidence that sweeteners stimulate hunger stems from the observation that preloads of high intensity sweeteners in water produce a more rapid rebound in hunger sensations than does water alone (Blundell et al., 1988). However, this response is not sweet-specific as a palatable salty food has the same effect (Mattes, 1994a), nor is it robust as it is not observed with ingestion of energy-yielding sweet foods and beverages (Rolls et al., 1989; Drewnowski et al., 1994). A heightened appetite has been reported after chewing gum sweetened with aspartame, although the effect was not dose related and varied according to sex and time post-exposure (Tordoff and Alleva, 1990a). Further, several other experiments have failed to replicate heightened appetite (Julis and Mattes, 2007; Hetherington

et al., 2008). Neuroimaging studies suggest there are differential responses to taste stimuli during states of hunger and satiety, adding another dimension to the possible correlation between sensory function and hunger (Small et al., 2001; Spetter et al., 2012). The type of sweet stimulus can modify neural processing. Specifically, saccharin and sucrose differentially activate reward areas of the brain, and frequency of saccharin consumption affects this activation, suggesting a learning effect (Green and Murphy, 2012).

Several early studies reported a reliable direct relationship between olfactory thresholds and appetite (Goetzl and Stone, 1947; Goetzl et al., 1950). This has been expanded by more recent evidence indicating hunger can increase olfactory thresholds to neutral stimuli while sated participants are better able to detect food stimuli (Stafford and Welbeck, 2011). Other work using similar methodology reported parallel results for food-related odors, but no impact of hunger on thresholds for non-food odors (Albrecht et al., 2009).

Textural attributes of food have also been shown to affect satiety. True (Mattes and Rothacker, 2001; Mars et al., 2009) and perceived (Cassady et al., 2012) viscosity are directly related to the expected satiety value of a food or beverage.

That being said, there are also data showing no associations between the different facets of chemosensory function and hunger (Janowitz and Grossman, 1949; Pangborn, 1959; Pasquet et al., 2006). In some work, scaling of glucose, sodium chloride, citric acid, and quinine sulfate was invariant with hunger status (Moskowitz et al., 1976; Scherr and King, 1982; Rolls et al., 1983; Looy and Weingarten, 1991; Laeng et al., 1993). These inconsistent findings are not surprising given the multitude of factors, including sensory system sensitivity and responsiveness, influencing hunger and the limited contribution of each.

### 37.2.2 The Chemical Senses and Food Hedonics

Food preference is driven by both inherent and acquired impressions of sensory stimuli. Though humans are drawn to certain qualities (e.g., sweet and salty) apparently independent of learning, this does not necessarily result in high levels of consumption of the palatable stimuli. Cultural practices and personal experience typically guide the use of these ingredients. This is reflected in different cuisines. One powerful determinant of the preferred concentration of a sensory stimulus in a food is the frequency of exposure to its quality. This has been documented for salt (Bertino et al., 1986), sugar (Liem and de Graaf, 2004), and fat (Mattes, 1993). However, acquired liking is interactive

with inherent proclivities as amelioration of neophobia (i.e., fear or avoidance of novelty) is more rapid for liked compared to unpleasant qualities (Mattes, 1994).

### 37.2.3 The Chemical Senses and Food Intake

Sensory factors have been implicated in the promotion of positive energy balance. Associative learning linking a food's sensory properties with its post-ingestive consequences is an important mechanism to guide food choice and portion size. This need not be conscious as specific flavor preferences can be conditioned in rodents by pairing flavors with intra-gastric infusions of energy (Sclafani and Glendinning, 2005; Yiin et al., 2005).

Recent work suggests corruption of such learning through inclusion of energy-modified foods in the diet can lead to eating dysregulation. Rodents provided with chow randomly modified in energy content eat more total energy than animals provided food with predictable associations between sensory properties and metabolism (Swithers and Davidson, 2008). Additionally, neuroimaging studies with humans suggest ingestion of products that have sensory properties not consistent with their metabolic consequences blunts neural signaling (Green and Murphy, 2012). However, behavioral data from humans fail to confirm effects on energy intake (Appleton and Blundell, 2007) or suggests such effects may hold for only a subset of the population (Shaffer and Tepper, 1994).

Palatable and unpalatable foods have been implicated in feeding in excess of need. Saltiness is inherently pleasant, like sweetness, as well as nutritionally required and so would be expected to stimulate reward centers and drive intake of foods containing the nutrient. Sodium may also stimulate intake indirectly. For instance, high sodium intake may prompt increased consumption of energy-yielding beverages, and these beverages evoke weak compensatory dietary responses, potentially leading to weight gain (He et al., 2012). Inherently unpleasant sensory properties can promote increased intake by prompting the addition of energy-yielding substances (e.g., sugar, fat) to foods to mask the unpleasant properties of foods consumed for purposes such as health beliefs (spinach) or psychoactive properties (coffee or alcohol).

Sensory variety is another determinant of intake. Variety tends to promote intake (Rolls, 1986; Murphy et al., 2006) and can lead to weight gain (Meiselman et al., 2000; Zandstra et al., 2000; Remick et al., 2009). In contrast, monotony in sensory input tends to suppress consumption over time (Zandstra et al., 2000; Sorensen et al., 2003; Raynor et al., 2005).

## 37.3 SENSORY INFLUENCES ON MACRONUTRIENT DETECTION AND SELECTION

### 37.3.1 Carbohydrate

The primary sensation associated with carbohydrates is sweetness, though starch may have its own taste (at least in rats (Sclafani, 2004)). When given orally, the sweetness from sucrose intensifies odors (Green et al., 2012) and suppresses other tastes (Green et al., 2010). Sweetness is inherently pleasing, as shown by increased fetal swallowing rates of amniotic fluid after intrauterine saccharin injection (DeSnoo, 1937; Liley, 1972) contrasted with decreased swallowing after injection of a bitter compound (Liley, 1972). Preterm infants also display stronger and more frequent sucks when exposed to glucose or sucrose (Tatzer et al., 1985; Maone et al., 1990). Full-term newborns can discriminate among different sugars and concentrations of a single sugar (Desor et al., 1975a) and exhibit positive mimetic (e.g. smiling) (Bergamasco and Beraldo, 1990) and autonomic (e.g. increased heart rate) (Crook, 1979) responses following exposure to sweet taste. Additionally, sweetness of sugars enhances the reward value of food (Epstein et al., 2011).

The preferred sweetness intensity is high during childhood and diminishes with age (Desor, 1975a; Desor and Beauchamp, 1987; Ventura and Mennella, 2011). This preference, however, may also be modifiable with increased exposure to sweetness, at least in children (Liem and de Graaf, 2004). The basis for children's liking of more intensely sweet foods is unknown, though several theories have been proposed. Some evidence indicates that children, especially males, may be less sensitive to sweetness in complex stimuli than adults (James et al., 1997; James et al., 1999). This may lead to greater intake to achieve a desired level of reward. However, physiologically reduced sensitivity to sweetness in children is unlikely, as children have also been shown to rate the intensities of sweet products higher than adults (Temple et al., 2002). Another theory for childhood sweet preference is that children have a greater need for energy to support growth (Coldwell et al., 2009). Genetics may also contribute more strongly to sweet liking in children than in adults as adult preferences may be influenced more markedly by culture and cognition (Mennella et al., 2005; Pepino and Mennella, 2005; 2006).

Concern has been expressed that early exposure to sweet foods high in carbohydrates may lead to a preference for such foods and subsequent overconsumption of sugars. Several studies indicate that infants show greater preference for flavors consumed by mothers during pregnancy or breastfeeding, due to exposure to the flavors through

amniotic fluid or breast milk (Mennella and Beauchamp, 1993; Mennella et al., 1995; Schaal et al., 2000; Forestell and Mennella, 2007; Beauchamp and Mennella, 2009). Less evidence exists for linking early, overall sweet exposure to adult sweet intake. Studies in rats imply that sweet foods in infancy may lead to increased consumption of such foods and weight gain in adulthood (Frazier et al., 2008; Silveira et al., 2008). Additionally, human infants exposed to sugar sweetened water during the first six months after birth drank more sweetened water at 6 months than infants not previously exposed (Beauchamp and Moran, 1982). However, at two years of age these same children maintained their reactions to sugar water but did not have significantly different responses to sugar sweetened fruit drinks (Beauchamp and Moran, 1984). Consequently, context and familiarity of the food may change acceptability and preference more than sweetness itself.

Numerous studies have attempted to elucidate the relationship among intensity ratings, liking, exposure frequency, and intake of sugary foods. With regard to sweetness exposure, low, medium, and high consumers of sweet foods assigned comparable intensity ratings for prepared samples, indicating no effect of frequency of exposure on ability to assign relative intensity ratings (Pangborn and Giovanni, 1984). Other work reveals significant positive associations between use of sweeteners and peak hedonic ratings for fruit-flavored solutions with graded levels of sucrose, fructose, or aspartame, but only in women with gestational diabetes mellitus. No significant associations were noted in healthy controls (Tepper et al., 1996). More recent work shows that in people who originally had low liking for sucrose, four weeks of sweetened soft drink supplementation increased their preferred concentration of sucrose (Sartor et al., 2011). This change was not evident in the participants who reported higher liking for sucrose initially. Overall, selection of food and preferred sweetness level depends greatly on familiarity. While a penchant for sugary foods can undoubtedly lead to high consumption of sugars, sweetness preference in specific foods is difficult to predict without knowledge of individual exposure to the food product and context.

### 37.3.2 Protein

Proteins encompass the whole range of taste qualities, though sourness or saltiness of peptides is likely attributable to acidic and charged residues rather than to the peptides themselves (Temussi, 2011). Sensory feedback through tastes and other properties, including odor and texture, may aid in the identification of protein sources. Infants (Vazquez et al., 1982) and elderly people (Murphy and Withee, 1987) who have inadequate or marginal protein intake show higher preferences for protein supplemented

soups, a preference not seen in adequately nourished individuals. Ingestion of an adequate quantity and balance of amino acids is central to survival. Rats demonstrate an ability to maintain this balance by adjusting their food intake and dietary choices to obtain necessary amounts of both individual amino acids and overall protein (Leung and Rogers, 1986; White et al., 2000). Proposed mechanisms to explain this dietary behavior in rats include associative learning, where sensory properties of foods that correct the amino acid deficiency become more hedonically pleasing (Gibson and Booth, 1986; Fromentin et al., 1997; DiBattista and Mercier, 1999), and also direct sensory cues of proteins or amino acids leading to a rapid modification of ingestive behavior (Vazquez et al., 1982; Deutsch et al., 1989). However, familiarity may also be involved in protein selection, even at birth, as the maternal diet of rats during pregnancy influences protein selection of pups (Leprohon and Anderson, 1980; Morris and Anderson, 1986).

Umami, characterized by the taste of monosodium glutamate (MSG), is pleasing to rats but may be either pleasing (in soup), neutral (in water for infants) (Vazquez et al., 1982; Beauchamp and Pearson, 1991; Schwartz et al., 2009) or unpleasant (in water for adults) (Beauchamp et al., 1998). The reason for MSG's augmentation of palatability when mixed with other foods is unknown. Nevertheless, this has led to this compound's widespread use, especially in savory applications. Similar to using fat or sugar, adding MSG to soup can better condition liking for a novel flavor compared to associative learning for the same flavor without MSG (Prescott, 2004).

Inverse associations between thresholds for MSG and inosine 5'-phosphate and preferences for protein have been observed (Luscombe-Marsh et al., 2008). Whether this increased MSG sensitivity is a cause, effect, or confounder of protein preference is unknown. Cultural components of perception of amino acids have also been documented. For example, Japanese, relative to Australians or Americans, have lower threshold sensitivity for and give higher hedonic ratings to MSG and 5' nucleotides (Ishii et al., 1992; Prescott et al., 1992). This raises the possibility that preferences for umami may be modifiable through exposure frequency.

### 37.3.3 Fat

Triacylglycerols, the predominant form of fats in foods, are perceived primarily through textural cues, but non-esterified fatty acids may also be detected through olfaction, irritation, and gustation (Chale-Rush et al., 2007). Evidence for gustatory detection, in particular, has been building over the past few years (for review, see Mattes, 2011a). Several potential mechanisms for oral fatty acid detection have been proposed, including various fatty acid receptors and passive diffusion (Gilbertson, 1998;

Khan and Besnard, 2009; Cartoni et al., 2010; Gilbertson et al., 2010; Martin et al., 2012). Mice lacking functional oral fatty acid receptors, including CD36 (Laugerette et al., 2005; Sclafani et al., 2007a; Gaillard et al., 2008), GPR120, and GPR40 (Cartoni, 2010) exhibit decreased preference for fat, though this decreased preference can be eliminated by post-oral ingestive feedback (Sclafani, 2007a).

Oral detection thresholds for a range of short to long chain non-esterified fatty acids are not correlated with somatosensory or other taste thresholds. Studies in rodents indicate that an aversion to a non-esterified fatty acid, linoleic acid, does not generalize to compounds widely accepted as eliciting the other basic taste qualities (Pittman, 2010) or to non-nutritive lipids (Smith et al., 2000). Such studies imply the sensory quality of fatty acids is unique. Mixed results have been reported on whether fatty acids can affect intensities for other taste modalities, with some rodent studies showing increased sensitivity to sweet but not salty, bitter, or sour tastes (Pittman et al., 2006), and human trials failing to replicate these findings (Mattes, 2007; Reckmeyer et al., 2010).

Humans do not appear to have an inherent preference for fat. Although fetal drinking is inhibited by injection of iodinated poppy seed oil into amniotic fluid (Liley, 1972), the fat component may or may not be responsible. If the fat is appealing, then it is not sufficiently so to override one or more negative components in this stimulus. Additionally, infants provided breast milk or formula varying in fat content do not differentially consume them (Chan et al., 1979; Woolridge et al., 1980; Nysenbaum and Smart, 1982). One study noted a stronger sucking response to a higher fat formula (Nysenbaum and Smart, 1982), but this has not been consistently replicated (Woolridge et al., 1980; Drewett, 1982). In adults, fat texture is palatable, high fat more so than low fat (Drewnowski, 1998; Grabenhorst et al., 2010), and cephalic phase responses are greater for higher fat concentrations (Crystal and Teff, 2006).

Early exposure to a high-fat diet results in a stable preference for that diet in rats and mice (Warwick and Schiffman, 1990; Teegarden et al., 2009). However, this does not necessarily translate to greater energy intake (Teegarden et al., 2009). In contrast, humans who cannot easily discern differences in fat content may consume more fat in their diet (Liang et al., 2012). Also of note in this study, these same “non-discriminators” of fat content also showed increased use of reduced- and low-fat foods, indicating that this population may be more accepting of lower fat alternatives. Findings are mixed on whether obese compared to lean individuals are more or just equally sensitive to NEFA compared to those that are lean (Stewart et al., 2011; Tucker et al., 2014). Individuals hypersensitive to oral fatty acids report reduced fat intake compared to hyposensitive subjects (Stewart et al., 2010, 2011). Preference for dietary fat may also be altered through experience.

After adherence to a reduced fat diet for 12 weeks, the preferred concentration declines (Mattes, 1993; Grieve and Vander, 2003; Ledikwe et al., 2007). Such hedonic shifts are not attributable to altered perceptual ability (Mattes, 1993). However, promotion of a broad shift may require modification of the total diet rather than selected individual foods.

### 37.3.4 Ethanol

Ethanol is an irritant and tastes both bitter and sweet. For rats, in utero exposure to ethanol alters responsivity to its odor postnatally (Dominguez et al., 1996; Arias and Chotro, 2005; Youngentob et al., 2009). Similarly, infants born to mothers who frequently consumed alcohol during pregnancy react more strongly to the odor of ethanol than infants born to mothers who infrequently drank (Faas et al., 2000). Breastfeeding infants are also able to detect ethanol in milk, leading to increased sucking (Mennella, 1997) and decreased consumption (Mennella, 2001). The latter may be related to the delayed time to ejection of breast milk (Chien et al., 2009) and/or reduced milk availability (Mennella, 2001) after ethanol ingestion by mothers. The increased sucking could also be due to familiarity with the stimulus from exposure in utero. Since bitter stimuli are typically rejected by newborns (Rosenstein and Oster, 1988), it is unlikely that ethanol is inherently pleasing. However, it is not known how newborns perceive the flavor of the low concentrations of ethanol found in breast milk.

While a connection between ethanol liking and sweet liking has been proposed (Kampov-Polevoy et al., 1997; Kampov-Polevoy et al., 1998; Bachmanov et al., 2003), most of the mechanistic work for this association has been conducted in mice or rats (for review, see Bachmanov, 2003). Because there are marked species differences in the perceived quality of ethanol, the suitability of animal studies for understanding human responsiveness is uncertain. Although other factors are also involved, some species (e.g., C57BL/6ByJ mice, Roman high-avoidance rats) derive a predominantly sweet note and consume high levels when available; whereas, others (e.g., 129/J mice, Roman low-avoidance rats) sense it as bitter and tend to reject it (Stewart et al., 1994; Razafimanalina et al., 1996; Coleman et al., 2011). Human data are available supporting the presence of both sweetness and bitterness of ethanol at and above threshold concentrations (Diamant et al., 1963; Martin and Pangborn, 1970; Wilson et al., 1973; Scinska et al., 2000). Approximately 60% of 50 non-alcoholic adults rated ethanol as predominantly bitter at threshold; whereas, only 6% reported sweetness (Mattes and DiMeglio, 2001). At one dilution step above threshold, a doubling of concentration, the proportions were 72% and 5%. At higher concentrations, ethanol is perceived as bitter and enhances the bitterness of other bitter compounds in foods (Noble, 1994). While some

research groups have shown increased sweet liking in male alcoholics (Kampov-Polevoy, 1997; Krahm et al., 2006), others have shown no correlation between alcohol intake (Mattes and DiMeglio, 2001) or alcoholism (Bogucka-Bonikowska et al., 2001; Wronski et al., 2007) and response to sweetness.

Genetics could potentially play a role in the sensory preference for ethanol. Selective breeding studies in rats clearly highlight a genetic component to ethanol taste which results in different behavioral responses to sensory qualities (Kiefer et al., 1995; Bachmanov et al., 1996a, b; Razafimananjara, 1996; Blednov et al., 2008; Brasser et al., 2012). In mice, changes in sweet receptor genes result in reduction of ethanol intake (Blednov, 2008; Brasser et al., 2010). However, other rat research indicates that changes in sweet or bitter susceptibility do not lead to changes in ethanol preference (Wolstenholme et al., 2011).

A genetic component has also been proposed in humans. For example, the genetically determined sensitivity to phenylthiocarbamide (PTC) or 6-n-propylthiouracil (PROP) has been associated with ethanol sensitivity (Bartoshuk, 1993; Duffy et al., 2004; Duffy et al., 2004). Another study showed that in college students, sensitivity to PROP was directly related to perceived bitterness and inversely related to perceive sweetness in alcoholic beverages; decreased bitterness and increased sweetness were then correlated with alcohol intake, implying a possible indirect effect of PROP taster status on alcohol consumption (Lanier et al., 2005). Some evidence indicates there is a higher proportion of PROP non-tasters among the children of alcoholics than non-alcoholics (Pelchat and Danowski, 1992). Additionally, male alcoholics (Wronski, 2007), women (Pepino and Mennella, 2007), and depressed children (Mennella et al., 2010) with a family history of alcoholism have increased preference for high concentrations of sucrose. However, conflicting data regarding PROP status, paternal history, and ethanol preference have also been published (Noble, 1994; Kranzler et al., 1996; Scinska et al., 2001). Consequently, while taste genetics may play a role in alcohol consumption, the importance of this role compared to other factors, such as cultural and pharmacological aspects of ethanol, remains disputed.

Thus, the importance of the sensory properties of ethanol on ingestion by humans has not been established. Among non-alcoholics, dislike of the sensory properties of ethanol is a commonly cited reason for abstinence (Moore and Weiss, 1995). Not liking the taste of alcohol also may contribute to lighter drinking among non-abstaining college students (Huang et al., 2011). On the other hand, taste is also frequently expressed as a motivation for consuming alcoholic beverages (Patrick et al., 2011). Mixed findings have been reported on an association between

taste thresholds for ethanol in model solutions and ingestion of the compound (Mattes, 1994b; Kranzler, 1996). This may reflect a pharmacological or exposure effect since abstinence for three weeks results in a reduction in sensitivity (Settle, 1978). Chronic exposure to ethanol leads to increased acceptance in rats (Kiefer et al., 1994). A pharmacological basis for differences in human intake has been proposed as well (Dewit et al., 1989; Mattes, 1994) but may ultimately relate back to sensory factors if the rewarding properties serve to condition a preference to the chemosensory characteristics of ethanol (Settle, 1978). Chronic alcohol abuse is associated with olfactory impairment (i.e., elevated thresholds, reduced scaling and/or identification performance) as well as reduced gustatory intensity ratings that may persist even after detoxification (Jones et al., 1975, 1978; Ditraglia et al., 1991; Rupp et al., 2003, 2004, 2006; Maurage et al., 2011).

### 37.3.5 Sodium Chloride

In most studies, human neonates show similar ingestive and facial responses to saline and water, suggesting they are either insensitive or indifferent to the taste of salt (Desor et al., 1975b; Crook, 1978; Beauchamp et al., 1986; Rosenstein and Oster, 1988). However, a few studies indicate rejection of, or mixed responses to, saline within a few days of birth (Beauchamp et al., 1994; Zinner et al., 2002). Nevertheless, there is clear evidence of sensitivity and positive hedonic responsiveness to saline solutions by 4–6 months of age continuing through 2 years of age (Beauchamp, 1986; Schwartz, 2009), and toddlers have been shown to consume more carrots (Beauchamp and Moran, 1984) and green beans (Bouhalal et al., 2011) when salt is added. Despite the delay in overt acceptability, the prevailing view holds that the liking for saltiness is inherent (Beauchamp et al., 1991). In rats and sheep, the developmental lag in salt taste sensitivity coincides with maturation of the gustatory system for this quality (Hill and Mistretta, 1990). A precise understanding of the development of human salt taste receptors is still lacking. However, exposure and learning appear to play a large role in the development of salt preference among adults.

There has been considerable concern regarding the influence of early salt taste exposure on salt preferences throughout the lifecycle. In 6 month old infants, those who had been exposed to starchy table food showed a greater preference for saline (0.34M) than infants not exposed to such foods (Stein et al., 2012). All of the infants in this study were indifferent to saline at 2 months of age, prior to any table food exposure. Additionally, short-term acceptability of foods with varying salt content has been associated with salt exposure in 6 month olds, but this may simply reflect recent consumption (Harris and Booth,

1985). In the longer term, one study reported 3 month olds who ingested formula containing either 4.78 M Na/kJ or 21.5 M Na/kJ for five months did not have differing salt use or preferences at eight years of age (Whitten and Stewart, 1980). Another study reported an association between salt use at 2 and 4 years of age (Yeung et al., 1984), but whether this was indicative of familial salt use or of establishing a specific salt preference is unclear. Context and learning are also important for salt preference as 31-month-old infants reject saline solutions with questionable dietary relevance but prefer salted over unsalted foods (Beauchamp and Moran, 1984).

Marked early sodium depletion is associated with heightened preference for and intake of salt later in life. This has been demonstrated in infants experiencing dietary chloride deficiency (Stein et al., 1996), in preterm neonates treated with diuretics (Leshem et al., 1998), and in infants with vomiting and diarrhea or whose mothers experienced severe vomiting while pregnant (Crystal and Bernstein, 1998; Leshem, 1998; Kochli et al., 2005; Shirazki et al., 2007). The enhanced salt preference in offspring due to severe morning sickness during pregnancy may extend into adulthood (Crystal and Bernstein, 1995).

Dietary experience can also modify the preferred level of salt in foods. As shown in a twin study, salt preference is primarily environmentally based (Wise et al., 2007). Furthermore, salt preference can be altered through changes in sensory exposure. Chronic (e.g., 8–12 weeks) reduction of dietary sodium consumption elicits a hedonic shift toward lower salt content of foods (Bertino et al., 1982; Thaler et al., 1982; Jeffery et al., 1984; Witschi et al., 1985; Blais et al., 1986; Beauchamp et al., 1987; Stamler et al., 1987; Mattes, 1990). Increased exposure leads to preferences for higher salt levels in foods (Bertino et al., 1986). The shift is not attributable to a change of taste sensitivity or taste intensity scaling ability (Bertino et al., 1982; Teow et al., 1984; Mattes, 1990). The shift also occurs when total sodium intake is unchanged but sensory exposure is curtailed (Mattes, 1990) and does not occur under the reverse conditions (Beauchamp et al., 1987). These observations suggest exposure frequency dominates metabolic factors in eliciting hedonic shifts for salt.

## 37.4 CHEMOSENSORY INFLUENCES ON NUTRIENT UTILIZATION

Sensory, especially chemosensory, stimulation initiates an array of physiological processes, termed first phase, pre-absorptive, or cephalic phase responses. These responses mimic those occurring during food (nutrient) ingestion, digestion, absorption, and metabolism and are neurally mediated (primarily through the parasympathetic nervous

system), occurring within seconds to minutes following exposure to foods. These cephalic responses are transient and typically small in magnitude relative to responses occurring during actual food ingestion. Although there are exceptions, there generally is a hierarchy in stimulus efficacy in eliciting these responses: swallowing > mastication > taste > smell > sight, audition, or thought. Further, concurrent stimulation of multiple sensory systems typically elicits a larger response than stimulation of a single system.

The functional role of cephalic phase responses is largely unexplored, but their importance as a signaling system is supported by evidence that their magnitude correlates with post-prandial responses. Thus, the prevailing view is that cephalic phase responses initiate and augment the efficacy of the normal digestive, absorptive, and metabolic processes associated with eating (Jordan, 1969; Nicolaidis, 1977). These responses have been hypothesized to influence food selection (Simon et al., 1986; Steffens et al., 1990) and have been implicated in varied diet-related disorders including insulin resistance and obesity (Ionescu et al., 1988; Konturek et al., 1994), eating disorders (LeGoff et al., 1988), and ulcers (Konturek et al., 1981) and have been the topic of a number of reviews (Brand et al., 1982; Powley and Berthoud, 1985; Mattes, 1997; Zafra et al., 2006; Power and Schulkin, 2008). The effective stimuli and nutritional significance of the better-documented and most recently identified cephalic phases are described in this section.

### 37.4.1 Cephalic Phase Salivary Response

Study of the effective stimuli for salivary flow and, as a consequence, composition, is limited but a rough ordering can be derived from the literature. Cognitive control over salivation has been documented in humans, though not consistently (Jenkins and Daws, 1966; White, 1978). Visual stimulation elicits a 1.5-fold increment over resting or cognitive stimulation (Hayashi, 1968; Wooley and Wooley, 1973; Pangborn et al., 1979). Salivation significantly increases after smelling and viewing (Aspen et al., 2012) or tasting without swallowing a stimulus (Bond et al., 2009). Relative to viewing and smelling food, mastication leads to about a 5-fold increment in flow (Richardson and Feldman, 1986). Because flow rate influences salivary composition, pH, and buffering capacity, this response can markedly influence sensory perception of stimuli, via dilution and chemical interactions, as well as digestive processes, through enzyme concentrations and activation (Pedersen et al., 2002; Engelen et al., 2003). There are some suggestions that salivation patterns are significantly different between lean and obese individuals. In humans, exposure to the sight and smell of food elicited

greater salivary response in overweight adults than their normal-weight counterparts, which subsequently led to a greater desire to eat (Ferriday and Brunstrom, 2011).

Repeated olfactory and gustatory stimulation leads to reduced salivary flow (Epstein et al., 1996) due to adaptation to the sensory stimulus rather than gland fatigue (Wisniewski et al., 1992; Epstein, 1996). Habituation to a taste stimulus through repeated oral exposure is significantly delayed in morbidly obese adults when compared to lean controls (Bond, 2009). Similar phenomena have been reported in overweight and obese children (Aspen et al., 2012). A decrease in salivation after habituation to repeated stimulus exposure can promote satiation (Swithers and Hall, 1994) and result in the termination of an eating episode (Wisniewski, 1992). Failure to habituate among the obese may therefore have implications for energy intake and body weight.

Because both appealing and aversive stimuli can enhance salivary flow, palatability is not a straightforward predictor of response (Pangborn and Berggren, 1973; Klajner et al., 1981; Sahakian et al., 1981; Christensen and Navazesh, 1984). Potent sialagogues include items that are sour, bitter, physically sharp, or difficult to clear from the mouth (Guinard et al., 1998). Experience can modulate the cephalic phase salivary response (Christensen et al., 1984); however, this is not a robust predictor (Pangborn, 1979). Although salivary enzymes contribute to macronutrient digestion, protein, fat, and carbohydrate are not potent sialagogues (Christensen, 1986; Matsuo and Yamamoto, 1989; Myers and Epstein, 1997); rather, the primary influence of these macronutrients may be on salivary composition. For example, sucrose and fructose prompt the release of amylase-rich saliva (Kemmer and Malfertheiner, 1983; 1985).

The nutritional significance of the cephalic phase component of salivary flow has not been well characterized, but saliva plays a number of key roles (Mattes, 2000). It facilitates swallowing, promotes oral health and functionality of taste receptor cells (Cano and Rodriguez-Echandia, 1980; Thesleff et al., 1988; Bodner, 1991; Matsuo et al., 1997), alters the sensory properties and palatability of foods, initiates macronutrient digestion, and may alter gastric and intestinal phases of digestion.

### 37.4.2 Cephalic Phase Gastrointestinal Motor and Secretory Response

The thought of foods can elicit a weak cephalic phase gastric response (Moor and Motoki, 1979), but progressively higher levels of secretion are observed with olfactory and gustatory stimulation. The taste and smell of foods stimulate the release of gastrin and gastric acid (Feldman and Richardson, 1986) at levels up to a third of those

occurring upon food ingestion. Food palatability increases these secretions (Janowitz et al., 1950). Sensory stimulation, including differential effects by the macronutrients, also elicits: (1) release of digestion enzymes (trypsin, lipase, and chymotrypsin are elevated by 35–66, 16–50, and 25–60%, respectively, during modified sham feeding) (Novis et al., 1971), (2) secretion of gut peptides (such as cholecystokinin, somatostatin, neuropeptide-1 (GLP-1) (Vahl et al., 2010; Williams, 2010), and ghrelin (Monteleone et al., 2008, 2010; Bello et al., 2010; Massolt et al., 2010) that are involved with intestinal absorption and satiety, (3) stimulation of a fed-like motor pattern in the stomach (Katschinski et al., 1992), and (4) gastric emptying (Rogers et al., 1993; Nagao et al., 1998; Cecil et al., 1999). Studies also suggest oral exposure to dietary fat augments and prolongs the postprandial triacylglycerol concentration (Mattes, 1996), possibly through enhanced fat absorption (Ramirez, 1985) or decreased clearance (Mattes, 2001). These responses presumably optimize food digestion and absorption of nutrients with the potential to contribute to overall health. At the same time, contributions to adverse health outcomes have also been suggested. Given the evidence that postprandial lipemia is an independent risk factor for cardiovascular disease (Bansal et al., 2007), sensory exposure to fats may contribute to this problem. The cephalic phase gastrointestinal response has also been implicated in the etiology or severity of duodenal ulcers (Konturek et al., 1978; Thirlby and Feldman, 1984; Feldman and Richardson, 1986), irritable bowel syndrome, ulcerative colitis, and colonic diverticular disease (Rogers, 1993).

### 37.4.3 Cephalic Phase Pancreatic Exocrine Response

Combined visual, tactile, and olfactory stimulation elicits a pancreatic exocrine response but not as large as that following gustatory stimulation (Sarles et al., 1968). Protein concentrations are selectively increased (Novis, 1971), and under certain conditions, trypsin secretion may increase four-fold (Anagnostides et al., 1984) while lipase and amylase secretion rates can exceed those obtained with pharmacological agents (Sarles, 1968). Oral detection of dietary fat stimulates pancreatic exocrine secretion (Hiraoka et al., 2003; Laugerette et al., 2005; Gaillard et al., 2008). Studies in dogs indicate the exocrine response is enhanced by palatable (i.e., sweet) relative to less palatable (sour, bitter) stimuli (Ohara et al., 1988). Food acceptability also modulates the response in humans (Sarles, 1968). The sensory-mediated release of an enzyme-rich pancreatic secretion could enhance digestive processes, but its importance is uncertain due to the large reserve capacity for enzyme secretion by this organ (Brannon, 1990).

### 37.4.4 Cephalic Phase Pancreatic Endocrine Responses

Insulin, pancreatic polypeptide, and glucagon (Teff et al., 1991a; Teff and Engelman, 1996a) are all released following appropriate sensory stimulation (Schwartz et al., 1979; Katschinski, 1992; Glasbrenner et al., 1995).

The relative potency of different sensory stimuli has not been established. Human studies reveal insulin secretion is stimulated by the sight, smell, and sound of cooking food (Rodin, 1978), as well as sweet taste from both nutritive and non-nutritive sweeteners (Just et al., 2008). Recent work documents the efficacy of oral fat exposure to stimulate insulin secretion (Chavez-Jauregui et al., 2010). The role of palatability is uncertain with some work supporting a direct association (Rodin, 1981; Bellisle et al., 1985; Lucas et al., 1987; Teff and Engelman, 1996a) and other work failing to note an effect (Rodin, 1978; Bellisle, 1985; Teff and Engelman, 1996a). Although effects remain to be confirmed, individual characteristics may modulate responses as greater insulin release occurs in restrained (i.e., individuals who cognitively controlling food intake) compared to non-restrained, females (Teff and Engelman, 1996a) and African Americans relative to Caucasians (Saad et al., 1990). Across studies, 10–15% of subjects exhibit no response to sensory stimulation, which suggests there may be a subgroup of non-responders, but this has not been established. Whether and to what degree oral stimulation promotes insulin secretion through neural activation or secondarily via promotion of GLP-1 secretion is uncertain. GLP-1 is the most potent incretin hormone and oral stimulation promotes release of GLP-1 directly from enteroendocrine cells on the tongue and in the intestinal tract (Jang et al., 2007).

Cephalic phase glucagon release has long been reported in animals (Fischer et al., 1976; Nilsson and Uvnas-Wallensten, 1977), but only more recently in humans (Secchi et al., 1995). However, this response was not observed in other animal (Berthoud and Jeanrenaud, 1982) or human studies (Teff et al., 1991b; Abdallah et al., 1997). Insulin release suppresses glucagon secretion (Meier et al., 2006), and this may explain why cephalic phase glucagon release was not observed in these studies. Cephalic stimulation of both insulin and glucagon secretions may appear counter-intuitive, but glucagon release helps to maintain appropriate blood glucose concentrations (Teff, 2000).

The effective stimulus for pancreatic polypeptide release is controversial. It is often measured as an index of neural activation, and its release is viewed as independent of the nutrient composition (Katschinski, 2000; Robertson et al., 2002; Heath et al., 2004) or physical form (Teff, 2010) of a stimulus. However, recent modified sham feeding studies in humans demonstrate that cephalic phase

pancreatic polypeptide secretion is stimulated only by mixed foods that are high in fat (Crystal and Teff, 2006) or with sweet and salty (Teff, 2010) taste qualities.

Accumulating evidence supports a functional role of the cephalic phase insulin response. Glucose tolerance is improved when sham feeding accompanies a glucose infusion (Lorentzen et al., 1987; Teff and Engelman, 1996b; Ahren and Holst, 2001). In contrast, when cephalic phase insulin release is inhibited by somatostatin, hyperglycemia and hyperinsulinemia result (Calles-Escandon and Robbins, 1987). Concurrent administration of insulin and meals leads to a two-fold decrease in incremental blood glucose among insulin-dependent diabetics (Kraegen et al., 1981) and a 33% lower glycemic response among non-insulin-dependent diabetics (Bruce et al., 1988) as compared to responses when sensory stimulation is delayed for 30 minutes after meal ingestion. A role for circulating glucose and/or insulin in appetitive sensations has been proposed (Smith and Campfield, 1993), but euglycemic clamp studies indicate independent manipulation of glucose and insulin is not associated with changes in hunger or fullness (Chapman et al., 1998). Insulin, pancreatic polypeptide, and glucagon also influence aspects of the gastric and intestinal phases of digestion as well as post-absorptive energy metabolism.

### 37.4.5 Cephalic Phase Thermogenic Response

Exposure to the sight and smell of food leads to a thermogenic response in dogs that is comparable to the level observed following food ingestion (Diamond and LeBlanc, 1985). Work in humans indicates the response is positively related to food palatability (LeBlanc and Brondel, 1985; LeBlanc and Cabanac, 1989; Westrate et al., 1990; Soucy and LeBlanc, 1999), especially in lean individuals (Hashkes et al., 1997). Sham-feeding of a high-fat meal leads to increased energy expenditure comparable to the values observed when the same meal is actually ingested (Smeets et al., 2009). Intragastric feeding is not associated with a rise in thermogenesis, and blocking the cephalic component with somatostatin or atropine infusion (Calles-Escandon and Robbins, 1987) diminishes the post-prandial increment in heat production. The thermic effect of food represents about 8–10% of total energy expenditure but can be greater with imbalanced diets (Stock, 1999). Consequently, this response may contribute to energy balance and body weight.

### 37.4.6 Cephalic Phase Cardiovascular Response

Cardiac output and stroke volume transiently decline by 11–13% and heart rate increases by 5–10% in response

to the sight and smell of food (Andersen et al., 1992; Fagius and Berne, 1994). Exposure to food also increases systolic and diastolic blood pressure (Nederkoorn et al., 2000) as well as microcirculation (e.g., resting and peak functional capillary density, red blood cell velocity, flow, vasoactivity; Buss et al., 2012). These responses are associated with an increase in pancreatic polypeptide secretion (Buss, 2012) suggesting they are neurally mediated. A 31% increase in mesenteric resistance has been noted in dogs viewing and smelling food (Vatner et al., 1970). While nutrient absorption from the gastrointestinal tract is very efficient, it is directly related to blood flow (Winne, 1979). Consequently, the cephalic phase hemodynamic effects may influence the kinetics of nutrient absorption. This, in turn, may alter endocrine responses (e.g., insulin and vasopressin release are largely determined by the rate of glucose and ethanol absorption, respectively).

### 37.4.7 Cephalic Phase Renal Response

Oral exposure to graded saline solutions alters the acute diuretic and natriuretic response in a stepwise fashion (Akaishi et al., 1991). Urine osmolality decreases or increases by 10–20% with exposure to hypotonic and hypertonic solutions, respectively. No response occurs following isotonic saline exposure. Comparable responses are observed with sodium chloride and mannitol challenges, suggesting the salient stimulus attribute is osmolality (Gebruers et al., 1985). However, palatability also alters the response as decreased diuresis is observed with ingestion of a less palatable beverage (Nagao et al., 1999). The nutritional significance of this response is not clear, but it may contribute to fluid and electrolyte balance.

## 37.5 TASTE RECEPTORS IN THE ORAL CAVITY AND ELSEWHERE

Taste receptors were long believed to reside solely on taste receptor cells in the oropharyngeal region. However, they have now been identified throughout the body and serve functionally diverse purposes. In the gastrointestinal (GI) tract, enteroendocrine cells express receptors and intracellular signaling proteins resembling those in taste receptor cells on the tongue, but when activated, they lead to responses relevant for the intestinal phase of digestion rather than the pre-ingestive phase. Thus, questions are now being asked about how food-related chemosensory signals in the gastrointestinal lumen influence the digestive and absorptive process, appetite, and toxin disposal. Emerging knowledge of chemosensory signaling by food constituents throughout the GI tract is highlighted below.

### 37.5.1 Sweet “Taste” Receptors

T1R2, T1R3,  $\alpha$ -gustducin, and TRPM5 are co-localized in gut enteroendocrine cells in the human gastrointestinal tract spanning from the esophagus to the colon (Steinert et al., 2011b; Widmayer et al., 2011). However, TRPM5-positive cells are more characteristic of tuft cells than enteroendocrine cells; hence, it is still unclear which cell types contain taste receptors and if all components of the transduction pathway are located in the same cell (Kokrashvili et al., 2009b; Tolhurst et al., 2012). T1R3 and T1R2 are also expressed in the intrahepatic bile duct, interlobular septa, and liver lobule (Taniguchi, 2004; Toyono et al., 2007). T1R2 and T1R3 are documented in cultured human and murine pancreas, and administration of a sweet receptor antagonist, such as lactulose, abolishes fructose and glucose stimulated insulin release (Kyriazis et al., 2012).

### 37.5.2 Fat “Taste” Receptors

G-protein coupled receptor 120 (GPR120) and GPR40 bind fatty acids and have been localized to enteroendocrine cells (Covington et al., 2006; Vinolo et al., 2012). In the murine STC-1 enteroendocrine cell line, unsaturated long chain fatty acids stimulate GPR120 and elicit GLP-1 secretion (Hirasawa et al., 2005). Recent studies also indicate that GPR120 expression is significantly higher in obese individuals than in lean controls (Widmayer, 2011; Ichimura et al., 2012), suggesting a role of GPR120 in lipid/energy balance. *In vitro*, linolenic acid increases cholecystokinin (CCK) secretion through GPR40 while GPR40 knock-outs do not display this effect (Liou et al., 2011). In humans, lauric acid (12 carbon fatty acid), but not capric acid (10 carbon fatty acid), significantly increased plasma CCK, suppressed appetite, modulated antropyloroduodenal motility (*stimulated* basal pyloric pressure waves and *suppressed* antral and duodenal pressure waves), and decreased energy intake (capric:  $4,109 \pm 588$  kJ, and lauric:  $1,747 \pm 632$  kJ) (Feltrin et al., 2004). However, five out of eight subjects experienced nausea with lauric acid exposure but not with capric acid exposure, suggesting the differential response may be non-physiological. Fatty acid translocase cluster determinant 36 (CD36) is a long chain fatty acid scavenger that mediates fatty acid sensing in the gustatory papillae in rodents and humans (Laugerette, 2005; Simons et al., 2011). In the human gastrointestinal tract, CD36 plays a functional role in the small intestine and the liver (Lobo et al., 2001; Miquilena-Colina et al., 2011). In the murine intestine, CD36 mediates the uptake of very long chain fatty acids (Drover et al., 2008). CD36 knockout mice have reduced chylomicron formation (Nauli et al., 2006), reduced fatty acid and cholesterol uptake (Chen et al., 2001), and decreased preference for and intake of fat (Sclafani et al., 2007a), but whether these

outcomes are specifically related to the absence of CD36 in the gut remains to be determined.

### 37.5.3 Amino Acid “Taste” Receptors

T1R1/T1R3 receptors are expressed in enteroendocrine cells (Bezencon et al., 2007) in the murine and human intestinal tracts. These receptors respond to aromatic amino acids and umami- L-glutamate (Li et al., 2002; Nelson et al., 2002). Despite these findings, the physiological relevance of T1R1/T1R3 in the gut remains uncertain. One functional response of the T1R1 receptor is regulation of peptide transporter 1 (PepT1) and glucose transporter 2 (GLUT2) in the rat small intestine, suggesting a role in regulating glucose absorption (Mace et al., 2009). The wide range of protein degradation products might contribute to numerous amino acid physiologic sensing abilities (Tolhurst, 2012). Although certain amino acids induce CCK release through GPR93 (Choi et al., 2007), more recent studies suggest that CCK release could possibly be stimulated through sodium-coupled neutral amino acid transporter 2 (SNAT2) (Young et al., 2010). Another study noted L-phenylalanine and L-tryptophan induce CCK release through activation of the calcium sensing receptor (CaSR) (Wang et al., 2010). The amino acid profile most effective for SNAT matches the amino acid specificity in STC-1 cells but does not match amino acid selectivity found earlier in T1R1/T1R3 STC-1 cells (Nelson, 2002).

### 37.5.4 Bitter “Taste” Receptors

T2R receptors and their transduction proteins (e.g., gustducin) are co-expressed in STC-1 cells (Wu et al., 2002; Rozengurt, 2006). Bitter compounds such as denatonium benzoate (DB), PTC, PROP, and cyclohexamide (CYX) elicit rapid increases in the intracellular  $\text{Ca}^{2+}$  concentration, suggesting T2R’s role in mediating sensing of bitter compounds in these cells (Wu, 2002). T2R and its signaling transduction cascades have also been proposed to mediate CCK release in response to the bitter stimulants DB, PTC and CYX (Chen et al., 2006). However, as mentioned above, more recent studies suggest the role of CaSR and SNAT2 as potential stimulators of CCK release.

## 37.6 IS THERE SENSORY-DIETARY SYNERGY?

Appetite and food intake are guided by multiple environmental factors that overlay highly conserved endogenous systems. The gut is not a passive player. The frequent finding that co-localization of taste transduction signaling molecules and gut hormones occurs in human

enteroendocrine cells raises the possibility that effective taste stimuli also activate processes in the gastrointestinal lumen that modify the gastric and intestinal phases of digestion (Rozengurt et al., 2006; Jang et al., 2007; Hass et al., 2010; Gerspach et al., 2011; Steinert, 2011). However, evidence for the nutritional implications of “taste” transduction signaling pathways post-deglutition are not straightforward.

### 37.6.1 Gut “Taste” Receptors, Flavor Preference, and Appetite

In contrast to the known function of the T1R2 and T1R3 heterodimers as sweet receptors on the tongue, rodent studies suggest that in the gut they do not mediate post-oral sweet preference conditioning. Unlike sucrose, infusion of sucralose into the gut does not condition a flavor preference. Furthermore, T1R3 knockout mice exhibit similar flavor conditioning responses to sucrose infusion as normal mice (Sclafani et al., 2010).

Modulation of appetitive sensations with nutritive and non-nutritive sweeteners also varies. Earlier human studies indicate that acute exposure to non-nutritive sweeteners in mediums of little or no energy increases hunger (Rogers et al., 1988; Tordoff and Alleva, 1990b). In rats, the ingestion of non-nutritive sweeteners may also lead to increased food intake and body weight (Swithers et al., 2010). However, human evidence fails to support modification of appetitive sensations with non-nutritive sweetener use (Steinert et al., 2011a).

### 37.6.2 Gut “Taste” Receptors, and Gastric Emptying

A primary role for enteroendocrine cells in the GI tract is to secrete peptides that regulate the passage of ingesta through the organ. Receptors on these cells that mimic those on taste receptor cells in the oral cavity bind bitter and sweet food chemicals that elicit the release of multiple peptides (e.g., GLP-1, CCK, PYY) that slow gastric emptying (Chen, 2006; Glendinning et al., 2008). The finding that a sweet stimulus, that reportedly signals the presence of a safe and available energy source, as well as a bitter stimulus, that theoretically signals toxicity, result in the same physiological response challenges an ecological interpretation of the phenomenon. Additionally, there may be species differences. Intragastric administration of bitter taste compounds such as PTC and DB delays gastric emptying (Janssen et al., 2011) in mice whereas similar administration of quinine and naringin does not modulate gastric emptying relative to saline in humans (Little et al., 2009).

A primary role for sensory versus nutritive signaling in gastric emptying is uncertain. Intragastric infusion of a nutritive sweetener (e.g., sucrose) in humans delays

emptying, but no effect is observed with a non-nutritive sweetener (e.g., sucralose) (Ma et al., 2009). Similarly, the addition of saccharin to an intragastric infusion of glucose did not alter gastric emptying compared to the glucose solution alone (Little, 2009).

### 37.6.3 Gut Peptides

Ghrelin, an orexigenic gut peptide, increases hunger and promotes energy intake when intravenously administered in humans (Wren et al., 2001). A greater number of ghrelin-positive cells among obese individuals has been reported, with speculation that there is a relationship between energy intake and the number of candidate chemosensory cells in the gastric mucosa (Widmayer, 2011). However, plasma ghrelin concentration peaks have also been observed in anticipation of eating a meal in people with habitual meal patterns rather than the ghrelin spikes eliciting feeding (Frecka and Mattes, 2008). Significantly greater changes in plasma ghrelin levels were also observed when food related pictures were shown to subjects with regular eating patterns (Schüssler et al., 2012). Other work noted that ghrelin concentrations lagged behind hunger sensations (Lemmens et al., 2011), suggesting that concentrations of this appetitive hormone are also regulated through non-taste receptor signaling pathways.

Certain bitter taste receptor agonists such as DB and PTC increase active ghrelin (octanoyl ghrelin) secretion. However, relative mRNA expression of ghrelin remained unchanged with and without the T2R agonists (Janssen, 2011). Furthermore,  $\alpha$ -gustducin knockout mice did not express lower concentrations of active ghrelin in response to bitter gavage relative to wild-type counterparts, questioning the relevance of T2R's role in ghrelin regulation (Janssen, 2011).

Cholecystokinin (CCK), a gut hormone that regulates appetite by reducing meal size and delaying gastric emptying, is particularly responsive to bitter taste compounds, long chain fatty acids, and certain amino acids (Dockray, 2012). CCK may also be released in response to sweet compounds. Infusion of the CCK1a antagonist, dexloxiglumide, inhibits gastric emptying, suggesting a role for CCK in carbohydrate regulation in humans (Little et al., 2010).

GLP-1 is a gut peptide that rises in anticipation of a meal and in response to nutrient intake, exerting both an anorectic and incretin effect (Baggio and Drucker, 2007). One study reported that human duodenal L-cells respond to glucose in the gut lumen by secreting GLP-1 (Jang, 2007). This study also reported dysregulation of plasma insulin and glucose in humans with compromised GLP-1 secretion. In addition, gastric gavage with glucose, sucrose, 2-deoxy-glucose (non-metabolized non-sweet sugar), and sucralose of mice elicits concentration-dependent release of GLP-1. However, conflicting data are also reported.

Activation of orosensory systems with sucralose, Stevia, Saccharin, D-tryptophan and Acesulfame K in Zucker diabetic fatty rats had no effect on GLP-1 and gastric inhibitory peptide –1 (GIP-1) concentrations (Fujita et al., 2009). Further, studies in humans have generally failed to confirm sensory influences on GLP-1 secretion or appetite (Ma, 2009; Ma et al., 2010; Wu et al., 2012). Exceptions are two trials showing oral exposure to a non-nutritive sweet beverage prior to an oral glucose tolerance test augments the GLP-1 response. However, there was no concomitant change of plasma c-peptide or insulin (Brown et al., 2009, 2012). The veracity of this finding has not been established.

### 37.6.4 Gut “Taste” Receptors and Glucose Homeostasis

In rodents, high intensity sweetener (i.e., sucralose, ace-sulfame K and, to a lesser extent, saccharin) ingestion at concentrations as low as 1 mM increases glucose transporter insertion in the apical membrane of enterocytes (Mace et al., 2007). Results from this and another study confirm that intestinal glucose transporters GLUT2, GLUT5, and SGLT1 were mostly expressed in cells with ultrastructural characteristics of taste receptor cells, and that concentrations of T1R1, T1R2, T1R3,  $\alpha$ -gustducin and PLA- $\beta$ 2 changed significantly with exposure to sucrose and sucralose (Mace, 2007; Merigo et al., 2011). High levels of apical GLUT2 are a characteristic of experimental insulin resistance states (Tobin et al., 2008). The absence of apical GLUT2 in lean participants but presence in 76% of obese participants suggests that GLUT2 accumulation might be an adaptation to metabolic pathology (Ait-Omar et al., 2011). Based on the premise that sucralose increases GLUT2 in the apical membrane, ingestion of sucralose should increase blood glucose concentrations. However, infusions of sucralose into the stomach or proximal small intestine of healthy adults result in no change of plasma glucose (Ma et al., 2009, 2010). This may reflect the very high efficiency of glucose absorption, so there is little variance to no treatment effects.

Taken together, the emerging evidence on chemo-detection in the GI tract suggests the potential for many nutritionally relevant sensory-dietary interactions. Presently, there is no clear picture of the interface, but this will likely change with improved testing methods.

## 37.7 EFFECTS OF PRIMARY CHEMOSENSORY DISORDERS ON FOOD ACCEPTABILITY, DIET, AND NUTRITIONAL STATUS

Data on the dietary and nutritional implications of specific primary chemosensory disorders are available from

several chemosensory clinical research centers. However, the number of patients in specific diagnostic groupings is often limited and evaluation and assessment measures differ among centers. In addition, patient characteristics may vary among clinics and account for apparent discrepancies in reported findings. Thus, while the following summary represents the current state of knowledge on this issue, the findings must be interpreted cautiously. It must also be noted that the numerous published reports of chemosensory abnormalities associated with specific pathologies are not reviewed here since many of the dietary and nutritional complications observed in these patients may be attributable to aspects of their pathology and not directly to their chemosensory complaint.

### 37.7.1 Anosmia

A total loss of the ability to smell is one of the most common complaints of patients presenting for treatment to chemosensory clinical research centers (Ferris et al., 1986; Goodspeed et al., 1987; Deems et al., 1991; Mattes and Cowart, 1994; Chapters 17 and 39). Given the importance of olfactory cues from food for judgments of food safety and palatability, anosmics would be predicted to be at nutritional risk. However, the evidence is mixed. There are reports that such patients do not markedly alter their dietary practices (Aschenbrenner et al., 2008; Schubert et al., 2012), while other reports note that between 10 and 40% of patients with non-congenital anosmia increased their use of sugar and seasonings after onset of olfactory dysfunction (Ferris et al., 1985; Mattes and Cowart, 1994; Aschenbrenner, 2008). While this dietary adjustment may enhance the appeal of foods and eating for some, it also poses a potential problem for individuals who must control their intake of sugar (e.g., diabetics) and sodium (e.g., patients with salt-sensitive hypertension). The prevalence of food complaints is inversely related to the duration of the sensory loss and is lowest in congenital anosmics whose responses resemble control subjects (Ferris et al., 1985). The food preference ratings of anosmics are only slightly lower than those of healthy controls. Noted differences varied by food classes, with the largest discrepancy occurring for homogenous items (e.g., puddings, sherbets) (Doty, 1977). Mean energy and macronutrient intake, as estimated by diet records, are similar in patients with anosmia and healthy controls (Ferris et al., 1985; Mattes and Cowart, 1994); however, a small sample of anosmics were less likely to be overweight compared to the healthy population (Robert-Koch-Institut, 2006). A subset of patients experiencing olfactory disorders, including anosmia, are at risk for either weight gain or loss. One study reported that approximately 14% of anosmic patients experience a gain of body weight exceeding 10% of their pre-disorder weight and about 6.5% lose at least this amount (Mattes

and Cowart, 1994). A weight change of this magnitude would not be expected in a healthy non-dieting individual.

### 37.7.2 Hyposmia

Most studies examining the effects of olfactory dysfunction on nutritional status and behaviors fail to distinguish between anosmia and hyposmia when reporting results. The few studies that do separate the various types of olfactory dysfunction estimate the prevalence of food complaints in hyposmic patients to range from 31% to almost 80% (Ferris et al., 1986; Mattes and Cowart, 1994). This wide range in prevalence estimates may be attributable to variations in sample sizes, differences in diagnostic criteria, or patient characteristics. For example, a diagnosis of hyposmia may include patients with small reductions in sensitivity to a limited number of odors as well as individuals who are nearly anosmic (Schubert et al., 2012).

Findings from several studies indicate that more than half of hyposmic patients express food complaints (Ferris et al., 1985; Mattes and Cowart, 1994; Miwa et al., 2001; Nordin et al., 2011). Logically, one might engage in dietary modification (e.g., increasing flavor by adding sweeteners or spices) in the attempt to garner more enjoyment from foods. Evidence of these practices is inconsistent. A recent trial noted no association between olfactory dysfunction and the frequency of adding salt or sugar to foods (Schubert et al., 2012), and another reported no differences in dietary modification practices between normosmic and hyposmic individuals (Aschenbrenner, 2008). In contrast, other work indicates that 20 to 50% of patients with hyposmia report altering their eating patterns and using seasonings. The prevalence of food complaints is inversely related to the duration of the sensory loss (Ferris et al., 1985). Decreased appetite is reported by 10–20% of such patients and a small proportion experience an increase. These patients apparently learn to compensate for their dysfunction by accentuating other aspects (i.e., taste, temperature, texture) of foods to enhance palatability (Davidson et al., 1987).

A decrease in appetite was reported by 56% of patients experiencing olfactory dysfunction (Temmel et al., 2002). However, how this translates into changes in intake and, ultimately, body weight is variable. In one report, over 85% of such patients maintained stable body weight subsequent to the onset of their disorder and indices of nutritional status were comparable between hyposmic patients and healthy controls. Among hyposmic patients who experienced excursions exceeding 10% of their pre-disorder weight, there was a tendency towards weight loss, with 10.6% having a loss of this magnitude or greater and 1.5% experiencing an increase. Another report found 21% of patients exhibiting olfactory dysfunction self-reported an average weight gain of 2.5 kg while 11% of patients reported weight loss averaging 5.1 kg; patients with weight

gain had significantly higher odor identification scores, were more likely to engage in dietary alterations (e.g., use more or less spices), and were younger than those who lost weight (Aschenbrenner et al., 2008). One study found that individuals who experienced marked changes of body weight did not differ by age, gender, or etiology (Mattes and Cowart, 1994). The influence of duration of the disorder on weight changes is variable, with findings of no impact (Mattes and Cowart, 1994) or a positive correlation (Aschenbrenner et al., 2008). At present, there is no predictive index of nutritional risk for patients with recent onset of symptoms.

### 37.7.3 Dysosmia

In one study, 24% of patients diagnosed as parosmic, a form of dysosmia, reported a disorder-related decrease of appetite and 83% indicated that they enjoyed food less (Mattes and Cowart, 1994). Approximately 60% stated that they had altered their eating patterns and use of seasonings. The majority of patients with dysosmia maintain adequate nutritional status, but individual responses may warrant aggressive dietary intervention. At present there are no means to identify patients at high nutritional risk.

### 37.7.4 Ageusia

Complete loss of taste is rare, accounting for less than 1% of patients reporting to chemosensory clinical research centers (Ferris, 1986; Goodspeed, 1987; Deems et al., 1991; Mattes and Cowart, 1994). With available data, it is impossible to draw any general conclusions about the effect of this sensory disorder on diet and nutritional status. Loss of appetite has been observed (Ferris et al., 1986), but increased and decreased body weight has also been reported.

### 37.7.5 Hypogeusia

The incidence of this taste disorder, independent of other chemosensory abnormalities, is low. Some, but not all, report decreased enjoyment of food and decreased appetite (Ferris et al., 1986). When present in combination with hyposmia or anosmia, hypogeusia leads to only a slightly higher incidence of food complaints relative to patients with hyposmia or anosmia alone (Ferris et al., 1986).

### 37.7.6 Dysgeusia

The only data on patients with a single diagnosis of dysgeusia indicate the incidence of decreased appetite is approximately 30% and decreased enjoyment of food is about 70% (Mattes and Cowart, 1994). Roughly 60% of such patients alter their eating patterns and 40% modify their use of seasonings. Based upon reports from patients who may have

had concurrent diminutions of sensory function, the foods most distorted in taste are meats, fresh fruits, coffee, eggs and carbonated beverages (Markley et al., 1983). However, this is highly idiosyncratic and affected items are not necessarily consumed in lesser amounts. A significant decline in fruit and vegetable intake has been observed, especially for individuals with the most severe dysgeusic symptoms. Mean nutrient and energy intake among dysgeusics with no additional sensory disorders were within normal ranges. These intakes were comparable to control subjects in one report (Mattes and Cowart, 1994) and reduced in another (Mattes-Kulig and Henkin, 1985). In neither of these studies was energy intake related to the duration of symptoms. Approximately 15–20% of dysgeusic patients experience a clinically significant change of body weight and/or body composition (Mattes-Kulig and Henkin, 1985; Mattes and Cowart, 1994).

In summary, a high proportion of patients with a primary complaint of a taste or smell disorder experience a loss of appetite and decreased enjoyment of food. Nutrient and energy intake is generally maintained at adequate levels, but individual patients with any of the above diagnoses may experience a marked increase or decrease of body weight. Increases may occur if patients are attempting to achieve a missed level of sensory stimulation or to mask an unpleasant sensation. A decline in intake often occurs if foods contribute to an unpleasant sensation or because of frustration with the lack of appeal of foods. Questioning patients about their compensatory dietary response may provide the best prognostic index of dietary change. Patients reporting increased or decreased intake or more dietary alterations are disproportionately represented in the sub-group of individuals experiencing shifts of body weight that could result in deleterious health consequences. In a study of 396 patients (Mattes and Cowart, 1994), 34 individuals (8.7% of the sample) reported a compensatory increase in intake and represented 35.3% of the group that gained more than 10% of their pre-disorder weight. The 47 patients (12.0% of the sample) who reported decreased intake constituted 38.3% of the sub-group losing this amount of weight.

## 37.8 NUTRITIONAL IMPLICATIONS OF CHEMOSENSORY ABNORMALITIES IN PATIENTS WITH SELECTED CHRONIC DISORDERS

### 37.8.1 Cancer

There is a high incidence of chemosensory complaints among patients with untreated cancers with 86% of cancer patients ( $n=66$ , excluding nasal, oral, and esophageal cancers) receiving palliative care reporting some sort of

chemosensory abnormality (Hutton et al., 2007). This is especially true for those with more advanced cancer (DeWys, 1974). Such symptoms are not a reliable prognostic index (DeWys, 1974; Walsh et al., 1982) in patients receiving treatment. However, some work suggests tumor stage corresponds with taste alterations between 6–12 months after successful radiation treatment of head and neck cancer patients (Epstein et al., 1999). Severity of chemosensory symptoms in hospice patients has been associated with time to death (Hutton, 2007). The nature of reported complaints is highly variable, even among patients with similar pathologies, and the causes are not well understood (Hovan et al., 2010). Reports range from enhanced or diminished sensitivity to specific taste qualities or odors to generalized alterations (Trant et al., 1982; Hutton, 2007; Sanz Ortiz et al., 2008; Boer et al., 2010). The relationship between chemosensory complaints and diminished appetite, altered food preferences, or loss of body weight in untreated cancer patients is variable, with some finding no association in patients undergoing active treatment (Carson and Gormican, 1977; Trant, 1982; Bruera et al., 1984) and others suggesting a negative relationship between the presence, number, and severity of chemosensory symptoms and intake in palliative-care patients (Hutton et al., 2007; Bovio et al., 2009). Patients who reported either dysgeusia or hypogeusia consumed about 300 kcal/day less than patients without the complaint (Bovio, 2009). Patients with the most severe complaints consumed between 900–1,100 kcal less per day than patients with no complaints, were more likely to report decreased appetite, and consumed more energy from carbohydrates, less from fat and a comparable amount, of protein (Hutton et al., 2007). Weight loss in the past six months was greater among those reporting a chemosensory problem than those without a chemosensory complaint.

External radiation therapy involving the oropharyngeal region diminishes the number of taste buds (Yamashita et al., 2006b), induces changes to receptors (Goldberg et al., 2005), and damages supporting tissues (e.g., salivary glands) (Cooper, 1968; Conger and Wells, 1969; Mossman, 1986; Ophir et al., 1988). Such changes can lead to dysgeusia and/or hypogeusia. Taste detection thresholds in oral cancer patients did not differ from healthy controls prior to radiation treatment; however, taste sensitivity was reduced relative to baseline when tested one month after radiation treatment and had recovered to baseline levels at six and twelve months after treatment for all four tastes (Sandow et al., 2006). Others report reduced taste function may persist for years after radiation therapy (Mossman et al., 1982). Advances in treatment may reduce these side effects. When partial loss occurs, salt and bitter are the most severely affected qualities. Taste impairment is generally noted during the second week of treatment (Mossman et al., 1994) but can start within two to three

days of treatment initiation (Sandow et al., 2006). Taste impairment is noted among patients with the greatest amount of tongue exposed to radiation (Yamashita et al., 2006a). Because the recovery rates for different aspects of gustatory function vary and individual awareness of these disorders differs, it is difficult to counsel patients regarding the expected duration of symptoms. Typically, the ability to detect or recognize low concentrations of a taste quality recovers within several months whereas suprathreshold sensations may require a year or more to normalize (Mossman et al., 1982; Epstein, 1999; Epstein et al., 2001) or, in some cases, fail to return to pre-treatment levels (Ripamonti et al., 1998; Epstein et al., 1999, 2001). Olfactory loss can occur if olfactory receptors are in the field of radiation and may be persistent (Ophir et al., 1988), but increased sensitivity to unpleasant odors is more frequently self-reported (for a review, see (Hong et al., 2009). Reduced food intake and loss of body weight are more common in patients experiencing radiotherapy-related chemosensory disturbances than in those with alterations attributable to the pathology alone (Mossman and Henkin, 1978; Bolze et al., 1982).

Chemotherapy regimens may also produce gustatory disturbances (Carson and Gormican, 1977; Mulder et al., 1983), with nearly 70% of patients reporting taste alterations during at least one point during treatment (Wickham et al., 1999; Ravasco et al., 2005; Zabernigg et al., 2010). Resolution of acute dysgeusia, typically bitter or metallic sensations, associated with chemotherapy treatment may occur between several hours of administration to three weeks (Wickham et al., 1999). Dysgeusia has also been linked to reduced energy intake and a higher incidence of food aversions, especially for meats (Markley et al., 1983). However, it cannot be assumed that this is primarily attributable to the chemosensory disturbance. Other complications of the disease or treatment (e.g., oral lesions, difficulty swallowing) may contribute to a reduction of appetite. Some efficacy of zinc sulfate administration in managing treatment-related taste disorders in patients with low zinc levels has been reported. However, changes in taste were not associated with changes of body weight (Ripamonti, 1998), and it must be emphasized benefits may be restricted to those with compromised zinc status. Current recommendations do not support the use of zinc gluconate to prevent chemotherapy- or radiation-related dysguesia (Hovan, 2010).

### 37.8.2 Hypertension

Various aspects of salt taste have been evaluated in selected sub-groups of hypertensive patients. Detection thresholds are similar in hypertensive and normotensive individuals. In the subset of studies noting a discrepancy between patients and controls for recognition thresholds, values

were higher for the former group (Mattes, 1984; Isezu et al., 2008), with one study finding differences only in women (Michikawa et al., 2009). Hypertensive patients have normal or reduced salivary sodium levels (Niedermeyer et al., 1956). The latter should enhance sensitivity to external stimulation by salt. No explanation for the conflicting evidence is apparent. Comparable intensity ratings for suprathreshold salt stimuli have been obtained from healthy controls and: (1) unselected samples of hypertensive patients (Mattes et al., 1983; Barylko-Picielna et al., 1985; Little and Brinner, 1985), (2) patients with low normal plasma renin activity (Bernard et al., 1980), and (3) individuals classified as salt-sensitive (Mattes and Falkner, 1989; Mattes et al., 1999). There is suggestive evidence that hypertensive subjects show larger shifts in salt intensity ratings when on a sodium-restricted diet as compared to controls (Zumkley et al., 1987), but the reliability and implications of this observation have not been determined.

While a heightened preference for salt has been noted in several studies of hypertensive patients, the preponderance of evidence indicates hypertensive and normotensive individuals do not differ on this attribute (Mattes, 1984; Little and Brinner, 1985). Similar hedonic ratings have also been observed between salt-sensitive and non-salt-sensitive subjects (Mattes and Falkner, 1989; Mattes, 1999), although the latter group shows a greater increment in acceptability of reduced salt foods when on a salt restricted diet (Mattes, 1999). There is no evidence of salt cravings in untreated or treated patients with hypertension.

A large number of drugs are known to cause taste disturbances (Tomita and Yoshikawa, 2002), including antihypertensive medications that do not only involve salty taste (Clee and Burrow, 1983; Schiffman, 1983; Coulter, 1988; Doty et al., 2003). Thiazide diuretics reportedly increase salt taste sensitivity (Langford et al., 1977), although other studies have failed to confirm this effect (Mattes et al., 1988; Mattes and Engelman, 1992). Angiotensin converting enzyme (ACE) inhibitors decrease taste sensitivity, with 70% of patients reporting symptoms (Doty, 2003). Zinc deficiency may be a consequence of ACE inhibitors as well as diuretics (Zumkley et al., 1985; Abu-Hamdan et al., 1988; Golik et al., 1998; Trasobares et al., 2007; Kusaba et al., 2009), but findings vary (O'Connor et al., 1987). Different measures of zinc deficiency and dosages of ACE inhibitors may explain the conflicting results. Angiotensin-II receptor blockers decrease detection threshold sensitivity for sweet, sour, bitter, and salty taste qualities (Tsuruoka et al., 2005b) even in healthy volunteers (Tsuruoka et al., 2005a). While taste disturbances generally resolve when the medication is eliminated, this is not always an option for patients.

### 37.8.3 Hypothyroidism

Case histories indicate that hypothyroidism, hyperthyroidism, or pharmacologic treatment of these conditions can result in alterations of olfactory sensitivity and odor recognition (McConnell et al., 1976; Lewitt et al., 1989; MacKay-Sim, 1991). Olfactory thresholds were elevated for some (e.g., pyridine, nitrobenzene), but not all (2-phenylethanol) test stimuli, suggesting the impairment is not generalized. Thresholds improve following hormone replacement therapy (Deems et al., 1991), but patient complaints about sensation may persist. The mechanism(s) underlying olfactory changes in hypothyroidism have not been determined but may include altered secretions in the nasal cavity, changes of the olfactory epithelium, and/or modified function of the olfactory bulb.

The incidence of taste dysfunction in hypothyroid patients is not known, but estimates range up to 83% (McConnell et al., 1976; Mattes et al., 1986; MacKay-Sim, 1991). Patients with hypothyroidism express little interest in eating, but available evidence is variable in terms of hedonic responses to foods with some reporting no change (Mattes, 1986; Lewitt et al., 1989) while others find decreased hedonic value for sweetness but increased values for salty and bitter (Bhatia et al., 1991). Dysgeusia may occur in as many as 39% of hypothyroid patients (Mattes, 1986). Consistent with studies in rats showing no change in taste sensitivity with propylthiouracil treatment (Brosvic et al., 1992), taste thresholds of patients with recent onset of hypothyroidism are comparable to controls (Mattes, 1986). In contrast, longer-standing deficiency may be associated with measurable changes (McConnell, 1976). Suprathreshold function may be impaired before changes of threshold sensitivity are manifest (Mattes, 1986). The degree of taste impairment is not correlated with disease severity (Pittman and Beschi, 1967). Ambiguous results have been obtained on measures of taste preferences, as different tests yield discrepant findings. Studies in rats have also noted inconsistent effects of hypothyroidism on hedonic responses (Rivlin et al., 1977; Brosvic et al., 1992). Restoration of normal hormone status leads to a normalization of threshold sensitivity and suprathreshold function as well as taste preferences (Mattes, 1986; Deems et al., 1991). However, burning mouth syndrome and dysgeusia have been observed in 23.1% and 20.5%, respectively, of patients treated with levothyroxine (Deems, 1991). Burning mouth syndrome has been associated with decreased body mass index (Deems et al., 1991). Medications for the treatment of thyroid disease are frequently associated with gustatory complaints (for a review, see (Doty et al., 2008)). The mechanisms underlying the gustatory changes associated with hypothyroidism have not been elucidated but may include alterations of salivary secretion, central

or peripheral neural function, cellular metabolism and/or epithelial integrity.

### 37.8.4 Obesity

Studies of the sensory function of obese individuals have largely focused on responses to sweets and fats. Threshold sensitivity and suprathreshold intensity judgments of sweet stimuli are similar in the lean and obese (Grinker et al., 1972; Grinker, 1978; Malcolm et al., 1980; Rodin, 1980; Witherly et al., 1980; Frijters and Rasmussen-Conrad, 1982; Drewnowski, 1987). Reported hedonic responses to sweetness are more varied. Both heightened and depressed pleasantness ratings have been noted in obese individuals (Rodin et al., 1976; Drewnowski, 1987; Mela, 2006), but the preponderance of evidence indicates there is no association between such ratings and body weight (Spitzer and Rodin, 1981; Frijters and Rasmussen-Conrad, 1982). In contrast, hedonic ratings of sweetness reportedly rise during restriction of energy intake (Cabanac, 1971; Rodin et al., 1976). Whether or not this hedonic shift influences adherence to energy restricted diets is unknown. In one of the few prospective studies on hedonic ratings and weight gain, pleasantness of sweet solutions did not change from baseline after weight was gained (Salbe et al., 2004).

Accumulating evidence supports the claim that humans can taste non-esterified fatty acids (NEFA) (for a review, see Tucker et al., 2014). Associations between sensitivity and BMI are variable with some finding negative associations between BMI and sensitivity to either NEFA in model solutions or triacylglycerols in foods (Stewart et al., 2010; Stewart and Keast, 2012) and others finding no difference (Liang et al., 2012). A retrospective analysis of earlier studies also found no evidence of association between BMI and detection thresholds to caproic, lauric, or stearic acid (Mattes, 2011a). Habitual dietary fat intake may influence sensitivity. A low-fat diet over four weeks improved sensitivity to oleic acid in both lean and overweight subjects, but consumption of a high-fat diet decreased sensitivity only in the lean group (Stewart and Keast, 2012). How NEFA detection influences dietary fat intake remains unknown.

The obese have exhibited a greater preference for high-fat foods than for low-fat items compared to lean controls in some (Drewnowski et al., 1985), but not all (Pangborn et al., 1985; Warwick and Schiffman, 1990), studies. These apparently conflicting findings may be attributable to the types of stimuli used in testing. Hedonic responses to fat by the lean and obese may be differentially influenced by other characteristics of the stimulus such as sweetness and rheology (Drewnowski, 1985; Drewnowski et al., 1989). In addition, sensory responsiveness may vary with the timing and duration of obesity (Drewnowski et al., 1990).

While earlier studies focused on hedonics, more recent work has focused on differences in chemosensory sensitivity between the lean and obese. Olfactory deficits occur more frequently in type IV obesity ( $BMI > 45$ ) than leaner subjects ( $BMI < 45$ ) (Richardson et al., 2004). Prior to gastric bypass surgery, patients were more likely to suffer from olfactory dysfunction than controls undergoing cholecystectomy; these deficits were still present one year after surgery, and 20% of patients with normal olfactory function before gastric bypass surgery developed olfactory disorders after surgery (Richardson et al., 2012). Thus, olfactory dysfunction seems to be independent of weight loss or gain and may be present regardless of weight status. Retronasal olfaction may also influence intake, with a trend for higher sensation to discourage *ad libitum* intake (Ruijschop et al., 2009). However, no studies have been conducted on this issue in an obese population. The exact time course of olfactory dysfunction and obesity onset has yet to be characterized.

Following gastric bypass surgery, increased taste sensitivity and decreased hedonic responses to sweet tastes have been noted (Rodin, 1980; Burge et al., 1995; Tichansky et al., 2006) (for a review, see (Miras and le Roux, 2010)). Sensory thresholds during weight loss by dieting are variable with one report noting no changes in recognition thresholds (Burge, 1995), and another documenting improvements in recognition thresholds (Umabiki et al., 2010). Changes in liking do not typically occur after weight loss due to dieting (Rodin, 1976; Johnson et al., 1979; Drewnowski and Holden-Wiltse, 1992), but others suggest that changes depend on the amount of weight lost and the amount of time that has passed since the weight loss (Kleifield and Lowe, 1991). More recent “big” losers liked sucrose solutions more than recent “smaller” losers, and long-term “big” losers liked sucrose solutions less than long-term “smaller” losers.

### 37.8.5 Diabetes

Disturbances of taste and smell occur in over 60% of patients with diabetes (Settle, 1991). It should be noted that these patients frequently suffer from comorbidities including hypertension and obesity, both of which may alter chemosensory function as discussed above. The most consistent sensory change is an elevated glucose taste threshold in patients with glucose intolerance and in individuals with a family history of diabetes. Taste perception of other qualities remains largely intact (Perros et al., 1996). The mechanisms have not been identified but may involve nerve degeneration, alterations in salivary glucose concentrations, and various biochemical changes. The specificity of changes and apparent genetic influence suggest an abnormality of glucose receptors in some cases, but evidence that the severity of gustatory symptoms increases

with progressing neuropathy (Abbasi, 1981) supports a neural explanation in others. Patients with uncomplicated diabetes had taste recognition and olfactory identification scores comparable to controls in one study (Naka et al., 2010), but others report taste recognition deficits in both controlled and uncontrolled diabetics compared to controls (Gondivkar et al., 2009). Differences in taste testing methodology might contribute to these contradictory findings. Aguesia to sweet taste was significantly more likely to occur in uncontrolled diabetics, and hypogeusia to sweet, sour, and salty tastes was significantly more likely to occur in diabetics compared to controls (Gondivkar, 2009). There is a direct relationship between disease severity and the risk for chemosensory complaints. There are also reports of olfactory deficits associated with degenerative complications and comorbidities (Le Floch et al., 1993; Weinstock et al., 1993; Naka, 2010). It should be noted that as the disease progresses, the likelihood of a patient taking medications that can influence chemosensory function increases. The influence of sensory changes associated with diabetes on food selection has not been determined, but there is evidence of heightened sweet preference and sweet food intake among women with gestational diabetes (Tepper and Seldner, 1999; Belzer et al., 2009).

### 37.8.6 Chronic Kidney Disease

Chronic kidney disease (CKD) patients often suffer from hypertension and problems with chemosensory function, especially due to medication use, likely extend to these patients as well. Elevated taste recognition thresholds may occur in patients with renal disease. However, the qualities affected have varied across studies and patient groups. Some indicate sweet and sour are the most severely affected (Burge et al., 1979; Anon, 1981) whereas others observed greater impairment for bitter and salty tasting stimuli (Fernstrom et al., 1996; Middleton and Allman-Farinelli, 1999). CKD patients reporting poor or very poor appetite were more likely to report taste and smell changes and have lower BMI scores compared to those with good appetites (Bossola et al., 2011). Dialysis leads to an improvement of chemosensory function (Anon, 1981; Burge et al., 1984), but dialysis patients may also experience dysgeusia in the form of a metallic taste (Dirschnabel et al., 2011). Renal transplantation may normalize taste sensitivity 12–18 months following surgery (Mahajan et al., 1984). Early studies suggested the impairment in taste sensitivity was related to reduced zinc status (Mahajan et al., 1980). The preponderance of data does not support this claim, although it may hold merit in the sub-group of patients with a documented marked deficiency (Anon, 1981; Burge et al., 1984). An explanation for the shift in threshold sensitivity has not been identified. In contrast, intensity ratings for suprathreshold concentrations of taste stimuli are similar

in uremic patients and controls as well as within patients over the course of a dialysis treatment (Shapera et al., 1986; Shepherd et al., 1987). Patients on hemodialysis and continuous ambulatory peritoneal dialysis report avoiding red meat, with hemodialysis patients reporting more foods, including poultry and fish, that were less pleasant than peritoneal dialysis or control subjects (Dobell et al., 1993). Dialysis patients are typically counseled to consume a high-protein diet; these taste changes may make compliance difficult. A recent trial noted one week of sodium restriction improved salty recognition thresholds but not detection thresholds in a group of CKD patients (Kusaba et al., 2009).

Olfactory quality recognition performance is typically lower in renal patients than healthy controls (Schiffman et al., 1978; Conrad et al., 1987; Griep et al., 1997; Landis et al., 2011); although, one study found that renal patients without malnutrition performed as well as healthy controls (Raff et al., 2008). Those patients suffering from olfactory dysfunction may not be aware of the decline (Frasnelli et al., 2002; Landis, 2011). However, in one study (Schiffman et al., 1978) patients rated food odors as less pleasant. Poor performance in odor perception was associated with higher serum urea and higher protein catabolism but not with BMI (Griep, 1997). Yet, another study found that patients who did poorer at identifying odors were more likely to be malnourished (Raff et al., 2008). Dialysis exerts no measurable effect on performance in some studies (Schiffman et al., 1978; Griep et al., 1997), further decrement in others (Conrad et al., 1987; Corwin, 1989), and improvement in a more recent study (Landis, 2011), which could reflect advances in hemodialysis compared to the earlier trials. These observations on dialyzed patients indicate that uremic toxins either do not account for the olfactory disturbances, or there are retained uremic toxins that have not yet been identified (Raff et al., 2008). The mechanism remains unknown, but an association between higher levels of C-reactive protein and poorer olfactory performance has been reported, suggesting that a pro-inflammatory state negatively impacts olfaction (Raff et al., 2008). Olfactory function normalizes after transplant (Griep et al., 1997). The effect of olfactory changes on food habits in this population is unknown.

### 37.8.7 Liver diseases

Decreased taste and smell threshold sensitivity occurs in patients with cirrhosis of the liver (Burch et al., 1978; Weismann et al., 1979; Garrett-Laster et al., 1984; Pabinger et al., 2000; Temmel et al., 2005), acute viral hepatitis (Smith et al., 1976), virus-associated hepatitis (Zucco et al., 2006; Nagao et al., 2010), and liver disease, cause not specified (Landis et al., 2004). Liver transplantation results in quality-specific (salt, phenethyl alcohol)

improvement of these disorders (Bloomfeld et al., 1999). While correlations between chemosensory function and plasma levels of zinc, vitamin A, and protein have not been observed, supplementation with these nutrients may result in a normalization of sensation. Whether or not alterations of chemosensory function contribute to the reduction of appetite and changes of food preferences associated with hepatic pathology is unknown (Deems et al., 1993). In one study of hepatitis C patients receiving treatment with pegylated interferon and ribavirin, recognition of sweetness and saltiness decreased and bitter tastes were rated as more unpleasant over the 12 weeks of treatment (Klimacka-Nawrot et al., 2010). Appetite decreased in these patients over the course of the treatment, but food preferences did not change. It has also been hypothesized that taste disorders accompanying liver disease have a neural origin (Bergasa, 1998).

In summary, chemosensory abnormalities have been documented in patients with a variety of health disorders. The extent to which a change of taste and/or smell alters food intake and thereby contributes to the etiology or sequelae of these diseases or hampers recovery by adversely influencing adherence to therapeutic diets or recuperative processes remains unknown.

### **37.9 GUIDELINES FOR THE DIETARY MANAGEMENT OF PATIENTS WITH CHEMOSENSORY DISORDERS**

Because no predictable dietary response has been identified for any chemosensory abnormality, the dietary management of patients must be individualized. The approach used must be based upon sound nutritional principals (i.e., balance, variety, and moderation) because for many patients, adherence will be required for extended periods of time. To be effective, it is necessary to address the full range of environmental and physiological factors influencing ingestive behavior. To date, no specialized dietary management approach has been developed and tested, but several recommendations may be made based upon the available data. One important issue concerns the use of nutrient supplements. It is preferable to obtain all nutrition from foods as this route is most likely to provide nutrients in biologically available forms and in reasonably balanced proportions. If this is not feasible, a supplement that provides up to 100% of the recommended dietary allowances for the individual may be appropriate. Patients should be advised that ingestion of high levels of specific nutrients, even water soluble vitamins, may be harmful and exacerbate their problem. Peripheral neuropathy has been reported following excessive intake of pyridoxine

(Schaumburg et al., 1983; Gdynia et al., 2008; Scott et al., 2008).

Evidence that zinc deficiency may lead to chemosensory abnormalities has prompted recommendations to treat such disorders with high levels of this nutrient. However, this practice may only be effective in individuals where a frank zinc deficiency is the underlying basis for the sensory disorder, and symptoms may resolve as quickly as one month after initiating treatment, provided the therapy is started within six months of deficiency (Takaoka et al., 2010). Double-blind studies indicate that for the majority of patients, zinc supplements will offer no therapeutic benefit (Henkin et al., 1976; Greger and Geissler, 1978; Gibson et al., 1989), and studies of patients with chemosensory dysfunction taking or not taking zinc supplements reveal no differences (Deems et al., 1991). Indeed, at the doses often recommended, other adverse effects such as gastric distress, iron-deficiency anemia, copper deficiency, neutropenia, and impaired immune function may occur (Fosmire, 1990; Takaoka et al., 2010).

A recent case report suggested that vitamin D administration in a vitamin D deficient cancer patient undergoing chemotherapy ameliorated dysgeusia (Fink, 2011). Vitamin D's role in cell proliferation, differentiation, and death may explain its effectiveness, as taste receptor cells turn over approximately every 10 days. The prevalence of vitamin D deficiency worldwide is estimated to be 50% (Nair and Maseeh, 2012).

Fortification of foods with natural food odors and tastes has been proposed as a means for enhancing the sensory appeal of items for individuals with diminished chemosensory ability (Schiffman, 2000). However, the available evidence is not strongly supportive of the efficacy of this approach (Mattes, 2011a). If a decrement of intake is not attributable to a decline of sensory function, this approach may not be effective. This method would also be ineffective with anosmic and/or ageusic patients and those with chemosensory distortions. Flavor amplification can reduce the appeal of foods if flavor notes unaffected by the chemosensory disturbance are amplified. Determination of the optimal level of flavor amplification for individual patients may be problematic, but the concept warrants further consideration. Rather than amplifying a flavor component that is not perceived normally by a patient, it may be useful to emphasize the other sensory characteristics of foods. Thermal, textural, irritant, and visual characteristics of foods are important determinants of acceptability and can be accentuated to provide greater variety and appeal to foods that cannot be tasted or smelled. However, this approach must be implemented under appropriate guidance since increased use of certain seasonings and food constituents (e.g., salt, sugar, fiber) can have adverse nutritional effects in selected individuals.

There are a number of additional modifications to the diet or eating process that may help reduce the impact of chemosensory disorders that are both easy and inexpensive to implement. The use of plastic utensils may help to diminish metallic sensations in the oral cavity (Hong et al., 2009). Consuming fluids while eating may help dissolve taste compounds and aid in reaching the taste bud, and chewing slowly may help with flavor release and saliva production (Mosel et al., 2011). Artificial saliva may also help with dysgeusia resulting from xerostomia (Diaz-Arnold and Marek, 2002) while candies or sugar-free gum may be recommended to increase salivary flow (Vissink et al., 1988). Case reports suggest improvement in dysgeusia with administration of an ice cube before eating (Fujiyama et al., 2010) and improvement in parosmia with the use of nose clips (Muller et al., 2006). Serving food at room temperature or chilled can reduce offensive odors.

## Conditioned Taste Aversions

KATHLEEN C. CHAMBERS

### 38.1 INTRODUCTION

#### 38.1.1 Description of Conditioned Taste Aversion

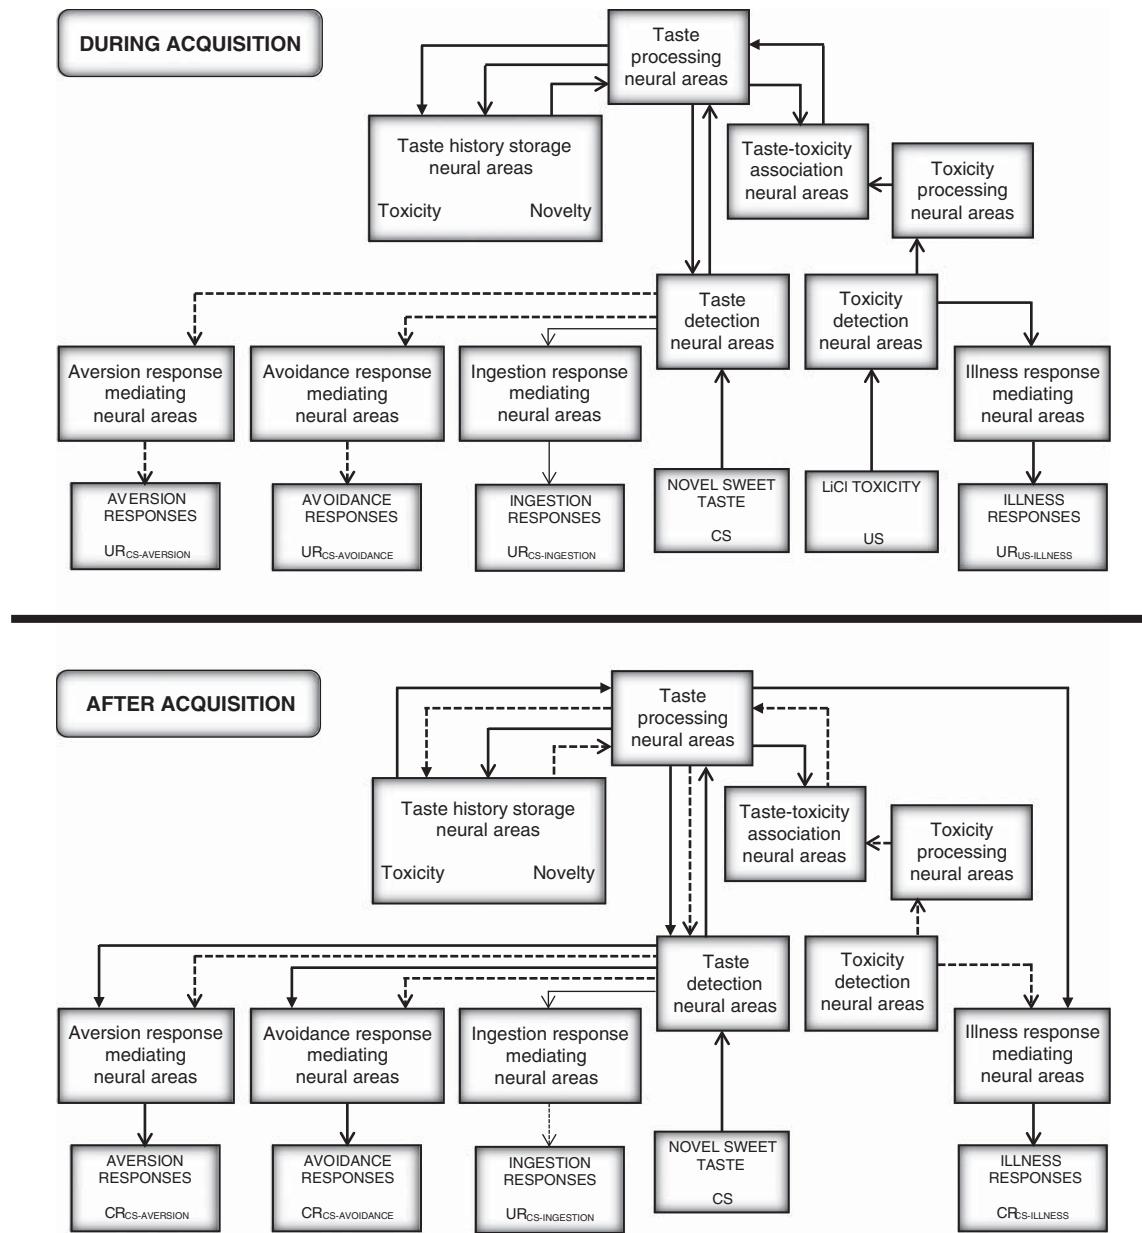

Conditioned taste aversions (CTAs) are those that develop on the basis of experience with a food or drink. The experience on which such aversions are based is often the consumption of a food or drink prior to a bout of illness. The illness can be a consequence of ingestion or it can be coincidentally associated with consumption of a food or drink, such as happens when one acquires aversions during a bout of flu. There is a strong propensity for humans and other animals to “blame” any illness on some ingested food (Garb and Stunkard, 1974). Learned aversions tend to be idiosyncratic, that is, individuals differ from one another with respect to the targeted food or drink that becomes associated with the illness. Most meals include a number of different food items and thus identifying the culprit can be problematic. Blame is more likely to be directed towards less preferred and less familiar foods. There also are certain types of foods that are more likely to be targets; close to half of all learned taste aversions are directed towards major protein sources (red meats, poultry, fish, and eggs) while infrequent targets include sweet (cakes and pies) and nonsweet carbohydrates (bread, crackers, rice, and potatoes; Logue, 1985; Midkiff and Bernstein, 1985; Mooney and Walbourn, 2001). Some humans have reported aversions persisting since childhood or more than 50 years (Garb and Stunkard, 1974). However, it has been shown in animals that learned aversion can be extinguished and palatability restored if the food is experienced without subsequent illness (Dwyer, 2009; Spector et al., 1983).

In the laboratory, CTA is most commonly induced by administering a chemical agent (usually the agent lithium chloride, LiCl) that produces some type of illness

(unconditioned stimulus, US), after consumption of a food or drink (usually a highly palatable solution such as sucrose or saccharin flavored water) that has a novel taste (conditioned stimulus, CS). After such a pairing, individuals learn an association between the sensory properties of the novel food or drink and the sensory properties of the toxic agent (CS-US association). As a result of this learned association, there is a change in the behaviors expressed when individuals again encounter the food or drink. These conditioned responses (CR) can be divided into three categories (see Figure 38.1).

First, individuals will exhibit responses that are similar to the unconditioned responses (URs) elicited by the illness-inducing agent. In rats, LiCl elicits lying-on-belly, hypothermia, and decreased heart rate and after a novel taste has been paired with LiCl, the conditioned taste will elicit these same responses (Bull et al., 1991; Kosten and Contreras, 1989; Meachum and Bernstein, 1990). In humans, simply hearing or thinking about a conditioned taste elicits reports of nausea (Garcia, 1989). This type of learned response to the CS is referred to as a conditioned illness response ( $CR_{CS-ILLNESS}$ ).

Second, individuals will show reduction in the consumption of the conditioned taste. Measurements of this reduction include comparisons before and after CS-US pairing in the amount consumed, the number of ingestive orofacial responses (a series of rhythmical mouth movements and alternations between tongue protrusions and tongue retractions that result in swallowing a liquid), the number of licks from a drinking spout, and the preference for the conditioned taste when it is made available along with another taste substance (Bernstein and Goehler, 1983; Grill and Berridge, 1985; Kent et al., 2002). This type of learned response to the CS is referred to as a conditioned avoidance response ( $CR_{CS-AVOIDANCE}$ ).

**Figure 38.1** A simplified schematic showing the hypothesized basic neural components that mediate conditioned taste aversion during and after acquisition. During acquisition, a taste conditioned stimulus (CS) is recognized by taste detection areas, which send the information to taste processing areas, which access storage areas for taste history, determine that the taste is novel, and then send this information to taste-toxicity association areas as well as back to the taste detection areas. The taste detection areas send a weak (neophobia) activation (innate sweet preference) signal to the ingestion unconditioned response (UR) areas but not the avoidance/aversion (allesthesia) UR areas. A toxic unconditioned stimulus (US) in the food is recognized by the toxicity detection areas, which send the information to toxicity processing areas, which send processed toxicity information to the taste-toxicity association areas and this converged information, is sent to taste storage areas via taste processing areas. Upon encountering the taste again, the forging of new connections during acquisition based on taste-toxicity integration are revealed: taste toxicity history conveyed to CS response mediating areas, which activate aversion/avoidance responses and to illness response mediating areas, which activate illness responses. Lines and Arrows: solid lines represent a connection that is activated, dotted lines represent a connection that is not activated, the open arrows represent the direction of the flow of taste or toxicity information, and the closed arrows represent the direction of the flow of integrated taste-toxicity information. Abbreviations: UR<sub>CS-INGESTION</sub>, ingestion UR in response to the CS; UR<sub>US-ILLNESS</sub>, an illness UR in response to the US; CR<sub>CS-AVOIDANCE</sub>, an avoidance CR in response to the CS; CR<sub>CS-AVERSION</sub>, an aversion CR in response to the CS; CR<sub>CS-ILLNESS</sub>, an illness CR in response to the CS.

Third, individuals will display responses that are indicative of a negative hedonic shift or an aversion. When rats are poisoned after consuming a sweet taste such as sucrose, which is liked at birth, their subsequent behavioral responses to sucrose resemble those exhibited after consumption of a bitter taste such as quinine, which is disliked at birth. These behavioral responses include increases in aversive orofacial/somatic responses, spillage of food from eating containers, and defensive burying of drinking spouts (Grill and Berridge, 1985; Parker, 1988; Rozin, 1967). In a series of studies, Parker and her associates have presented compelling evidence that the combination of the orofacial/somatic responses paw treading, chin rubbing, and mouth gaping (tongue retraction followed by long-duration tongue protrusion and mouth closure) best represent conditioned aversion in rats and that gaping is the predominant aversive response (see Parker et al., 2009). The muscular movements of the gaping response shown by rats who do not vomit are similar to those made by emetic species and orofacial topography of gaping is strikingly similar to the retch response that precedes vomiting in the insectivore shrew, *Suncus murinus*, suggesting that for the rat, gaping is an incipient vomiting response<sup>1</sup> (Parker et al., 2009; Travers and Norgren, 1986). Other species have their own species typical aversive responses. For example, coyotes respond to beef previously paired with poison by urinating on and rolling over it (Garcia et al., 1985). Anecdotal reports in humans indicate that thoughts of learned food aversions elicit facial expressions of loathing similar to those expressed in response to innately disliked foods and those who avoid food that previously had been followed by emesis report that the avoided food is distasteful (Garcia, 1989; Steiner, 1979). This type of learned response to the CS is referred to as a conditioned aversion response (CR<sub>CS-AVERSION</sub>).

The majority of investigations of CTA have assessed aversion learning by only measuring CR<sub>CS-AVOIDANCE</sub>. However, there is consensus that true CTA involves a hedonic shift and thus some evidence of aversion is required before one can call the reduced consumption a CTA (Garcia, 1989; Hunt and Amit, 1987; Parker, 1995). The importance of this verification is demonstrated by two types of studies, one type showing that some agents induce avoidance but not aversion and the other type showing that conditioned reductions in consumption can occur for reasons other than learned aversion. With respect to the first type of study, there are drugs such as apomorphine that are regarded as rewarding because they are effective

positive reinforcers in a drug self-administration paradigm (Hunt and Amit, 1987). The fact that they do not produce CR<sub>CS-AVERSION</sub> but induce CR<sub>CS-AVOIDANCE</sub> at the same doses that are rewarding suggests that the learned reductions in consumption are based on something other than taste aversion conditioning (Parker, 1995; Parker and Brosseau, 1990). It has been suggested it is based on reward comparison (Grigson 1997). In a typical example of this type of situation, animals are given access to a saccharin solution, which is less preferred, before they are given access to a sucrose solution, which is more preferred. They learn that the presence of the saccharin solution predicts the future availability of the sucrose solution, and they consequently reduce their consumption of the saccharin solution (Flaherty and Checke, 1982; Lucas et al., 1990). When applied to rewarding drugs, animals learn that the saccharin CS, which is given first, predicts the future availability of the rewarding drug US, which neurally activates similar hedonic areas as highly preferred sucrose.

With respect to the second type of study, reduced consumption can be learned on the basis of satiety. In both rats and humans, pairing a food with satiating properties can produce learned reduction in the consumption of that food (Booth, 1985). In one study, human subjects were given either high-calorie or low-calorie soups along with a plate of small sandwiches on each of two separate occasions, for a total of four exposures (Booth et al., 1972). The high- and low-calorie soups had different and distinctive flavorings and the caloric value of the high-calorie soup was obtained by adding a starch that could not be detected by taste. During the first exposure to each of the soups, the subjects ate the same number of sandwiches. However, during the second exposure to each of the soups, the subjects ate fewer sandwiches with the high-calorie soup and more sandwiches with the low-calorie soup. Thus, in one trial, the subjects were able to learn to associate the taste of the soup with the satiating properties of the food and to adjust their consumption levels accordingly. The implication of these studies is that the neural mechanisms mediating learned reduction in consumption based on illness, reward comparison, or satiety are different.

### 38.1.2 What Kind of Learning?

Although CTAs have been of scientific interest since 1887 (Poulton, 1887; Rzoska, 1953; Steiniger, 1950), it was not until Garcia and his associates presented it as a challenge to existing theories of learning that the study of this topic mushroomed (Garcia et al., 1966; Garcia and Koelling, 1966). Countless discussions of whether CTA constituted a new kind of learning or whether it could be considered a

<sup>1</sup>Nausea has been placed in the illness response category for humans because LiCl can induce nausea and vomiting in humans and as such it is a UR. In contrast, there are no reports in rats that the retch-like gaping response is a UR to LiCl; therefore it has been placed in the aversion response category.

form, albeit anomalous, of instrumental or classical conditioning ensued. Most investigators placed CTA within the Pavlovian or classical conditioning framework. In classical conditioning paradigms, a US that elicits a UR is paired with a CS that does not elicit the  $UR_{US}$  and learning is inferred when presentation of the CS produces a CR similar to the  $UR_{US}$ . The critical problem when thinking about CTA within the framework of classical conditioning is that behaviors that are generally regarded as the CR, avoidance and aversion responses, are entirely part of the repertoire of unconditioned elicited responses for the taste CS, that is, the  $UR_{CS}$  (Chambers, 1990). Under most circumstances before conditioning, a sweet taste will elicit consumption and positive reactions, such as ingestive orofacial/somatic responses, in rats, but when they are satiated, this taste will elicit negative reactions, such as avoidance and aversive orofacial/somatic responses (Grill and Berridge, 1985). Furthermore, although the reduction in consumption of the CS after conditioning appears similar to the unconditioned anorexia elicited by the illness US, it is specific to the CS rather than generally applied to most foods as is the case during illness<sup>2</sup>. This information led some investigators to suggest that CTA is different from many other forms of classical conditioning. However, there is no need to invoke a new form of learning for CTA (Chambers and Bernstein, 2003).

In studies of traditional classical conditioning situations, the  $CR_{CS}$  often closely resembles the  $UR_{US}$ , although it generally does not become identical to the  $UR_{US}$  (Holland, 1984; Rescorla, 1988). It can lack the intensity and some of the repertoire of the  $UR_{US}$ . There are cases, however, when the  $CR_{CS}$  produced by a given CS can include some responses that are not part of the  $UR_{US}$  and can even include a  $CR_{CS}$  that is opposite that of the  $UR_{US}$ , e.g., increases in heart rate elicited by a shock US and decreases in heart rate elicited by a tone CS (de Toledo and Black, 1966; Rescorla, 1988). These results led Holland (1984) to suggest that the  $CR_{CS}$  is composed of two behavioral elements: one that is similar to the  $UR_{US}$  or at least in some way appropriate to the US and one that is similar to the responses elicited by the CS prior to conditioning ( $UR_{CS}$ ). Thus, comparable to traditional classical situations, the CR in CTA is composed of behavioral elements similar to the UR elicited by the US ( $CR_{US-ILLNESS}$ ) and behavioral elements similar to responses that can be elicited by the CS prior to conditioning ( $CR_{CS-AVOIDANCE}$  and  $CR_{CS-AVERSION}$ ).

<sup>2</sup>In this chapter, the term anorexia will refer to reductions in eating that are found during illness, dysfunctional states, or chronic disease states while hypophagia will refer to normal reductions in eating that are the result of satiety signals in normal functioning individuals.

## 38.2 CONDITIONED TASTE AVERSION IN THE CONTEXT OF THE FEEDING SYSTEM

### 38.2.1 Plasticity of Preferences and Aversions

Food and some drinks provide nutrients and are a source of calories necessary for survival. For omnivores such as humans, a wide range of substances potentially can serve as food. Some of these substances have nutritive and caloric value, some have no food value, and some are harmful. Particular characteristics associated with the substance, such as taste, odor, texture, and appearance, serve as identifiers and become signals of the consequences of ingestion. For most mammals, taste or flavor (a combination of taste, smell, and texture) appears to be the primary cue used as an identifier. Preferences for sweet tastes and for the taste of salt, starch, and fat and aversions to bitter tastes and the flavor of chili peppers are thought to be innate at the time of birth in that individuals show the preferences or aversions without having had prior postnatal experience with the tastes (Ackroff et al., 1990; Ganchrow et al., 1986; Mattes, 1997; Moe, 1986; Rozin and Schiller, 1980; Sclafani, 1987; Steiner, 1973, 1979). This use of the word innate does not preclude the possibility that fetal learning processes contributed to the preference or aversion shown at birth. In rats, the ability to acquire taste avoidance is present during near-term fetal life (Gruest et al., 2004), so if fetal learning is involved, it would have to have occurred prior to that period.

The neural pathways mediating these innate preferences and aversions are plastic, as postnatal experience can strengthen, weaken, or reverse them and new preferences and aversions can be established through experience with different foods. Four processes have been suggested to contribute to increases in existing innate preferences and establishment of new preferences: (1) repeated exposure without negative consequences (Booth, 1985; Sullivan and Birch, 1990); (2) learned associations that occur when consumption of a food is followed by calorie or nutrient repletion (Birch et al., 1990; Gietzen et al., 1992); (3) learned associations that occur when a food is paired with another food that has high positive hedonic value (Bolles, 1985); and (4) learned association that occur when a food inhibits a negative hedonic process, as exemplified by sweet tastes which elicit reductions in emotional distress and physical pain in rat pups and in infants and prepubertal children, but not adults (Kehoe and Sakurai, 1991; Papino and Mennella, 2005; Segato et al., 1997).

Innate preferences for highly preferred tastes can be reversed and changed to aversions if consumption of these tastes is followed by illness (Garcia et al., 1955). In contrast, reversals of innate aversions are rare in animals,

although they are frequently found in humans (Rozin et al., 1979). For example, prolonged exposure to chili flavoring in rats does not alter the aversion and repeated pairings of a chili-flavored food with recovery from thiamine deficiency illness attenuates, but does not reverse the innate aversion to the taste of chili. However, millions of people in many parts of the world have come to prefer the taste of chili peppers. The mechanism that accounts for this change remains unknown, although it is likely that at least one of the processes described above is involved.

Although animals come into life with innate predispositions and learning mechanisms that aid them in choosing amongst a vast array of potentially edible substances, this is not the end of story. Socially interactive animals have at their disposal help from conspecifics. Verbalizations and behavioral modeling by significant adults and peers influence food preferences in children (Birch, 1980; Capretta et al., 1973). In rats, the mother and adult conspecifics convey information to their young about what constitutes acceptable foods through gustatory cues in the rat mother's milk that reflect the taste of her diet and the physical presence of adult rats at feeding sites (Galef, 1977; Galef and Clark, 1971; Galef and Henderson, 1972). Social cues continue to play a role throughout adulthood. For example, adult rats can detect illness in a conspecific and will use that information to avoid consumption of a diet. Mother rats will decrease consumption of a novel taste when ingestion of that substance is followed by the illness of her pups (Gemberling, 1984) and similar effects are found with adult cage mates (the "poisoned-partner" effect; Lavin et al., 1980).

Apart from social guidance, as young mammals gain more independence, they begin to sample new and different foods that are present in their environment on their own. They rely on strategic mechanisms to guide their selection of foods. For example, opportunistic omnivores such as rats exhibit neophobia to new foods, even to those that have a sweet taste (Barnett, 1958; Domjan, 1977). Neophobia also is found in nonhuman primates (Itani, 1958; Weiskrantz and Cowey, 1963) and 2-year-old children (Birch and Marlin, 1982). The advantage of neophobia is that if the food is toxic, cautious sampling might lead to illness but not death.

Food selection, then, involves a complex interaction of innate predispositions, personal and social experiences, and strategic mechanisms that eventually lead to a relatively stable pattern of food preferences and aversions. Although stable, the hedonic value of these preferences and aversions does not remain constant. Preferred foods can become temporarily less positive and aversive foods can become temporarily less negative as the internal state of the individual changes (Cabanac, 1971, 1979; Fantino, 1984). The shift in hedonic value is temporary because when the body-state is restored, the hedonic value also is restored. As mentioned above, reactions to calorie-rich sweet solutions change from positive to negative as rats

and humans go from food depletion to food repletion (see *What Kind of Learning*; Cabanac, 1971; Grill and Berridge, 1985). In addition, deprivation of specific substances such as sodium increases preferences for foods or solutions that contain these substances, even when the solution contains concentrations that are normally aversive (Berridge et al., 1984). These temporary shifts in hedonic value are referred to as allesthesia.

### 38.2.2 Estradiol, Satiety, CTA, and Anorexia Nervosa

Estradiol is a member of a group of steroid hormones called estrogens. It is present in both males and females and its primary source in the circulatory system of rodents is the granulosa cells in the ovaries of females and the aromatization of testosterone in the testes of males (de Jong et al., 1973; Shoham and Schachter, 1996). Secondary sources include neural sites such as the lateral parabrachial, hypothalamic preoptic area, and amygdala (Balthazart et al., 1990; Chambers et al., 1991; Saleh et al., 2002).

**38.2.2.1 Estradiol and Food Intake.** Substantial evidence unequivocally establishes estradiol as a hypophagic hormone. In a number of species, food intake decreases during the follicular phase of the cycle when estradiol levels are elevated and increases during the luteal phase when estradiol levels are lower (see Chambers and Bernstein, 2003). Ovariectomized rats and rhesus monkeys exhibit hyperphagia with increased body weight and estradiol treatment that mimics physiological levels of the hormone is sufficient to normalize both eating and body weight (Czaja and Goy, 1975; Geary and Asarian, 1999). Estradiol acts as a satiety hormone in that it reduces food intake by decreasing the size of meals rather than the number of meals (Blaustein and Wade, 1976). In addition, it is regarded as a long-term satiety hormone because it induces hypophagia as a means of regulating body weight, causing only a transient decrease in eating when administered to ovariectomized females, but a lasting decrease in body weight (Wade, 1972).

The area postrema (AP) and paraventricular hypothalamus (PVH) have been implicated in mediation of estradiol hypophagia. Production of a marker for neuronal activity, c-fos like immunoreactivity (c-FLI), is activated in the AP of ovariectomized female rats 24 hours after injection of estradiol benzoate, which is the time period when estradiol-induced hypophagia is expressed (Chambers and Hintiryan, 2009) and lesions of the AP eliminate the hypophagia expressed by male rats placed under chronic estradiol treatment (Bernstein et al., 1986). Eating increases expression of c-FLI in the PVH of food-deprived ovariectomized rats and activation of c-FLI is found within

this same neural area when ovariectomized females are given pretreatment with a dose of estradiol that mimics follicular phase blood levels (Eckel and Geary, 2001). Furthermore, lesions of the PVH reduce the responsiveness of ovariectomized rats to estradiol, intracranial application of estradiol into the PVH, but not other hypothalamic regions, induces hypophagia in ovariectomized rats, and implanting the protein inhibitor anisomycin into the PVH disrupts the hypophagic effects of estradiol (Butera and Beikirch, 1989; Butera et al., 1990, 1992, 1993).

**38.2.2.2 Estradiol and CTA.** Estradiol strengthens acquisition of LiCl-induced taste avoidance when it is present during acquisition, accelerates extinction when it is present before acquisition or before extinction, and prolongs extinction when it is present during extinction (Chambers and Hayes, 2002; Yuan and Chambers, 1999). We have suggested that all of these data can be accounted for by estradiol acting as an illness inducing agent (Chambers and Hintiryan, 2009). First, supraphysiological doses of estradiol can induce CTA in rats as evidenced by expression of both  $\text{CR}_{\text{CS-AVOIDANCE}}$  and  $\text{CR}_{\text{CS-AVERSION}}$  (Ossenkopp et al., 1996; Yuan and Chambers, 1999). Second, evidence demonstrates that when two USs are administered after CS consumption, they induce stronger taste avoidance than when either is administered alone (Hayes and Chambers, 2005b). This suggests that estradiol strengthened acquisition when present during acquisition because of the additive effect of its US properties with those of LiCl. Third, evidence indicates that acquisition can be strengthened by giving multiple CS-US pairings (Garcia et al., 1956). This suggests that estradiol prolonged extinction because its presence during extinction constituted multiple pairings of the sucrose CS with a US, LiCl in the first pairing, and estradiol in subsequent pairing. Fourth, studies have established that substances capable of inducing  $\text{CR}_{\text{CS-AVOIDANCE}}$  can serve as preexposure agents to attenuate acquisition and accelerate extinction when they are given prior to acquisition in the absence of the taste substance targeted for future conditioning or prior to extinction in the absence of the conditioned taste stimulus (Cannon et al., 1977; Mikulka et al., 1977; Rabin et al., 1989). This occurs when the preexposure agent is the same as or different than the agent used to induce the taste avoidance (Cannon et al., 1977). This suggests that estradiol accelerated extinction when it was present before acquisition or extinction of the LiCl-induced taste avoidance because it was acting as a preexposure agent.

Due to the timing of the unconditioned effects exerted on eating by estradiol, the role of this hormone as a true conditioning agent has been challenged (Flanagan-Cato et al., 2001). In studies using estradiol as the US, taste avoidance has been observed when the first test for acquisition was

given 24, 48, or 72 hours after CS-US pairing (De Beun et al., 1991, 1993; Hintiryan et al., 2005; Merwin and Doty, 1994; Ossenkopp et al., 1996). Unconditioned hypophagia also has been shown to occur within the first 24 hours following administration of estradiol in ovariectomized rats and to persist for at least 72 hours (Asarian and Geary, 2002; Chambers and Hintiryan, 2009; Rivera and Eckel, 2005; Tarttellin and Gorski, 1973). Consequently, it is possible that the taste avoidance observed after pairing a novel sweet taste with estradiol may have been due to the unconditioned hypophagia produced by estradiol and not to conditioning capabilities of the hormone. However, a series of studies conducted in our lab strongly indicates that the reduced consumption of sucrose after sucrose-estradiol pairing is a conditioned response (Hintiryan et al., 2009). First, when the initial post-pairing test was given 9 days after sucrose-estradiol pairing, reduced sucrose consumption was expressed even though unconditioned lab chow hypophagia was not evident. Second, when sucrose was paired with a physiological dose of estradiol, reduced sucrose consumption was not expressed at the time of the post-pairing test even though unconditioned lab chow hypophagia was evident. Third, when sucrose-estradiol pairing was non-contingent, reduced sucrose consumption was not expressed even though the post-pairing test was held at a time when unconditioned lab chow hypophagia is evident.

Gustavson and his colleagues have suggested that estradiol-induced nausea parallels the nausea induced by LiCl (Gustavson and Gustavson, 1987; Gustavson et al., 1989b). Consistent with this hypothesis is the similarity between LiCl and supraphysiological estradiol in their aversiveness. Both agents can induce nausea and vomiting (Gustavson et al., 1989b; Schou, 1968), elicit  $\text{CR}_{\text{CS-AVERSION}}$  after it is paired with a novel taste stimulus (Breslin et al., 1992; Ossenkopp et al., 1996), and produce conditioned place avoidance (Cunningham and Niehus, 1993; De Beun et al., 1991). Also consistent are the results of US preexposure studies. Because attenuation of taste avoidance when preexposed to a US is more easily obtained if the same agent is used as both the preexposure agent and the conditioning agent, Rabin and colleagues (1989) proposed that the closer the neural pattern activated by the preexposure agent is to the conditioning agent the greater the likelihood that attenuation of the taste avoidance would occur. It has been demonstrated that preexposure to estradiol weakens acquisition and accelerates extinction of taste avoidance induced by LiCl as well as estradiol and preexposure to LiCl attenuates acquisition of taste avoidance induced by estradiol as well as LiCl (Chambers and Hayes, 2002; De Beun et al., 1993). This symmetrical preexposure attenuation of taste avoidance suggests that the aversive effects of estradiol and LiCl are mediated by the same neural pathway.

### 38.2.2.3 Estradiol and Anorexia Nervosa.

Anorexia nervosa is an eating disorder with unknown physical or emotional causes that occurs most often in young women and is characterized by a failure to maintain body weight within the normal range for age and height, an intense fear of gaining weight, and a disturbance of body image (DSM-IV-TR, 2000). A number of theories, ranging from psychosocial to physiological, have been proposed to account for anorexia nervosa, but most theories remain unsubstantiated or inadequate. In general, psychological therapy has had limited success as evidenced by follow-up studies twenty years after treatment showing that 71% of patients had not recovered and of these, 21% had died of suicide or complications of the disorder (Ratnasuriya et al., 1991). Many different kinds of chemical interventions also have been employed with little success (Mitchell, 1989). In recent analyses of psychotropic medication use, it was concluded that although a high number of individuals with anorexia nervosa use these medications, there is no conclusive evidence supporting their efficacy (Fazeli et al., 2012; Kishi et al., 2012).

There is an estrogen based hypothesis that does have supporting evidence (Chambers and Bernstein, 2003; Gustavson and Gustavson, 1986; Gustavson et al., 1989b; Young, 1991). At its core is the proposition that the brain of some females is altered during fetal and early postnatal development such that estrogen responsive tissues become hypersensitive and consequently some of the normal physiological and behavioral effects of this hormone become exaggerated. Four effects that could contribute to anorexia are: (1) triggering unconditioned satiety at lower levels of estradiol such as found during the luteal phase of the reproductive cycle (see Estradiol and Food Intake); (2) resetting existing conditioned satieties and acquiring new ones (see Introduction); (3) inducing unconditioned illness anorexia at lower levels of estradiol such as found during the reproductive cycle (see Anorexia and Illness); and (4) inducing CTAs (see Estradiol and CTA). These four factors could interact at puberty in individuals with estrogen hypersensitivity to induce anorexia and precipitate substantial weight loss.

The evidence supporting the estrogen hypersensitivity hypothesis is as follows. First, anorexia nervosa is more prevalent in women than men, with more than 90% of cases of anorexia nervosa occurring in females (DSM-IV-TR, 2000). Second, early satiety has been reported in patients with anorexia nervosa, suggesting an involvement of unconditioned and/or conditioned satiety in this disorder (Holt et al., 1981). Third, diethylstilbestrol (DES), a synthetic non-steroidal estrogen, alters the brains of female rats when administered during fetal/neonatal development such that when they are adults, they acquire taste avoidance with lower doses of estradiol, thus indicating a heightened sensitivity to the conditioning properties of

estradiol (Gustavson et al., 1989a). Fourth, there is an association between DES usage and increased incidence of anorexia nervosa. The agricultural usage of DES began around 1950 (Nash et al., 1983; Rico, 1983; Rumsey, 1983) and the medical usage began in 1947 when physicians began to prescribe it to pregnant women in hopes of avoiding complications associated with pregnancy (Hammes and Laitman, 2003). This usage peaked in 1964 and continued through 1971 when the FDA encouraged the discontinuation of its use because of its association with vaginal and cervical cancer. The usage corresponds with the increase in the incidence of anorexia nervosa in 14–20-year-old females, but not other age groups, in the US and Switzerland beginning about 1965 and continuing through 1976 (Jones et al., 1980; Willi and Grossmann, 1983). Fifth, women who were exposed to DES fetally are five times more likely to show inexplicable weight loss and to be diagnosed with an eating disorder such as anorexia nervosa or bulimia nervosa, compared to women who were not exposed to the drug (Gustavson et al., 1989a, 1991). Although one cannot draw a causal relationship between these two findings, they do allow the possibility that there is one and that this relationship was forged by chemically induced alteration of the developing fetal/neonatal brain. Sixth, an association among estrogen, illness, anorexia nervosa, and CTA has been reported in humans. In patients with anorexia nervosa, episodes of vomiting are associated with estrogenic vaginal smears and estrogen therapy worsens the vomiting episodes (Moulton, 1942). Consistent with this report is a case study of a 15-year-old girl who suffered incidences of nausea and repeated vomiting subsequent to being placed on birth control pills containing ethinyl estradiol (Gustavson et al., 1988, 1989b). Over the course of months, she eventually met the criteria for anorexia nervosa; the range of foods that she would eat became limited and her body weight decreased from 26% more than expected for her age and height to more than 27% below her expected weight. For a few of the foods she indicated a negative shift in palatability, which also has been reported in other patients with anorexia nervosa (Drewnowski, 1989), and identified food as the source of her illness. When she was taken off the birth control pills, the vomiting subsided. She then participated in a CTA experiment one month after she stopped taking the birth control pills (Gustavson et al., 1988, 1989b). She showed suppression in consumption of flavored water that had been paired with an ethinyl estradiol tablet but not to flavored water that had been paired with a sucrose tablet. The estradiol tablet had triggered nausea and vomiting responses. There is enough support for an estrogen-based hypothesis to warrant serious consideration and further study, especially in light of the fact that anorexia nervosa remains a serious and intractable eating disorder. This hypothesis does not preclude the contribution of other

factors. Certainly, social and cultural factors are powerful forces that could help maintain and exacerbate the anorexia that estrogen triggered.

### 38.3 CONDITIONED TASTE AVERSION IN THE CONTEXT OF ILLNESS SYSTEMS

#### 38.3.1 Anorexia and Illness

**38.3.1.1 Systemic Infections.** Animals exhibit a constellation of physiological and behavioral changes during the acute phase response to infection, including activation of the hypothalamic-pituitary-adrenal (HPA) axis, fever, lethargy and reduction in motor activity, depression and reduction in general environmental responsiveness, decreases in social exploration, increases in sleepiness and slow-wave sleep, and anorexia as well as reductions in food motivated behaviors (see Hart, 1988 and Kent et al., 1992). These responses are thought to be part of a homeostatic behavioral strategy that has evolved to facilitate survival of individuals suffering from systemic illnesses caused by a variety of microorganisms, including bacteria and viruses (Asarian and Langhans, 2010; Hart, 1988; Murray and Murray, 1981). The importance of anorexia in fighting against infection is demonstrated by the following: force-feeding mice during bacterial infections reduces survival time and increases mortality (Murray and Murray, 1979), while depriving mice of food two to three days before bacterial infection increases survival rates (Wing and Young, 1982). Three cytokines that are part of the cytokine cascade triggered by endotoxin infection have been implicated in the anorexia accompanying infection. Lipopolysaccharides (LPS) from gram-negative bacteria cell walls trigger release of interleukin-1 (IL-1), tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), and high mobility group-1 (HMG-1) protein and reduce food intake in rodents (Langhans et al., 1993b; Nathan, 1987; Wang et al., 1999). Evidence suggests that this reduction is mediated by the released cytokines as administration of each of these cytokines produces anorexia (Agnello et al., 2002; Langhans et al., 1993a; McCarthy et al., 1984). The specific role of each of these cytokines and the nature of their interaction in producing anorexia is yet to be fully delineated.

**38.3.1.2 The Chronic Disease State Cancer.** It is well established that anorexia is a significant problem for individuals suffering from various kinds of cancer. It has been suggested that early satiety and symptoms of abdominal fullness as well as altered taste quality, which are commonly found in cancer patients, promote anorexia (DeWys, 1985). However, these factors may be secondary to the contribution of cytokines. A series of experimental and clinical studies have demonstrated that advanced-stage cancer

patients with anorexia have high serum levels of IL-1 and TNF- $\alpha$  and treatment with megestrol acetate, which down-regulates the synthesis and release of cytokines, increases appetite (Mantovani, et al., 1998).

**38.3.1.3 Toxicity.** LiCl triggers nausea and vomiting and as such is regarded as an illness-inducing agent. However, it also triggers many of the same physiological and behavioral responses as infectious illnesses, including activation of the HPA axis, decreases in motor activity, general environmental responsiveness, and social exploration, increases in sleepiness and slow-wave sleep, and anorexia (see Chambers and Bernstein, 2003; Eckel and Ossenkopp, 1993). This aftermath of exposure to LiCl and infectious agents is so strikingly similar that it is tempting to view illness as a unitary phenomenon with one mediating mechanism that controls its multifaceted expression. However, differences have been found in the effects of LiCl and LPS exposure. For example, both of these agents induce a fall in body temperature within a few minutes after injection, but while fever then ensues within the next 6 minutes for LPS, it is not a consequence of LiCl injection (Bull et al., 1991). Furthermore, LiCl promotes anorexia through a mechanism that does not involve cytokines; it acts via vasopressin V<sub>1</sub> receptor-mediated activation of an  $\alpha$ -adrenergic mechanism, in support of this hypothesis (Langhans et al., 1991). Vasopressin also mediates anorexia provoked by cytotoxic chemotherapy, which compounds the anorexia associated with cancer itself (see Scalera and Bavier, 2009). Although it has been proposed that cytokines mediate chemotherapy-induced anorexia, animal research implicates vasopressin (Sinno et al., 2010). During methotrexate treatment, food intake is reduced and c-FLI is expressed in vasopressin neurons located in the hypothalamic supraoptic and paraventricular nuclei. In contrast, there is no evidence of IL-1 activation. These data indicate that different illness promoting agents employ different mediating mechanisms to activate similar response mechanisms. Illness, then, appears to be a multi-faceted phenomenon, each illness defined by the specific sensory, mediating, and response mechanisms involved.

#### 38.3.2 CTA and Illness

A number of investigators have suggested that the formation of CTAs could contribute to the anorexia observed during systemic infections, cancer, and chronic toxicity exposure. Evidence supports this hypothesis in that taste avoidance can be induced by pairing a novel diet or solution with LPS, IL-1, HMG-1, implantation of experimental sarcoma, and chronic infusion of LiCl (Agnello et al., 2002; Bauer et al., 1995; Bernstein and Goehler, 1983; Bernstein et al., 1985; Weingarten et al., 1993). However the ability

of these agents to induce CR<sub>CS-AVOIDANCE</sub> does not extend to familiar diets, which limits the contribution that conditioning makes to anorexia and suggests that CTA may not play a role under normal feeding conditions. Still, there is a caveat to this conclusion. In all of the above studies, the animals had limited experience with different diets before they had been given the novel diet. Nothing is known about the impact of CTAs when animals are maintained from an early age on varied diets, a situation that is more typical of the eating patterns of humans and of rodents living in the wild or kept as pets. This issue is important since it is possible that for individuals on varied diets, the rules of conditioning change. Although conditioned avoidance of substances consumed since weaning is difficult to obtain in animals with limited diet variation (Elkins, 1974; Kalat and Rozin, 1973), for animals exposed to a variety of flavored foods and drinks, familiarity may not so easily exclude a particular food/drink from conditioning.

It also has been concluded that learned food aversion plays an inconsequential role in the anorexia of cancer patients undergoing chemotherapy (Mattes et al., 1992). This conclusion was based on the failure to find associations between the experiences of nausea/vomiting and the incidence of food aversions, the degree of loss of appetite and the likelihood of developing food aversions, and the presence of food aversions and the presence of anorexia. However, it has been demonstrated that aversions to specific foods consumed before treatment are learned in patients receiving gastrointestinally toxic chemotherapy (Bernstein, 1978; Bernstein and Webster, 1980). Furthermore, when a distinctive flavored food (such as coconut or root beer Lifesavers) is used as a target food by giving it to children and adults after consumption of a meal but before administration of chemotherapy, this “scapegoat” interferes with the development of aversions to items in the meal (Broberg and Bernstein, 1987; Mattes et al., 1987). Thus, the impact of chemotherapy on preferences for normal meal items can be reduced. Considering all of the data, it is likely that food aversions learned as a consequence of chemotherapy do play a role in the anorexia of cancer patients. This role may be more important in young patients since aversions develop more easily before the age of 20 (Garb and Stunkard, 1974; Logue et al., 1981).

## 38.4 CONDITIONED TASTE AVERSION IN THE CONTEXT OF STRESS SYSTEMS

### 38.4.1 The Hormonal Stress Response

Most stress researchers agree that stress is composed of three components (see Levine, 2005):

1. a stimulus or stressor, which is an environmental event that can be sensed by an individual, has aversive properties, is potentially harmful to the individual, and elicits an acute and/or chronic response;
2. an evaluation, which is the ability of an individual to process the stimulus, detect its hedonic value, and translate this information into a response; and
3. the stress response, which includes a complex interplay of physiological, behavioral, emotional, and cognitive changes in the individual.

Hormones play a vital role in activating the physiological changes and neural mechanisms necessary for responding effectively to stressors. Increased release of corticotropin releasing factor (CRF) and arginine vasopressin (VP) occur in less than 1 min, followed by increased secretion of adrenocorticotropin hormone (ACTH), renin, catecholamines, prolactin, glucagon, and growth hormone in less than 10 min and glucocorticoids in less than 1 hr (see Sapolsky et al., 2000). Four of these hormones have been found to play a role in CTA: CRF, VP, ACTH, and glucocorticoids.

Stressors, acting via neural systems dedicated to sensory detection and processing, induce an increase in the release of CRF and VP from the parvocellular portion of the PVH into the portal vessels. Vasopressin has little ACTH-releasing capability on its own but acts synergistically with CRF on corticotrophs in the anterior pituitary to increase release of ACTH into the general circulation. ACTH, in turn, triggers increased synthesis and release of glucocorticoids (predominantly cortisol or corticosterone) from the adrenal cortex (see Fulford and Harbuz, 2005). Besides its synergistic role as part of the HPA system, VP has diffuse effects on peripheral tissues via increased release into the general circulatory system from magnocellular neurons in the PVH and supraoptic hypothalamus whose axons terminate near capillaries in the pars nervosa of the posterior pituitary (Swab et al., 1975; Swanson and Sawchenko, 1980). In addition to their endocrine roles, both CRF and VP have been localized in and are synthesized by a number of neural sites outside the PVH, which indicates their ability to function as neurotransmitters or neuromodulators (see Steckler, 2005 and Douglas, 2005).

### 38.4.2 Stress Hormones and Acquisition of CTA

Exposure to LiCl triggers increases in blood levels of corticosterone and VP in rats and it induces c-fos expression in VP neurons in the PVH and supraoptic nucleus (Ader, 1976; Hennessy et al., 1976a; Olszewski et al., 2001; Verbalis et al., 1986). However, an elevation in corticosterone after CS-US pairing is not necessary for acquisition of CTA because neither adrenalectomy nor hypophysectomy

eliminate the ability of animals to acquire taste avoidance (Ader et al., 1978; Rabin et al., 1983). Whether the same is true of VP is unknown, although it is likely to be the case.

Evidence suggests that increased secretion of both hormones serve the function of reducing the impact of LiCl. Studies of glucocorticoids have shown the following: (1) glucocorticoids (cortisol, prednisone, methylprednisolone, and dexamethasone phosphate) attenuate LiCl-induced taste avoidance when administered before or between CS-US pairing (Hennessy et al., 1976a; Revusky and Martin, 1988); (2) dexamethasone phosphate alleviates emetic distress in humans when administered before cancer chemotherapy (Cassileth et al., 1983; Markman et al., 1984); and (3) corticosterone fails to induce taste avoidance even after 12 pairings with a sweet solution (Smotherman and Levine, 1978). Similar to glucocorticoids, studies have shown that low doses of VP: (1) attenuate LiCl-induced taste avoidance (as measured by accelerated extinction) when administered 50 min after sucrose-LiCl pairing (Chambers and Hayes, 2005; Hayes and Chambers, 2002, 2005a); (2) reduce the effect of the illness-inducing cytokine IL-1 by partially reversing its suppression of social exploration of conspecific juveniles by adult animals (Dantzer et al., 1991); and (3) fail to induce taste avoidance even after multiple pairings. Furthermore, VP accelerates the completion of extinction, not the initiation, which is the same change that occurs when the dose of LiCl is reduced from 1.5 to 0.3 mEq/kg (Chambers and Wang, 2004). It has been suggested that one of the ways VP reduces exposure to the toxic effects of LiCl is by reducing intestinal blood flow through constriction of splanchnic blood vessels (Stricker and Verbalis, 1991).

CRF may play an opposite role during acquisition as there is a positive association between the neural CRF system and measures of aversive states. Intracerebroventricular administration of CRF induces conditioned place avoidance (Cador et al., 1992) and unlike corticosterone and VP, it can serve as a US to induce taste avoidance (Benoit et al., 2000; Gosnell et al., 1983). Further evidence for the aversive role of CRF is demonstrated by peripheral administration of urocortin 1 (Ucn1, a member of the CRF-peptide family that is a non-selective CRF receptor agonist) which increases corticosterone levels, produces diarrhea, reduces meal frequency and size, and induces taste avoidance (Fekete et al., 2011). These results are noteworthy as it has been hypothesized that the CRF neural system plays a role in mediating the aversive state during stress and activating negatively valenced avoidance tendencies (Cador et al., 1992; Heinrichs and Koob, 2004). This could mean that the CRF neural system plays a role in defining whether a particular agent is aversive and that the ability of CRF to induce taste avoidance is related to its ability to directly activate those circuits involved in

evaluating and concluding that certain properties of an agent are harmful.

### 38.4.3 Stress Hormones and Extinction of CTA

Extinction is delayed when ACTH and VP are given before each extinction trial (Kendler et al., 1976; Rigter and Popping, 1976; Vawter and Green, 1980). These hormones have an immediate suppressive effect on CS consumption during extinction. When ACTH was administered prior to the second extinction test under forced drinking conditions (given one bottle containing the CS after 48 hours of water deprivation), consumption of the CS was reduced on that test and when VP was given before the fifth extinction test, CS consumption on that test was suppressed despite the fact that the animals had begun extinguishing their avoidance (Cooper et al., 1980; Hennessy et al., 1976b). Given that endogenous ACTH and VP are released after LiCl injection, it may be that the exogenous presence of these hormones before encountering the CS during extinction served to act as a reminder cue which evoked taste avoidance memory. It has been suggested that ACTH facilitates retrieval of the avoidance memory (Hennessy et al., 1976b). Support for this hypothesis is provided by a study with infant rats that were given three different CS-US intervals during acquisition (0-hr, 1-hr, and 24-hr) and injected with ACTH<sub>4–10</sub> or saline prior to the retention test (Dray and Taylor, 1982). The ACTH<sub>4–10</sub> and saline animals acquired equivalent taste avoidances with the 0-hr interval and no taste avoidances with the 24-hr interval. With the 1-hr interval, ACTH<sub>4–10</sub> infants acquired taste avoidance while the saline rats did not. Thus, the avoidance memory was present in the 1-hr interval infants, but hard to retrieve without ACTH<sub>4–10</sub> augmentation. This effect is not dependent on the glucocorticoid response that accompanies ACTH treatment because ACTH<sub>4–10</sub> is devoid of steroidogenic activity. The same is true for the delayed extinction effect in adults as ACTH<sub>4–10</sub> also suppresses CS consumption during extinction (Rigter and Popping, 1976).

Retention of other types of inhibitory avoidance behavior, such as step-through shock avoidance, also is augmented by ACTH<sub>4–10</sub> (van Wimersma Greidanus et al., 1979; Wan et al., 1992). Evidence suggests that this peptide produces its effect via modulatory effects on the release of neurotransmitters in the limbic system. Infusion of ACTH<sub>4–10</sub> directly into the hippocampus increases concentrations of serotonin (van Wimersma Greidanus et al., 1983). Furthermore, there is a positive association between increased hippocampal serotonin and the ability to retrieve and express retention of step-through avoidance (Ramakekers et al., 1978). In untreated rats, levels of serotonin are elevated 24 hr after acquisition and retention is expressed. If rats are subjected to amnesic carbon dioxide

treatment immediately after acquisition, levels of serotonin fail to rise and avoidance is not expressed. However, if amnesic rats are administered ACTH<sub>4-10</sub> 1 hour before the retention test, serotonin levels rise and retention of the avoidance is expressed. It is unclear how ACTH achieves its effect on extinction of taste avoidance but a similar type of mechanism is possible, although not necessarily the same neurotransmitter or neural structure. For CTAs, a functional amygdala appears to be necessary as bilateral lesions eliminate the ability of ACTH to delay extinction (Burt and Smotherman, 1980).

## 38.5 NEURAL MECHANISMS FOR CONDITIONED TASTE AVERSIOS

### 38.5.1 Acquisition of the CS-US Association

If rats are force-fed with saccharin and then poisoned with LiCl while under pentobarbital anesthesia or bilateral reversible decortication via cortical spreading depression (CSD), they do not acquire taste avoidance but they do exhibit unconditioned signs of illness (Bures and Buresova, 1989; Buresova and Bures, 1973). Similarly, taste avoidance cannot be learned when rats are decerebrated at the supracollicular level, which leaves a functional nucleus of the solitary tract (NST) and parabrachial nucleus (PBN) that are cut off from forebrain intercommunication (Grill and Norgren, 1978). However, when either anesthesia or CSD is given after exposure to saccharin but before LiCl administration, taste avoidance learning is not prevented (Bures and Buresova, 1989; Buresova and Bures, 1973). These results suggest that acquisition of taste avoidance requires cortical involvement in taste processing, but subcortical areas are sufficient for illness detection and processing.

**38.5.1.1 Taste Stimulus Detection.** Taste information is transmitted from taste receptor cells located primarily in the tongue to the chorda tympani and superficial petrosal branches of the facial nerve, the lingual branch of the glossopharyngeal nerve, and the vagus nerve (Hamilton and Norgren, 1984). The gustatory afferent fibers from these nerves terminate in the ipsilateral rostral NST. Second order gustatory neurons in the rostral NST project ipsilaterally to neurons in the medial PBN (mPBN), ventral subnucleus of the lateral PBN (lPBN), and waist region in rodents and to neurons in the parvocellular ventroposteromedial thalamic nucleus in primates (VPMpc; see Pritchard and Norgren, 2004; Herbert et al., 1990; Travers et al., 1987). Neural areas rostral to the PBN are not critical for innate hedonic reactions to taste in rats as intraoral taste stimulation elicits the same ingestive

and aversive patterns of taste responsiveness at the same concentrations in intact and supracollicular decerebrated rats (Grill and Berridge, 1985).

**38.5.1.2 Toxicity Stimulus Detection.** The stimuli that activate other sensory systems such as vision, audition, gustation, and olfaction, are well known and the sensations produced by activation of these systems are clearly definable. This is not the case for the illness sensory system; we do not have a clear picture of what stimuli constitute illness. Within the context of the studies reviewed in this chapter, identification of stimuli that can activate the illness sensory system has been done almost entirely on the basis of whether a given stimulus can induce CR<sub>CS-AVOIDANCE</sub>. Given this criterion, the list of stimuli that can activate the illness sensory system and thus are considered illness-inducing agents seems limitless, at least for the rat.

The sensation of illness is a conscious awareness of negative changes in the body. One sensation that is commonly reported during illness, and specifically reported after lithium administration, is nausea (Karniol et al., 1978; Schou, 1968). Garcia (1989) has held that nausea is the unifying symptom that ties together all the agents that can induce CTA, as defined by both reduced consumption and negative hedonic shift. Of course investigations of nausea in animals are hampered by the inability to assess what constitutes feelings of nausea. This issue has been circumvented by making two assumptions: (1) any drug that causes nausea in humans will induce nausea in animals, and (2) retching and vomiting in emetic species and aversive orofacial/somatic responses in the nonemetic rat comprise the behavioral manifestation of nausea. In this vein, it has been shown that both lactose, which does not produce nausea in humans, and LiCl, which does, induce comparable decreases in consumption in rats, but only LiCl produces aversive orofacial/somatic responses (Pelchat et al., 1983). This suggests that nausea mediates CR<sub>CS-AVERSION</sub> but not CR<sub>CS-AVOIDANCE</sub>. Support for this hypothesis comes from studies examining the effects of antinausea drugs on LiCl-induced CR<sub>CS-AVOIDANCE</sub> and CR<sub>CS-AVERSION</sub> in rats (Parker, 2003). Acquisition of taste aversion, but not taste avoidance, is disrupted by administration of antinausea drugs that reduce serotonin availability (Limebeer and Parker, 2000, 2003). Furthermore, 5,7-DHT lesions of the dorsal and median raphe nuclei, which effectively reduce serotonin availability, also prevent acquisition of taste aversion, but not taste avoidance (Limebeer et al., 2004). Parker has suggested that LiCl-induced nausea may be mediated, at least in part, by serotonergic pathways (Parker et al., 2009).

If nausea mediates CR<sub>CS-AVERSION</sub> in rats than what mediates CR<sub>CS-AVOIDANCE</sub>? Studies using VP as

an illness-inducing agent have suggested its vascular pressor property (vasoconstriction) as a possible stimulus mediating learned taste avoidance. This hypothesis is supported by three pieces of evidence. First, doses of VP that do not alter systemic blood pressure also do not induce CR<sub>CS-AVOIDANCE</sub> when VP is infused intracerebroventricularly (De Wied et al., 1984). Second, VP analogs with weak or no pressor-agonist activity do not induce CR<sub>CS-AVOIDANCE</sub> (Bluthe et al., 1985; Ettenberg, 1984). Third, VP-induced CR<sub>CS-AVOIDANCE</sub> can be blocked by subcutaneous or intracerebroventricular administration of the V<sub>1</sub> pressor antagonist dPTyr(Me)AVP and the amount required to block avoidance also blocks peripheral changes in blood pressure (Bluthe et al., 1985; Lebrun et al., 1985). That the pressor property of VP also mediates LiCl-induced CR<sub>CS-AVOIDANCE</sub> is supported by the fact that LiCl triggers increases in both VP and blood pressure (O'Connor et al., 1987; Verbalis et al., 1986).

Because LiCl is the putative illness-inducing agent, knowledge of the neural illness sensory system involved in CTA has been based primarily on studies using this agent as the US. The investigation has led to the AP (area postrema) as a necessary and sufficient site of action for illness detection. The evidence is as follows:

1. permanent lesions of the AP prevent expression of many of the UR effects of LiCl, including lying-on-belly, decreased motor activity, delayed stomach emptying, and hypothermia (Bernstein et al., 1992; Ladowsky and Ossenkopp, 1986);
2. c-FLI is induced in the AP after CS-US pairing (Swank et al., 1995);
3. permanent lesions of the AP prevent acquisition of taste avoidance and aversion (Eckel and Ossenkopp, 1996; Ritter et al., 1980);
4. acquisition of taste avoidance is blocked when reversible cooling lesions start immediately after sucrose consumption and continue through the peak effectiveness of LiCl but are not administered during post-acquisition testing (Wang et al., 1997a,b); and
5. electrical stimulation of the AP can serve as a US in a taste avoidance paradigm (Gallo et al., 1988).

Although Li is concentrated throughout the brain after administration of LiCl (Muckherjee et al., 1976), the fact that this agent is unable to induce CTA when the AP is lesioned suggests that the only CTA-associated neurons directly activated by LiCl are in the AP. It is thought that LiCl information is transmitted to other neural areas involved in CTA via general visceral projections from the AP. It should be noted that the AP is not a necessary and sufficient site of action for all agents. For example, nicotine also induces CTA, but lesions of the AP do not reduce CR<sub>CS-AVOIDANCE</sub> (Ossenkopp and Giugno, 1990; Parker, 1995).

It has been suggested that the pressor property of VP induces CR<sub>CS-AVOIDANCE</sub> by acting via baroreceptor vagal connections to the brainstem (Bluthe et al., 1985; Hreash, et al., 1990). However, bilateral subdiaphragmatic vagotomy does not prevent acquisition of LiCl-induced taste avoidance (Martin et al., 1978). It is more likely that LiCl-triggered VP acts directly on pressor regulating neurons in the AP. This circumventricular structure has neurons that contain V<sub>1</sub> receptors, is directly activated by VP, and has been implicated in pressor regulation (Borison, 1989; Carpenter et al., 1988; Phillips et al., 1988; Skoog et al., 1990; Skoog and Mangiapane, 1988; Tribollet et al., 1998).

### **38.5.1.3 Integration of Taste and Toxicity.**

Convergence of gustatory and LiCl information at a particular neural site or sites and ultimately on single neurons in the site(s) is essential for association to take place. Evidence of such a site should include strong evidence that it is involved in CTA acquisition and that it receives both gustatory and toxicity information. Furthermore, based on the anesthesia and CSD data discussed in the introduction to this section, the site should be a subcortical area and the gustatory information it receives should come either directly or indirectly from gustatory processing areas in the cortex.

A substantial amount of evidence has established the involvement of three neural areas in acquisition of taste avoidance, the PBN (lateral and medial), basolateral amygdala (BLA, an anatomical unit composed of lateral and basal nuclei), and the central insular cortex (cIC). After pairing saccharin with LiCl, c-FLI is induced in all three areas, including both IPBN and mPBN (Koh and Bernstein, 2005). Furthermore, bilateral electrolytic and ibotenic lesions abolish expression of LiCl-induced CR<sub>CS-AVOIDANCE</sub> in both the IPBN and mPBN (Agüero et al., 1993; Grigson et al., 1998; Reilly and Trifunovic, 2000; Sakai and Yamamoto, 1998; Spector et al., 1992) but only attenuate expression in the BLA and cIC (see Braun et al., 1982 and Reilly, 2009; Dunn and Everitt, 1988; Morris et al., 1999; Nachman and Ashe, 1974; Nerad et al., 1996; Sakai and Yamamoto, 1999; Simbayi et al., 1986; St. Andre and Reilly, 2007).

**THE CENTRAL INSULAR CORTEX** The cIC is an area that receives both ascending gustatory and visceral input (Hanamori, 1998). However, because neither CSD nor reversible tetrodotoxin lesions of the cIC applied during the CS-US interval impairs acquisition of taste avoidance, the cIC plays a gustatory role (Burešova and Bureš, 1973; Gallo et al., 1992; Roldan and Bures, 1994). This role is not simple sensory detection as lesioned rats are able to display a significant preference for saccharin when given a choice between water and a saccharin solution (Dunn and Everitt, 1988). The predominant hypothesis at present is that the role is associated with determination of CS novelty

and that cIC lesions reduce the degree to which the CS is perceived as novel (see Bernstein et al., 2009 and Reilly, 2009). This hypothesis is supported by the following: (1) animals with cIC lesions show normal acquisition when the CS is familiar but attenuated taste avoidance when it is novel (Kiefer and Braun, 1977; Roman and Reilly, 2007); (2) stronger c-FLI induction is found in the cIC after novel saccharin-LiCl pairing than after familiar saccharin-LiCl pairing (Koh and Bernstein, 2005); and (3) both electrolytic and ibotenic acid lesions of the cIC reduce the neophobic response of animals to the CS (Dunn and Everitt, 1988). Koh and Bernstein (2005) have suggested that the cIC performs two functions during taste conditioning: processing taste to be stored in memory as it progresses from novel to familiar and providing online comparisons between incoming tastes and stored taste memories.

Two studies have demonstrated the importance of connections between the IC and the amygdala and PBN for taste avoidance acquisition. Contralateral lesions of the IC (by tetrodotoxin before CS presentation) and amygdala (by tetrodotoxin before LiCl injection) disrupt acquisition of taste avoidance but ipsilateral lesions have no effect (Bielavská and Roldan, 1996). Likewise, contralateral lesions of the IC (by reversible CSD before CS presentation) and PBN (by reversible tetrodotoxin before LiCl injection) disrupt avoidance learning while ipsilateral lesions have no effect (Gallo and Bures, 1991). If the function of the cIC is to inform the amygdala and PBN of the novelty status of the CS, then the contralateral data indicate that for one side of the brain, the CS consumed before illness was not novel (IC lesioned but amygdala and PBN not lesioned) and for the other side of the brain, illness did not follow consumption of a novel CS (amygdala and PBN lesioned but IC not lesioned). In either case, acquisition of taste avoidance would be compromised. The question to be answered is whether the disrupted acquisition is based on CS-US convergent neurons in the amygdala and PBN some other factor.

**THE BASOLATERAL AMYGDALA** Looking first at the amygdala, there are gustatory projections from the IC to the lateral and basal amygdala (Ottersen, 1982; Nakashima et al., 2000), the involvement of the BLA is limited to novel tastes as lesions attenuate learned avoidance to novel but not familiar tastes (Morris et al., 1999; St. Andre and Reilly, 2007), BLA lesions disrupt taste neophobia (Reilly and Bornovalova, 2005), and stronger c-FLI induction is found in the BLA after pairing LiCl with novel saccharin than with familiar saccharin (Koh and Bernstein, 2005). Furthermore, lesions of the cIC reduce the amount of c-FLI induction in the BLA in response to novel saccharin-LiCl pairing to the level found after familiar saccharin-LiCl pairing and reversible lesions of the cIC with muscimol during familiarization (CS preexposure) of saccharin increases c-FLI induction in the BLA

in response to familiar saccharin-LiCl to the level found after novel saccharin-LiCl pairing (Koh and Bernstein, 2005). Because the BLA does not respond differentially to novelty in the absence of the cIC, the BLA is informed by the cIC as to novelty status. It has been suggested that BLA lesions reduce the degree to which the CS is perceived as novel thus producing a CS preexposure-like (latent inhibition-like) effect (see Reilly, 2009).

The BLA also receives LiCl information; c-FLI is induced in the BLA after LiCl (Koh and Bernstein, 2005) and evidence suggests there are two indirect general visceral pathways from the IPBN to the BLA (Groenewegen and Berendse, 1994; Sakai and Yamamoto, 1999). These data taken together with the contralateral/ipsilateral data described above (Bielavská and Roldan, 1996) suggest that receipt of LiCl information by the BLA from the IPBN is important for successful acquisition. Although the data are consistent with an integration hypothesis, it also is possible that the BLA only conveys CS novelty and LiCl information to the site(s) of integration.

**THE PARABRACHIAL NUCLEUS** Receipt of both taste and LiCl information by the PBN is important for successful taste avoidance acquisition (Bielavská and Rolday, 1996). The most compelling evidence for integration of that information comes from electrophysiological and anatomical studies that have identified convergence of taste and general visceral sensory projections within the PBN. Visceral neurons in the NST project to neurons within the gustatory zone (Herbert et al., 1990) and the threshold of the gustatory evoked responses of some neurons in the PBN can be modified by visceral (vagal) afferent stimulation (Hermann and Rogers, 1985). Although not directly applicable to LiCl-induced CTA, vagal rather than postremal stimulation, it does identify the PBN as an area of neuronal convergence. Direct support for the integration hypothesis awaits studies showing actual convergence of gustatory input from the cIC (either directly or indirectly) on neurons receptive to LiCl.

Most investigators are in agreement that the PBN is a site of CS-US integration, but they differ in their view as to whether the specific site is in the IPBN or mPBN (Chambers and Wang, 2004; Reilly, 1999; Spector et al., 1992; Yamamoto et al., 1994). The AP projects directly and indirectly (via the caudal NST) to the IPBN (Herbert et al., 1990; Shapiro and Miselis, 1985) and although stimulation of the AP is an effective US in intact rats, it is ineffective in inducing CR<sub>CS-AVOIDANCE</sub> in animals with electrolytic lesions of the IPBN (Agüero et al., 1993). However, induction of c-FLI is found in both the IPBN and mPBN after LiCl administration, indicating the LiCl information does reach the mPBN (Koh and Bernstein, 2005). Because expression of CR<sub>CS-AVOIDANCE</sub> can be blocked when temporary and reversible cooling lesions of the IPBN are applied

only during LiCl processing, the IPBN is not necessary for CS detection and processing or CR retrieval. This leaves the possibility that the IPBN is involved in making and storing the taste-illness association as well as in processing LiCl (Wang and Chambers, 2002). Three specific subnuclei in the IPBN have been implicated in acquisition of taste avoidance. After sucrose-LiCl pairing, c-FLI is induced in the central, external, and crescent IPBN and there is strong correspondence between amount of c-FLI induction and strength of  $\text{CR}_{\text{CS-AVOIDANCE}}$  in each of these three subnuclei (Chambers and Wang, 2004). With respect to the mPBN, failure to acquire taste avoidance after mPBN lesions cannot be accounted for by deficits in taste or illness detection and processing because animals with mPBN lesions are capable of learning a conditioned taste preference for a noncaloric flavor paired with calorie-rich sucrose and a learned place avoidance based on LiCl administration (Reilly et al., 1993). This leaves the possibility that mPBN lesions produce deficits in the ability to make, store, retrieve, or express the taste-illness association. At the present time, there is no conclusive data that eliminates either one of these two PBN areas from consideration as an integrative site.

**AN EMERGING PICTURE** The gustatory information the PBN receives is sent to the cIC to be assessed for novelty status. That information is sent back to convergent neurons in the PBN where it can wait for hours for the arrival of toxicity information. If toxicity information arrives (from the AP in the case of LiCl), an association is formed and when the taste is encountered again, taste avoidance ensues. These three neural components are essential for acquisition of LiCl-induced CTA. The BLA also receives gustatory information from the cIC and it receives toxicity information from the IPBN. Thus, integration may take place in this structure as well as the PBN. If so, the integration in the BLA is not necessary for acquisition of CTA, as lesions only attenuate learned taste avoidance. Instead it serves an additive function and as a result, a stronger CTA is achieved.

### 38.5.2 Expression of the CS-US Association

When an animal encounters a taste stimulus after it has been paired with a toxin, expression of illness, avoidance, and aversion responses is a reflection of successful association, storage of the association, and retrieval of the association from storage. Two approaches have been taken in the study of neural pathways mediating conditioned responses. One is the examination of changes in electrophysiological responses and c-FLI induction in response to the CS after acquisition and the other is the determination of whether

lesioning a discrete neural area after acquisition abolishes expression of a conditioned response.

It is unlikely that the AP is involved in conditioned responses to the CS. Lesions of the AP after acquisition do not prevent expression of  $\text{CR}_{\text{CS-AVOIDANCE}}$  or the decrease in heart rate that occurs in response to a CS (Kosten and Contreras, 1989; Rabin et al., 1984). Also, after pairing a sweet solution with LiCl, c-fos-like immunoreactivity is not induced in the AP when rats are exposed to the CS (Houpt et al., 1994; Swank and Bernstein, 1994).

There is evidence of the involvement of the NST in the mediation of conditioned responses. The pattern of activity of sugar responsive NST neurons changes after conditioning such that exposure to a saccharin CS triggers a brief burst of activity that is absent in unconditioned rats (Chang and Scott, 1984). Likewise, intraoral infusion of sweet tastes before conditioning does not induce c-FLI in the medial intermediate NST, but c-FLI is induced in this area when exposed to sucrose after it has been paired with LiCl (Houpt et al., 1994). A change in induction of c-FLI in response to saccharin also has been found in the PBN after conditioning. Saccharin induces c-FLI in the dorsal and central IPBN in naive rats, but in rats with acquired taste avoidance to saccharin, c-FLI is induced predominantly in the external IPBN (Yamamoto, 1993, 1994; Yamamoto et al., 1994). Lesions of the rostral gustatory NST and mPBN do not affect expression of  $\text{CR}_{\text{CS-AVOIDANCE}}$  acquired prior to lesioning, which indicates that these areas of the NST and mPBN are not essential for expression of this conditioned response (Grigson et al., 1997). On the other hand, rats decerebrated at the supracollicular level do not express an avoidance acquired prior to transection (Grill and Norgren, 1978). Taken together, these data suggest that regions within the NST and/or PBN but outside the gustatory zones lesioned in the Grigson study are necessary for expression of  $\text{CR}_{\text{CS-AVOIDANCE}}$ .

Both the BLA and cIC also have been implicated in expression of conditioned responses. Electrolytic/ablation and cytotoxic lesions of both of these structures disrupt expression of taste avoidance learned prior to lesioning (Braun et al., 1981; Nachman and Ashe, 1974; Ormsby et al., 1998; Simbayi et al., 1986; Yamamoto, 1994; Yamamoto et al., 1980). The cIC probably is involved in retrieval rather than storage since fetal transplants can restore expression of an avoidance learned prior to lesioning (Ormsby et al., 1998). This suggests that the cIC plays a role in accessing an experiential memory of the CS that includes not only a novel-familiar dimension but a safe-toxic dimension.

### 38.5.3 Extinction of the CS-US Association

Extinction is a reflection of the integration of two different processes. In a CTA situation, it is a reflection of the strength of the taste-illness association, which impacts the vigor with which the association is retained in storage and the facility with which the association is retrieved from storage. The course of extinction also reflects the ability to forge a new memory, as extinction is a learning process (Hull, 1943). The prevailing view is that animals learn a new association while retaining memory of the CTA, rather than unlearning or forgetting the original aversive learning experience and consequently replacing that memory. Evidence for this assertion comes from other learning paradigms in which the rate of reacquisition after extinction is more rapid than the original acquisition, spontaneous recovery of the conditioned behavior occurs after exposure to the US in the absence of the CS (Bouton, 1993; Leung et al., 2007; Pavlov 1927; Rescorla, 2001). What constitutes the US in the new association formed during extinction of CTA is a subject of debate, but generally, the new association is referred to as learned safety. Whether no-illness is an identifiable neural response is at the heart of the debate.

After extinction, a conditioned sweet taste no longer induces c-FLI in the medial intermediate NST, which means that there is a reversal back to the c-FLI response to the sweet taste prior to conditioning (see Expression of the CS-US Association; Houpt et al., 1994). Furthermore, when c-Fos antisense is infused into the NST prior to the first post-acquisition test, it prevents initiation of extinction (Swank et al., 1996). Taken together, these results suggest that the NST plays an important role in extinction. It is noteworthy that some neural responses in the NST remain after extinction. Examination of the subpopulation of sugar responsive neurons showing brief bursts of activity in response to saccharin after conditioning has revealed that after expression of the CR<sub>CS-AVOIDANCE</sub> is fully extinguished, these neurons continue to respond to saccharin with a well-defined burst of activity that has reduced amplitude and slightly longer latency than in fully conditioned rats (see Expression of the CS-US Association; McCaughey et al., 1997). The authors have suggested that this neural response may be a permanent marker for saccharin as a predictor of illness that could influence any subsequent reacquisition of the taste avoidance.

Amygdalar and cortical areas also have been implicated in extinction. Initiation of extinction is prevented when the protein synthesis inhibitor anisomycin is infused into the BLA and cIC before and into the infralimbic-prelimbic areas of the VPMpc after the first post-acquisition test (Akirav et al., 2012; Bahar et al., 2003; Berman and Dudai, 2001). In addition, if a second infusion into the cIC is given prior to the second

post-acquisition test, extinction remains blocked, but if no infusion is given, initiation of extinction proceeds (Berman and Dudai, 2001). Increases in c-FLI induction also have been found in these three areas during extinction (Mickley et al., 2002, 2005). The cortex, however, may not be critical for extinction. Animals are able to extinguish a previously learned avoidance when they are anesthetized or under CSD (Bures and Buresova, 1979).

## 38.6 CONCLUSION

Conditioned taste aversion is a member of the classical conditioning category of learning paradigms and as such the responses elicited by the taste change from ingestive responses to illness, avoidance, and aversion responses after the taste-illness association has been learned. These learned responses play a critical role throughout our lifetime in protecting us from eating harmful substances. Although CTA typically is learned from firsthand experience, we also can learn to avoid foods that have made others ill. In addition to its role in the learning and feeding systems, CTA intersects with a number of other neural systems, including illness and stress systems. When infected by bacteria or viruses, a constellation of physiological and behaviors responses are elicited that play a critical role in defending against the invasion and increasing our ability to survive. The toxins that induce CTA elicit some of the same physiological and behavioral responses triggered by infectious microorganisms and it is possible that some of the response components of this illness system are employed to effect the taste-illness association. In turn, the illness system uses CTA to promote its anorectic defense against infection. Stress hormones also are triggered by CTA-inducing toxins and although they may not play a critical role in acquiring the taste-illness association, they produce physiological changes that reduce exposure to the toxin and potentially save us from lethal exposure. Because of the intersection of CTA with these neural systems, the study of this learned behavior and the neural mechanisms that mediate it could provide insight into how the different systems function and interact with one another to promote our well-being.

## Clinical Disorders Affecting Taste: An Update

STEVEN M. BROMLEY and RICHARD L. DOTY

### 39.1 INTRODUCTION

The importance of taste as a chemical sense is typically underappreciated until it is lost or distorted. Unfortunately the medical world is commonly reactive, rather than proactive, in regards to taste dysfunction. Indeed, very few medical schools provide even a single lecture on this important sensory system and the topic of gustation is lacking in the most popular of neurology textbooks. Such lack of interest contrasts with that exhibited by the corporate world's food and flavor industries, where knowledge of taste function is critical for the success of their products (see Chapters 47–49). Both the medical and corporate worlds, however, have a common need to understand the psychological and biological factors that drive consumption. From the industrial perspective, this relates to providing consumers with the highest quality food products at the lowest possible cost. From the medical perspective, this relates to managing patients with taste dysfunction and the development of programs for improving nutrition, health, and weight management of patients and society at large. Impaired taste function in acutely hospitalized older persons is strongly associated with mortality (Solemdal et al., 2014) and, in general, intact taste functioning can be considered a marker for good health. Even minor distortions in taste perception can represent underlying disease, toxin exposure, or changes in normal anatomy and physiology (Doty and Bromley, 2011).

As is apparent from other chapters of the *Handbook*, considerable progress has been made in understanding the mechanisms of taste transduction and perception. This understanding will undoubtedly influence how taste disorders will be treated in the future and how pharmaceuticals

will be developed to minimize their adverse effects on taste function (see Chapters 30 and 40). For example, it is well established that diseases associated with chronic inflammation and immune system dysfunction adversely influence taste function. Type II taste receptor cells (see Chapters 29 and 31), which mediate the perception of sweet, bitter, and umami taste sensations, have been found to be specific targets for autoimmune disease in animal models (Kim et al., 2012), providing a potential focus for directing therapeutics to mitigate their adverse effect on taste. Interestingly, we now know that some patients with taste dysfunction have alterations in the expression of members of the T2R taste receptor gene family (for details of taste receptor genetics, see Chapter 31). In hypogeusia (decreased taste function), the frequency of the T2R40 gene is significantly reduced (Onoda et al., 2011), whereas in phantogeusia (taste sensations in the absence of a stimulus), the frequency of this gene appears to be increased (Hirai et al., 2012). Such a basic understanding may, in the future, lead to gene-related treatments for such disorders.

While it has been known for more than two centuries that taste sensations are mediated via taste buds within the lingual gustatory papillae and the palate (Chapter 29), the relatively recent discoveries of taste receptors in the respiratory epithelium, larynx, epiglottis, stomach, pancreas, and colon will undoubtedly influence the future practice of medicine (for history, see Chapter 1). The gut receptors represent a form of gastrointestinal chemosensation that impacts digestion, chemical absorption, insulin release, and ultimately the metabolism of swallowed foods and beverages (e.g., Breer et al., 2012; Reimann et al., 2012). Gut taste receptors explain why the pancreas releases more insulin when glucose is ingested than when directly

injected into the blood stream (Geraedts et al., 2012). The dysfunction of such receptors may also explain, at least in part, some cases of anorexia and obesity, and have the potential for providing new therapeutic targets for controlling metabolism (Janssen and Depoortere, 2013). Their decrease provides one explanation of why gastric bypass patients have an immediate decline in their underlying insulin resistance (Geraedts et al., 2012) and often find sweet and fatty meals to be less pleasant (Miras and le Roux, 2010). This new knowledge helps to explain why, to maintain optimal health, one must utilize the gut to receive nutrients rather than to rely on parenteral or intravenous means of feeding.

Despite such advances, the fact remains that relatively little is known about how diseases alter taste function. Even though disorders of taste are common in the general population, the spectrum of disorders influencing taste is broad, and patients are often at a loss as to where to turn for appropriate medical care. From a management perspective, a multidisciplinary mindset on the part of the physician or healthcare professional is clearly needed (Table 39.1). For example, which physician should manage an elderly patient who complains about a persistent “salty” taste, and is known to have hypertension, thyroid disease, poor dentition, and gastroesophageal reflux? Should it be an internist, endocrinologist, dentist, or gastroenterologist? What about the depressed patient with throat or brain cancer, who suffers from seizures or Bell’s palsy, continues to lose weight, has recurrent oral lesions, and complains that things “don’t taste right”? Such complexity is one reason why many physicians are at a loss as to how to manage such patients and where to refer them.

The goals of this chapter are to (1) explore the numerous ways that patients present to their physician with taste complaints and what those complaints may imply, (2) provide an approach to obtaining a taste-focused medical

history, physical exam, and sensory evaluation, (3) present the gamut of clinical disorders, across multiple specialties, that can be associated with taste disturbance, (4) discuss clinically-relevant anatomy and physiology associated with taste in the context of specific taste disorders, and (5) suggest options for patient management.

## 39.2 RANGE OF SYMPTOMS AND THEIR IMPLICATIONS

There is tremendous variability in the ways patients present with taste problems. The range of disturbances include: (1) perceived loss or diminution of function (ageusia or hypoguesia), (2) the distortion of everyday flavors (dysgeusia), (3) persistent abnormal taste sensations in the absence of taste stimuli (phantogeusia), (4) inability to recognize a taste sensation, even though gustatory processing, language, and general intellectual functions are essentially intact (gustatory agnosia), and (5) syndromes of pain with or without taste triggers (e.g., burning mouth syndrome). The overlapping and redundant innervation of the lingual taste buds from multiple cranial nerves and their branches (Chapter 29) makes taste disturbance less likely, but not impossible, in cases of selective neural injury. In fact, distortions of normal gustatory perception may occur with isolated injury to any one of the major nerve pathways, although the patient may not always recognize the problem.

One important distinction that should be made is whether the patient has difficulty with the perception of primary tastes versus the overall *flavor* of a substance. Primary taste sensations include *sweet*, *sour*, *salty*, *bitter*, and possibly *metallic* (iron salts), *umami* (monosodium glutamate, disodium gluanylate, disodium inosinate), and *chalky* (calcium salts). Chemical compounds can vary tremendously in their ability to stimulate these primary taste sensations. Like primary colors, these sensations blend to create variable “hues” of taste experience, and when they are combined with the sensory input from the olfactory and trigeminal systems, tasted substances acquire an aroma, texture, temperature, and spiciness – allowing for the overall perception of *flavor*. The primary flavor component of many “tastes” is, in fact, mediated by olfaction (e.g., chocolate, coffee, rose, strawberry, etc.). Stimulation of olfaction occurs during deglutition, when the molecules emanating from the food reach the olfactory mucosa from the oral cavity via the so-called retronasal route. Therefore, when a patient complains of distorted flavor perception, it is essential to also consider coexisting or isolated impairment of the olfactory and trigeminal systems (see Chapters 17 and 50).

Impairment of taste can be devastating to a patient since it not only affects the ability to enjoy food products, but can ultimately alter food choices and patterns of

consumption, thereby resulting in weight loss or weight gain, and in some cases malnutrition. People rely on taste function to gauge the quality of ingested nutrients; thus, in patients who are diabetic or hypertensive, the loss of taste may lead to dangerous overcompensation for the loss by adding too much sugar or salt to food. Without proper gustatory function, people are at risk for ingesting potential toxins and spoiled foodstuffs (which usually taste “bad”). Importantly, taste is needed to trigger normal ingestive and digestive reflex systems such as the secretion of oral, gastric, pancreatic, and intestinal juices (Chapter 36).

## 39.3 MEDICAL EVALUATION

### 39.3.1 Medical History

A focused clinical history for a person complaining of chemosensory dysfunction, particularly taste, begins with an accurate description of the subjective problem, including (a) onset, (b) frequency, (c) timing, (d) severity, (e) exacerbating or relieving foods or products, (f) relation to daily activities, bodily functions, and states of mind, (g) prior treatments and their efficacy, and (h) co-morbid medical conditions. A determination of current medications is essential. Particular note should be made in the history of problems with speech articulation, salivation, chewing, swallowing, oral pain or burning, dryness of the mouth, periodontal disease, foul breath odor, recent dental procedures or surgeries, recent radiation exposure, medications, and bruxism. Also, inquiry into the patient’s diet and oral habits may reveal exposure to oral irritants. Questions about hearing, tinnitus, and balance are important since the vestibulocochlear nerve (CN VIII) travels in close proximity to the facial nerve and can be susceptible to similar etiologies of disturbance (e.g., cerebellopon-  
tine angle tumor). Considering the occasional effect of gastroesophageal reflux on taste, asking about stomach problems may also be relevant. Asking about constitutional symptoms, such as fever, malaise, headache, body pains, and rashes, may also be important since such symptoms often accompany cancers or systemic inflammatory conditions (e.g., lupus). The possibility of seizure should be entertained, especially if the patient describes having “black-outs” or witnessed abnormal movements or actions.

### 39.3.2 Physical Examination

In the evaluation of the oral cavity, an examiner should attend to the condition of the teeth and gums. Notably, a dysgeusia may result from exudates that commonly appear with gingivitis or pyorrhea. The nature and integrity of the fillings, bridges, and other dental work should be inspected. Visual inspection of the tongue surface may show signs

of scarring, inflammation, or the absence, atrophy or overgrowth of papillae. A whitish plaque on the tongue can be from candidiasis, lichen planus, leukoplakia, or food product. Inflammation of the tongue, or glossitis, may be present, and can reflect local or systemic conditions. The physician should pay particular note to the color and degree of salivation. Palpation of the tongue should be performed to detect masses, neoplastic lesions or collections deep in the tongue’s musculature. The neck should also be evaluated for the presence of masses, thyromegally, and carotid bruits. Neurologically, the integrity of CN VII, IX, and X can be evaluated by screening for deficits in non-gustatory functions of these nerves, such as facial movements and expression, swallow function, gag, salivation, and voice production. To establish whether taste pores or papillae appear normal or are present in adequate numbers, the tongue can be stained with a dye and then photographed using a low power magnification (e.g., Doty et al., 2001; Miller and Reedy, 1990). Although not performed routinely, biopsy of circumvallate or fungiform papillae for detailed microscopic examination can establish whether pathological changes are present in taste bud tissue. Visual inspection of the ears, externally and internally, via an otoscope is essential. Normally, the tympanic membrane has a pale shiny gray color; erythema, vesicles, bulging, or an air-fluid level behind the membrane suggests infection. Breath odor can be diagnostic of a medical condition that affects taste function, such as fishy ammonia (renal failure), fruity chewing gum or acetone (diabetic ketoacidosis), musty (fetor hepaticus/ liver disease), putrid (oral or lung infection), or stale smoke (cigarette smoking). There are specific taste and flavor disturbances in conditions such as chronic hepatitis C infection, chronic kidney disease, and other metabolic disorders (Musialik et al., 2012; Armstrong et al., 2010; Palouzier-Paulignan et al., 2012). Considering the direct influence that olfaction has on perceptions of flavor, it is also important to examine the nose, nasal cavity, and paranasal sinus structures (Bromley and Doty, 2010).

### 39.3.3 Diagnostic Testing

Since most complaints of taste loss really reflect smell loss, olfactory testing should be performed, which is now easy to do given the commercial availability of quantitative smell tests (see Chapter 11). Unfortunately, taste testing is less practical, largely because of time considerations (see Chapter 34). While a number of whole-mouth taste tests have been described in the literature, regional taste testing is required to establish the function of each of the nerves innervating specific taste bud fields, as whole-mouth tests are insensitive to even complete dysfunction of one or several of the nerves that innervate the tongue. Two approaches are available to regionally assess taste function psychophysically. In *chemical testing*, liquid stimuli are

presented to selected target regions of the tongue or oral cavity via pipettes, special delivery devices, or filter paper disks. In *electrical testing* (also termed electrogustometry), low levels of electrical current are presented to taste bud fields (Frank and Smith, 1991). At low current ranges, gustatory – not somatosensory – afferents are activated. Equipment designed to present such electrical current to the tongue, termed electrogustometers, typically employ batteries to produce the current. It should be emphasized, however, that even the most simplistic of assessments can have tremendous utility in the clinical setting. For example, for a neurologist trying to distinguish a Bell's Palsy from a stroke syndrome causing facial weakness, the application of a sugar slurry (readily made with packets of sugar and a little water) to the affected side of the tongue (anterior 2/3) followed by the unaffected side can identify a unilateral deficit in taste that is typically found in Bell's Palsy alone.

Imaging studies can be helpful in the evaluation of gustatory disturbance. Plain radiographs of the teeth and jaw may reveal focal lesions of the teeth (e.g., fracture, cavity, impaction) or periodontal tissues (e.g., abscess extension) in proximity to gustatory fibers (e.g., chorda tympani-lingual nerve) and the tongue. Computed tomography (CT), however, is of greater utility in visualizing peripheral and central structures of the head and neck that are frequently affected by trauma, surgery, infection, cancer, and systemic disease. For example, fine axial “cuts” through the mastoid portion of the temporal bone can demonstrate subtle bony defects and mass lesions in and around the middle ear. Coronal CT scans are useful to evaluate paranasal anatomy. Noncontrast CT is used to show bony defects and acute blood accumulations, whereas contrast-enhanced CT highlights areas of inflammation or abnormal vascularity (as seen with many tumors). Magnetic resonance imaging (MRI) is the method of choice for soft-tissue anatomy and central nervous system structures. Particularly when sequences such as DWI (diffusion-weighted imaging) and FLAIR (fluid-attenuated inversion recovery) are used, MRI can discern infarcts of variable ages and other changes within central gustatory pathways. Indeed, gustatory dysfunction has been related to MRI-established ischemia, hemorrhage, or demyelinating plaques in the brainstem and higher cortical areas of some persons with chronic dysgeusia (Tsivgoulis et al., 2011; Onoda and Ikeda, 1999; Yabe et al., 1995). Gadolinium-DTPA (diethylenetriamine pentaacetic acid) enhancement is usually necessary to visualize lesions caused by demyelination, tumor, and infection. An electroencephalogram (EEG) should be obtained in all patients suspected for having seizure activity. Brain stem auditory evoked response (BAER) testing is useful to evaluate the continuity and symmetry of the brain stem auditory pathways and nuclei, and therefore, provides a screen for focal subcortical injury in this region. Although restricted in their

resolution and general availability, functional imaging of the brain using Positron Emission Tomography (PET), Single Proton Emission Computed Tomography (SPECT), and functional MRI (fMRI) may be helpful in evaluating cortical and sub-cortical structures related to gustatory processing – particularly in the context of cerebrovascular disease, epilepsy, and dementia. Depending on the suspected underlying medical problem affecting taste, there are a number of laboratory studies that are also available (Bromley, 2000).

### 39.4 CAUSES OF TASTE DYSFUNCTION

A wide range of disorders and interventions has been associated with at least some disturbance of taste function. Mechanisms for the alteration of taste may include: (1) the release of bad-tasting materials from oral medical conditions and appliances (e.g., gingivitis, purulent sialadenitis), (2) transport problems of tastants to the taste buds (e.g., causes by excessive dryness of the oral cavity, damage to taste pores from a burn, candidiasis), (3) destruction or loss of taste buds themselves (e.g., local trauma, invasive tumor), (4) damage to one or more neural pathways innervating the taste buds (e.g., Bell's Palsy, trauma, dental or surgical procedures), (5) involvement of central neural structures (e.g., tumor, epilepsy, stroke), and (6) systemic disturbances of metabolism that presumably affect the taste system via any of the aforementioned mechanisms (e.g., medications, hypothyroidism, diabetes, liver or kidney disease).

Although total loss or markedly diminished whole-mouth gustation exists, such conditions are rarely produced by non-metabolic diseases or disorders unassociated with central ischemic or other damage, since regeneration of taste buds can occur and peripheral damage alone would require the involvement of multiple pathways. Thus, while 433 of 585 patients (74%) with verifiable olfactory loss complained to us of both smell and taste disturbance, less than 4% had verifiable whole-mouth gustatory dysfunction, and even that dysfunction was limited (Deems et al., 1991). Regional deficits in taste dysfunction are much more common. For example, in one study, sensitivity to three relatively low concentrations of NaCl was measured on the tongue tip and 3 cm posterior to the tongue tip in 12 young (20–29 years of age) and 12 elderly (70–79 years of age) subjects. On average, the young subjects were more sensitive to NaCl on the tongue tip than on the more posterior stimulation site and exhibited, at both tongue loci, an increase in detection performance as the stimulus concentration increased. The elderly subjects, who would be expected to exhibit, at worse, moderate deficits on whole-mouth testing, performed at near-chance level (Matsuda and Doty, 1995).

Patients with focal regions of taste impairment can, in some instances, perceive an alteration in overall gustatory perception. Thus, in one series, nearly 57% of patients presenting with Bell's palsy complained of dysgeusia (Adour, 1982) and, in a different study, more than 9% of patients with surgically confirmed acoustic neuromas experienced loss of taste as a primary complaint (Harner and Laws, 1981). However, many people are unaware of such deficits. In fact, it is unusual for patients to specifically recognize their loss of taste sensation on half of the anterior tongue following unilateral sectioning of the chorda tympani in middle ear surgery. This lack of awareness stems, in part, from the redundancy of the multiple taste nerves, as well as compensatory mechanisms.

Interestingly, unilateral anaesthetization of the chorda tympani nerve (CN VII) enhances taste perception on the rear of the tongue (CN IX), particularly on the side contralateral to that of the anaesthesia (Kveton and Bartoshuk, 1994; Yanagisawa et al., 1998). Such enhancement – which would be expected if significant regional lingual damage occurs – seems to be accentuated for unpleasant tastants and, moreover, may induce phantom tastes. Yanagisawa et al. (1998) have reported that this procedure increases the perceived intensity of bitter substances, such as quinine, applied to posterior taste fields, whereas the reverse occurs for the salty taste of NaCl. When both chorda tympani nerves were anesthetized, the effect was perceived bilaterally. In about 40% of their subjects, a phantom taste, usually localized to the posterior tongue contralateral to the anesthesia, appeared in the absence of stimulation and disappeared when the region of origin was anesthetized. Such phantoms may reflect central interactions among the taste nerves (e.g., release of inhibition), since the taste pathways do not cross until they reach the thalamus.

### 39.4.1 Disorders of the Oral Cavity and Related Structures that Affect Taste

**39.4.1.1 Oral Mucosa.** The mucous membranes of the mouth, tongue, and oropharynx are directly exposed to the outside environment, and as such, are unique in their ability to protect, adapt, and regenerate in response to continuous chemical, mechanical, and thermal challenges. Digestion begins in the mouth with tastants being solubilized in saliva and exposed to a myriad of enzymes and resident microflora. A testimony to the durability of the oral mucosa is the fact that humans ingest many diverse foods over a broad range of temperatures and textures, often in the context of abrasive oral appliances and harmful habits such as tobacco use. Moreover, this mucosa tolerates large microbial concentrations of the magnitude found elsewhere only in the colon. This durability stems, in part, from antimicrobial properties of saliva, and the

high basal turnover rate of oral epithelial cells (Beidler and Smallman, 1965). Microorganisms that bind to surface cells of the mucosa are rapidly sloughed as the surface is renewed. Subsequently, disorders that alter the secretion and contents of saliva, the turnover rate of epithelial cells, and the balance of microorganisms within the epithelium, have the potential to alter proper mucosal function and to distort taste.

By providing moisture and lubrication, saliva facilitates the chewing and swallowing of food, aids in the production of speech, acts as a buffer to acids and bases, and increases the delivery of solubilized chemicals to taste receptors (Chapter 28). Inadequate salivary flow via impaired production or secretion (e.g., numerous medications, sialolithiasis, irradiation of salivary glands) can result in (1) the tendency of oral mucosa to stick together, (2) impairment of eating and speech function, (3) aggravation of oral infections, (4) impaired ability to properly wear dental prostheses, and, in some instances, (5) abnormal flavor sensations. Clinically, this constellation of problems is considered *xerostomia*, and is one means by which many local and systemic diseases may cause taste disturbance. Importantly, saliva likely plays a significant role in taste bud maintenance (Morris-Witman et al., 2000).

Some lesions involving the oral epithelium can be associated with altered taste perception, tactile irritation, and possibly oral pain (Table 39.2), either by direct involvement with taste-related structures or through association with a taste-altering systemic illness (e.g., local or systemic cancer, autoimmune disorder, vitamin deficiency). Most healthy tissues of the oropharynx appear pink because the epithelium and connective tissues of the lamina propria are relatively translucent and allow red light to reflect from the underlying capillary bed. Disruption of the epithelial architecture, from such pathological processes as chemical necrosis of the surface layers, microbial colonies, exudate, and epithelial thickening from continued trauma, can scatter and reflect incident light creating a discolored whitish lesion. In regions of particular inflammation within the mucosa (e.g., glossitis), reddish lesions can predominate. For example, continued exposure to the heat and smoke from burning tobacco can lead to a rough, white, and fissured tongue surface often with associated areas of inflammation – known as nicotinic stomatitis (Rossie and Guggenheimer, 1990). Leukoplakia is a clinical diagnosis reserved for whitish lesions that cannot be scraped off the tongue surface. Approximately 20% of these lesions represent premalignant epithelial dysplasia, carcinoma *in situ*, or frank invasive squamous cell carcinoma (Rodriguez-Perez and Banoczy, 1982; Allen and Blozis, 1998). The apparent overgrowth or the exaggeration of the length and thickness of the filiform papillae (e.g., “hairy tongue”) can result from conditions that impair appropriate desquamation either by reducing salivary flow, limiting oral movements,

**Table 39.2** Disorders involving structures of the oral cavity that can alter taste perception.

EPITHELIAL ABNORMALITIES	
Autoimmune	
Behcet's syndrome	
Crohn's disease	
Lupus erythematosus	
Pemphigus vulgaris	
Reiter's syndrome	
Scleroderma	
Sjogren's syndrome	
Wegener's granulomatosis	
Discolored lesions	
Acanthosis nigricans	
Chronic ulcerative stomatitis	
Diffuse or multiple papillary/ verrucous lesions (e.g., Hairy tongue)	
Erythema multiforme	
Leukoplakia	
Lichen planus	
Median rhomboid glossitis (MRG)	
Nicotinic stomatitis	
Reactive papillary hyperplasia	
Metabolic	
Primary amyloidosis (affecting tongue)	
Infection	
Candidiasis	
Ulcerative lesions	
coxsachievirus	
gonorrhea	
herpes simplex virus	
mycoses	
syphilis	
varicella/ zoster	
Local injury	
Burns/ chemical injury	
Radiation/ chemotherapy	
Trauma

SALIVARY GLAND ABNORMALITIES
radiation/ chemotherapy
salivary gland tumor or cyst
sialolithiasis
Sjogren's syndrome
viral infections
Chronic sialoadenitis from:
congenital or trauma-related stenosis
foreign body
recurrent sialolithiasis
salivary gland tumor or cyst
PARANASAL SINUS ABNORMALITIES
Post-nasal drip
Purulent sinusitis
GASTROESOPHAGEAL REFLUX DISEASE

or causing temporary imbalances in the growth of normal microbial flora. Numerous drug therapies, primarily antibiotics, have been implicated as a cause for this condition (Thompson and Kessler, 2010). Hairy tongue can sometimes be associated with a disagreeable taste or sensations of gagging when swallowing (Thompson and Kessler, 2010).

Squamous cell carcinoma is particularly worrisome, since: (1) it is responsible for more than 90% of oral cancers, (2) has a considerable mortality rate (5 year survival rate of approximately 52%), and (3) may have only subtle affects – if any – on one's taste function (Salisbury, 1997). Arising from mucosal epithelium, squamous cell carcinoma is common on the ventral and lateral surfaces of the tongue and can be invasive, producing swelling and induration (Allen and Blozis, 1998). After several months of growth, the cancer can develop into an exophytic (sometimes endophytic), painful, ulcerated mass that bleeds easily and has a necrotic odor (Salisbury, 1997). The treatment of oral cancer, as well as other cancers of the head and neck, with agents like radiation and chemotherapy is more often associated with impairment of taste function than the cancers themselves. Radiation therapy alters taste bud cell turnover and can affect taste function, although return after radiation treatment has been observed (Conger, 1973). Additionally, radiation therapy fields often include salivary glands (e.g., parotid or submandibular) that are near the site of the primary tumor or lymph nodes that need treatment; this can result in irreversible damage to acinar cells, profound impairment of salivary flow, subsequent dessication of the mucosa, and xerostomia (Salisbury, 1997). Also, susceptibility to opportunistic infections (e.g., dental caries, candidiasis) increases after therapy. Necrosis of the tongue after arterial chemotherapy has been reported, in addition to the known direct effect on basal cell and taste

receptor production (Shih et al, 1999; Duhra and Foulds, 1988).

Local injury to the oral cavity from such insults as physical trauma, burns, and toxic chemical exposures can acutely alter flavor perception and create a dysgeusia associated with the region of mucosa involved. Applying a caustic substance to the oral mucosa can produce variable degrees of epithelial necrosis – resulting in whitish lesions, erosions, ulcerations, or blisters. For example, the inappropriate use of aspirin as a topical anesthetic causes a common and severe form of chemical burn to the mucosa (Allen and Blozis, 1998). Although most etiologies of local injury produce only transient lesions that last 1 to 2 weeks, repeated exposures (e.g., heavy use of O<sub>2</sub> liberating mouthwashes) or injury (e.g., prolonged intubation with an oral endotracheal tube), especially in the context of underlying xerostomia, can produce more lasting and symptomatic lesions, and, in some patients, taste disturbances. Interestingly, taste function is relatively resistant to the toxic effects of smoking, although morphological changes to surface papillae on the tongue are observed in heavy smokers (Konstantinidis et al., 2010).

Infections are common causes of distorted taste and oral pain. In fact, any local infection in and around the neural pathways or receptor sites associated with taste perception has the potential to disturb or impair taste. The involved mechanisms can be direct inflammation and injury to a taste-related neural structure or the associated release of mucopurulent material that generates a bad flavor. Important anatomical regions include: (1) the surface of the tongue, mouth, and oropharynx, (2) the teeth and periodontal tissue, (3) the salivary glands, and (4) the middle ear. *Candida albicans* is a commensal yeast that normally exists, in small numbers, in the oral flora. However, when the oral immune system is not functioning optimally – as seen in the very young or old, in the HIV-infected, in patients with leukemia, or in those who have recently taken corticosteroids, chemotherapy, or broad-spectrum antibiotics – candidiasis of the tongue and oropharynx can ensue. The development of a pseudomembrane overlying an inflamed oral mucosa is called “thrush,” and can be treated with antifungal therapy (Allen, 1992). There are other types of infectious diseases causing oral lesions, many of them viral, and most resulting in some form of pharyngitis, stomatitis, and an ulcerative or blistered lesion of the oral mucosa. Typically they are treated with topical or systemic antibiotics.

There are several autoimmune syndromes that affect the oral mucosa, usually by causing xerostomia and/or ulceration that, on rare occasion, can result in taste disturbance (for review, see Campbell et al., 1983). Sjogren’s syndrome (SS) is associated with salivary and lacrimal gland dysfunction – resulting in dry eyes and dry mouth (also called sicca syndrome) – and arthritis. If the symptoms

of SS occur in the context of another autoimmune disease (e.g., lupus, scleroderma, rheumatoid arthritis), it is said to be *secondary SS*. Systemic lupus erythematosus (SLE) is an multisystem inflammatory disease of small blood vessels that can produce a wide range of clinical symptoms including superficial ulcerative, vesicular, and white keratotic lesions of the tongue and oral mucosa. Behcet’s syndrome is also a multisystem disorder consisting of recurrent oral and genital ulcers, inflammatory disease of the eyes and gastrointestinal tract, arthritis, and on rare occasion cranial neuropathies or meningoencephalitis. *Pemphigus vulgaris* is characterized by serum antibodies directed against components of the epidermis and mucosa, forming characteristic bulla that progress to superficial and friable eroded areas most often involving the palate, buccal mucosa, and tongue (Laskaris et al, 1982). One report describes a patient with Giant cell arteritis presenting with ageusia and lower extremity claudication (Mathew et al., 2010).

**39.4.1.2 Tongue.** The tongue is a highly mobile muscular structure with multiple functions, including (1) manipulating food during mastication (chewing), (2) squeezing food into the pharynx during deglutition (swallowing), (3) forming words during articulation (speech), (4) oral cleansing, and (5) taste. Embryologically, the anterior 2/3rds of the tongue (oral part) develops from the first brachial arch while the posterior third (pharyngeal part) develops from the second and third brachial arches, producing two distinct geographic regions identifiable by their nerve supply (CN VII and IX, respectively) and lymphatic drainage. The tongue’s arterial supply is chiefly through the lingual artery which arises from the external carotid. Within the pharynx, the oral and nasal cavities communicate, allowing volatile chemicals released during chewing to pass into the nasal passages. Disorders of the tongue, such as neoplasms, infarction and swelling, cannot only affect overall lingual function, but distort surface structures and impair taste. In primary amyloidosis, amyloid deposition within the lingual tissues can impair taste and can be an early symptom of the disease (Ujike et al, 1987).

#### **39.4.1.3 Gingival/Dental/Periodontal Structures.**

Most diseases affecting the periodontal soft tissues (the gingiva) and the soft and hard palates (periodontium) have an infectious component to their pathology. Dental infections are common among patients who neglect regular dental care. A dentoalveolar abscess, usually resulting from dental caries, can erode from the tooth to the adjacent gingival tissues to create a draining gingival fistula. These fistulas can drain bitter and foul-tasting purulent material. A peridental cellulitis and/or abscess can involve the adjacent bone or perimandibular soft tissues and is usually associated with

significant gingivitis, variable degrees of facial swelling, and fever. Acute necrotizing ulcerative gingivitis (ANUG, also known as *trench mouth* from the outbreaks among the troops in the trenches during World War I) is now not considered to be contagious, but rather, an opportunistic overgrowth of relatively common microbes in the mouth (Melnick, 1988). Predisposing factors include psychological and environmental stress, nutritional inadequacies, poor oral hygiene, and smoking. The clinical presentation is stereotyped, and involves the sudden onset of gingival pain, bleeding, a bad taste in the mouth, and a fetid mouth odor that can be recognized by the patient (Melnick, 1988). A periodontal infection that is strategically located in the area of the chorda tympani-lingual nerve as it passes near the third molars can injure this nerve and affect taste on the ipsilateral side of the tongue.

**39.4.1.4 Salivary Gland Disorders.** In addition to producing saliva, the anatomical orientation of the salivary glands is important to taste since CN VII emerges from the stylomastoid foramen to enter the substance of the parotid gland. Therefore, lesions of the parotid (e.g., tumors, abscesses) can eventually involve this nerve and affect taste. Infections of the salivary glands (saladinitis) can be acute or chronic. Bacterial infections of the gland parenchyma are typically retrograde in nature and the result of a mechanical blockage or diminished production of saliva (Berndt et al, 1931; Gayner et al, 1998). However, there are viral infections, such as the mumps or HIV, which can produce localized gland disease (Gayner et al, 1998). Local symptoms of suppurative sialadenitis include pain, swelling, induration, and suppurative discharge from the duct orifice into the oral cavity yielding a foul taste. Although infections can occur in any salivary gland, the parotid is the one most commonly involved (Gayner et al, 1998). High pH and viscosity of gland saliva likely contribute to calcium phosphate stone formation within the salivary duct, resulting in obstruction, stagnant salivary flow, dry mouth, and a suppurative infection. Contributing factors to infection include poor oral hygiene and compromised host resistance.

**39.4.1.5 Gastroesophageal Reflux Disease.** Gastroesophageal reflux disease (GERD) is defined as a recurrent regurgitation of acidic gastric contents up the esophagus as a result of transient or chronic relaxation of the lower esophageal sphincter (Isolauri et al., 1997). GERD symptoms can be obvious, such as recurrent mid-chest discomfort from esophageal irritation (*heartburn*), or they can be rather subtle, only manifesting as chronic cough, halitosis, hoarseness, or a recurrent acid or sour taste (Richter, 1998; Nelson et al., 2000). While it is not clear whether GERD can result in permanent injury to

the gustatory mucosa, dysgeusias due to GERD do occur, but typically resolve with proper treatment of the reflux.

### 39.4.2 Disorders of the Multiple Peripheral Neural Pathways that Affect Taste

Depending on their location, taste receptors within the taste buds are innervated by branches of several cranial nerves, including CN VII, IX, X, which, unlike CN I, are mixed motor and sensory nerves transmitting multiple forms of information. This becomes important when considering clinical syndromes that involve taste dysfunction since variable degrees of either motor or sensory disturbance may be present, depending upon where and to what extent the taste-mediating cranial nerve is injured (see Table 39.3). All the peripheral gustatory fibers enter the brainstem and project to the nucleus of the tractus solitarius (NTS), which begins in the rostralateral medulla and extends caudally along the ventral border of the vestibular nuclei.

**39.4.2.1 The Facial Nerve (CN VII).** The facial nerve (CN VII) supplies the muscles of facial expression, the stapedius muscle of the middle ear (which helps to dampen the movement of the stapes in response to loud auditory stimuli), the sublingual and submandibular salivary glands, the lacrimal glands, and the membranes of the oral and nasal cavities. In addition, this nerve conveys taste sensation from the taste buds found in the fungiform and filiform papillae on the ipsilateral anterior two-thirds of the tongue (via the lingual nerve to the chorda tympani) and on the soft palate (via the lesser palatine nerve branch of the greater petrosal nerve). Because of the relative long and winding course of the facial nerve, it is susceptible to peripheral injury in a number of locations. Thus, from the tongue, gustatory fibers travel through the lingual nerve, passing within the soft tissue of the jaw along the medial surface of the mandible in close proximity to the mandibular third molar. At this point they become the chorda tympani nerve, which penetrates the skull via the stylomastoid foramen and which turns within the tympanic cavity of the middle ear along the medial surface of the tympanic membrane between the malleus and the incus. The fibers then synapse with the geniculate ganglion at the bend of the facial nerve within the facial canal, where the projection becomes the nervus intermedius, which travels next to the eighth nerve through the internal auditory meatus into the cerebellopontine angle. This nerve subsequently penetrates the caudal border of the pons near the medulla and enters the brainstem. Thus, tumors anywhere along the nerve path of the facial nerve — from the oral cavity through the skull base, temporal bone and middle ear, to the cerebellopontine angle and the brainstem — can cause a neuropathy of the nerve.

**Table 39.3** Disorders of peripheral nerves that may alter taste perception.

## CRANIAL NERVE VII (FACIAL NERVE)

## Infection/polyneuritis

- Bell's palsy
- Botulism
- Guillain-Barré syndrome
- Herpes zoster
- Human immunodeficiency virus
- Kawasaki disease
- Leprosy
- Lyme disease
- Otitis Media
  - Acute bacterial
  - Chronic bacterial
  - Cholesteatoma
- Syphilis
- Tuberculosis

## Neoplastic

- Glomus tumor
- Primary parotid tumor
- Schwannoma / Acoustic neuroma
- Temporal bone cancer / metaseses

## Trauma

- Barotrauma
- Birth trauma
- Injection of local anesthesia (e.g., dental procedure)
- Middle ear surgery
- Temporal or mandibular bone fracture
- Third molar extraction

## Neurovascular

- Brain stem stroke (pontine)

## Inflammatory

- Multiple sclerosis
- Sarcoidosis
- Melkersson syndrome

## CRANIAL NERVE IX (GLOSSOPHARYNGEAL NERVE)

## Trauma

- Bronchoscopy
- Laryngoscopy
- Penetrating neck trauma
- Skull base fracture
- Tonsillectomy

## Neoplastic

- Glomus Jugulare tumor
- Neurofibroma
- Skull-based metastases

## Neurovascular

- Carotid artery aneurysm or dissection
- Brain stem stroke (pontine, medullary)

## Infection

- Botulism
- Guillain-Barré syndrome
- Herpes zoster of petrosal ganglion (rare)
- Leprosy
- Meningitis
- Otitis media

**Table 39.3 (Continued)**

## CRANIAL NERVE IX (GLOSSOPHARYNGEAL NERVE)

## Pharyngeal / retroparotid abscess

## Inflammatory

- Multiple sclerosis
- Sarcoidosis

## CRANIAL NERVE X (VAGUS NERVE)

## Trauma

- Neck surgery
- Penetrating trauma
- Skull base fracture

## Infection

- Cytomegalovirus
- Guillain-Barré syndrome
- Leprosy
- Meningitis
- Pharyngeal / retroparotid abscess
- Poliomyelitis

## Neoplastic

- Glomus Jugulare tumor
- Neurofibroma
- Skull-based metastases

## Neurovascular

- Brain stem stroke (medullary)
- Carotid artery aneurysm or dissection

## Degenerative

- Multisystem atrophy
- Progressive bulbar palsy

## Inflammatory

- Multiple sclerosis
- Sarcoidosis

Bell's Palsy (BP) is a common facial nerve injury associated with gustatory loss. Clinical criteria include the sudden weakness of all muscles of one side of the face in the absence of CNS, ear, or cerebellopontine disease (Taverner, 1973). The etiology is still considered idiopathic, although viruses are often involved (Adour et al., 1975; Takahashi et al., 2001). Thus, the herpes simplex virus-1 genome has been isolated from facial nerve endoneurial fluid in affected patients (Murakami et al., 1996). BP affects both sexes and all ages. Although it is frequently associated with ipsilateral loss of taste over the anterior two-thirds of the tongue, the patient may or may not recognize this loss. Involvement of taste in BP localizes the lesion to the neural pathways from the pons, along the nervus intermedius portion of the facial nerve, through the geniculate ganglion, to the point where the chorda tympani joins the facial nerve in the facial canal. A more severe form of BP, Ramsy-Hunt syndrome, results from active herpes infection of the geniculate ganglion, and involves pain and vesicles in the external auditory canal or soft palate. Bartoshuk and Miller (1991) describe a patient with this syndrome whose neural involvement included both

CN V and CN IX on the left side. Intensity ratings of the four major taste qualities were obtained at regular intervals across a nearly two-year period for the front, back, and palate regions. The entire left side of the patient was devoid of taste function about three months after the *Herpes zoster oticus* attack. Although all taste qualities were perceived on the left rear and palate regions after about a year, only sweetness was perceived on the left front. Even by the end of study, full taste recovery of the anterior tongue was not evident.

BP usually begins with pain in or behind the ipsilateral ear with subsequent unilateral facial weakness with maximum paralysis occurring within 48–72 hours). In addition to ipsilateral taste loss, hyperacusis (due to weakness of the stapedius muscle) is often present. The taste-salivary reflex also can be compromised. This reflex results in salivation when a gustatory stimulus, such as a weak acid, stimulates the anterior tongue, and reflects a relay from the nucleus of the solitary tract to the parasympathetic fibers innervating the salivary glands. Regeneration of the facial nerve after BP may be abnormal, such that novel innervation to nearby structures can produce synkinesis of the facial musculature when chewing, or tearing of the ipsilateral eye while eating (“crocodile tears”). Melkersson syndrome, a familial disorder of recurrent BP, can result in permanent facial palsy, and is associated with lingua plicata (furrowed or fissured tongue) and recurrent facial edema.

Taste dysfunction resulting from trauma is much less common than post-traumatic smell dysfunction, with solitary ageusia of one or more primary taste modalities occurring in less than 1% of persons with major head injury (Sumner, 1967; Deems et al., 1991). Our understanding of focal nerve injury (and recovery) associated with potential taste disturbance has improved recently, particularly in iatrogenic situations involving surgical interventions of the head and neck (Graff-Radford and Evans, 2003; McManus et al., 2012; Guinand et al., 2010). However, in cases of global trauma to the head and neck, trauma-related taste disturbances are only rarely unaccompanied by smell impairment. The prognosis for post-traumatic ageusia is far better than for post-traumatic anosmia, and recovery from ageusia usually occurs over a period of a few weeks to months. The etiology of post-traumatic taste disturbance varies. Head trauma that results in injury to the middle ear, a finding often encountered with temporal bone fractures, can potentially result in both ipsilateral impairment of taste function and injury to the preganglionic parasympathetic fibers, thereby preventing salivary secretion. Approximately 7–10% of temporal bone fractures result in facial nerve dysfunction (Chang and Cass, 1999). Injury to the lingual nerve from trauma in and around the mouth and tongue is another cause of taste impairment. This branch of the mandibular division of the trigeminal nerve (CN V<sub>3</sub>)

is the most proximal pathway to the tongue for general somatic sensation (touch) and special visceral sensation of taste (due to coexisting chorda tympani fibers). Thus, injury to the jaw resulting in mandibular fracture (e.g., punch with a fist), or to the inside of the mouth (e.g., difficult orotracheal intubation, aggressive dental procedure), can result in numbness and taste loss over the anterior two-thirds of the ipsilateral side of the affected tongue. Compression injury to the chorda tympani-lingual nerve may have a greater effect on taste than on fine-touch sensory components, since the chorda tympani fibers of the conjoined nerve are more superficial and posterolateral, and therefore more susceptible to partial transection or pressure on the side of the nerve (Wantanabe et al., 1995).

In general, the classification of nerve injury pathology defined by Seddon in 1943 continues to apply to situations of head and neck injury to taste-mediating neural structures and to prognosis (Seddon, 1943). *Neuropraxia* is a conduction block through a nerve resulting from mild trauma without axonal damage and recovery of sensory deficits within, at most, days to months. *Axonotmesis* is a more severe injury to the nerve associated with afferent fiber degeneration, preservation of the nerve sheath, possible neuroma formation, incomplete sensory recovery, and, in most cases, significant dysesthesia/sensory distortions. *Neurotmesis* is the most severe injury typically associated with cutting the nerve all together, anesthesia/loss of function in the nerve distribution and no sensory recovery – particularly if the nerve path is within soft tissue. If the nerve path is within bone at the point of neurotmesis, regeneration may occur (Seddon, 1943; Graff-Radford and Evans, 2003).

A number of surgical procedures can influence taste function. Taste disturbances after tonsillectomy are not uncommon, with as many as eight percent of patients having subjective taste problems six months after surgery. One percent of tonsillectomy patients report suffering continued dysgeusia up to 2–12 years after surgery (Heiser et al., 2010, 2012). Ear surgery, including tympanoplasty, mastoidectomy, and stapedectomy, can damage CN VII, CN VIII, and middle ear structures (Moon and Pullen, 1963; Kveton and Bartoshuk, 1994; Guinand et al., 2010). In the case of mastoidectomy, the risk of hearing loss and facial nerve injury must be emphasized in any consent form. However, the chorda tympani nerve fibers are particularly at risk, and in situations of open cavity middle-ear surgery, chorda tympani division is almost inevitable (Kiverniti and Watters, 2012). This nerve is typically stretched, sectioned, or sacrificed during such surgery, often resulting in taste loss or a metallic dygeusia. Such sensory aberrations can last long after the operation. Bull (1965) found that 78% of patients with bilateral section and 32% of patients with unilateral section of the chorda tympani had persistent adverse symptoms. In a recent review, McManus et al.

(2012) found that 15–22% of patients who have undergone middle ear surgery experience symptoms of taste disturbance and/or dryness of the mouth. Most experienced a gradual recovery to normal function, but in some persistent and troublesome complaints continued. It should be noted that the effects of chronic otitis media alone can impair ipsilateral perception of sour, bitter and salty tastes, with subsequent improvement in function one month following middle-ear surgery *when the chorda tympani nerve is preserved* (Huang et al., 2012). If there is intra-operative injury to the chorda tympani nerve, the post-operative gustatory function a month later remains the same as the pre-operative baseline (McManus et al., 2012). With regard to patient symptoms following open cavity mastoidectomy to both ears, a recent survey showed that 24.3% were aware of a taste disturbance immediately after the surgery; only 8.7% had persistent long-term disturbance (Kivernitis and Watters, 2012). Laryngoscopy and endotracheal intubation can have rare complications that result in lingual nerve injury, often with coexisting hypoglossal nerve damage (Gaut and Williams, 2000; Silva et al., 1992; Evers et al., 1999). However, the specific incidence of taste disturbance with and without somatosensory loss following these procedures has not been well defined.

The common dental procedure, third molar (*wisdom tooth*) extraction, is clearly associated with risk of damage to the lingual nerve/chorda tympani fibers (Graff-Radford and Evans, 2003; Valmeseda-Castellon et al., 2000; Blackburn and Bramley, 1989). The reported incidence of this problem varies widely (from 0.2 to 22%), possibly reflecting variability in the surgical techniques that are employed (Robinson et al., 2000; Scrivani et al., 2000). The chorda tympani-lingual nerve lies in close proximity to the mandibular third molars making it susceptible to dental manipulation and injury. This nerve may also be injured by the injection of local anesthesia, either by direct contact with the needle or as a result of neurotoxic effects of the anesthetic compound (typically lidocaine and epinephrine) (Shafer et al., 1999; Nickel, 1993). Shafer et al. (1999) quantitatively evaluated taste function in 17 patients before third molar extraction, and at 1 month and 6 months thereafter. These investigators found that taste deficits can persist for at least 6 months after surgery, even though they do not typically result in patient complaints of taste loss, and patients with the most deeply impacted teeth exhibit the most severe loss. In a retrospective study of patients' perception of taste after lingual nerve injury and repair, Scrivani et al. (2000) found that among 22 patients who experienced a sensory deficit to the lingual nerve, 20 patients perceived a subjective disturbance of whole mouth taste function before surgical repair. While repair of this nerve provided significant improvement in trigeminal somatosensory function (82%), improvement in whole mouth taste was moderate at best (35%).

Infections can also result in taste disturbance. Otitis media is a suppurative infection of the middle ear caused by such organisms as *S. pneumoniae*, *H. influenzae*, *M. catarrhalis*, and group A streptococci. Recurrent and aggressive cases of otitis media can result in unilateral taste loss or dysgeusia due to chorda tympani nerve injury as it passes through the middle ear. One series reports that otitis media accounts for approximately 3.1% of acute facial palsies (Takahashi et al., 1985). CNS infections such as lyme, TB, and occasionally HIV are routine suspects when a patient presents with a possible "Bell's Palsy," often warranting a lumbar puncture for cerebrospinal fluid analysis. Other inflammatory disease states, such as sarcoidosis or Wegener's granulomatosis, can also cause isolated facial nerve injury and possibly taste disturbance (Bibas et al., 2001).

**39.4.2.2 The Glossopharyngeal Nerve (CN IX).** The glossopharyngeal nerve (CN IX) innervates the stylopharyngeus muscle (motor), the parotid gland (autonomic), the tympanic cavity and plexus (sensory), the eustachian tube (sensory), the carotid sinus baroreceptors (sensory), and the pharyngeal mucosa (sensory). The lingual-tonsillar branch of CN IX supplies circumvallate and most foliate taste buds within the posterior third of the tongue. The pharyngeal branch of the CN IX innervates taste buds in the nasopharynx. The nerve cell bodies of these gustatory afferent fibers are located immediately outside the jugular foramen – through which they eventually pass to enter the skull – in the petrosal ganglion. Clinically important functions of this nerve include: a) the salivary reflex (a flow of saliva from the parotid gland through Stensen's duct in response to highly seasoned foods on the tongue), b) the gag reflex (an elevation and constriction of the pharyngeal musculature retraction of the tongue in response to stimulating the base of the tongue and posterior pharyngeal mucosa), and c) the carotid sinus reflex (vagally-mediated reflexive parasympathetic slowing of heart rate with mechanical stimulation of the carotid sinus).

CN IX is small, and unlike CN VII, relatively well protected, making isolated lesions of this nerve extraordinarily rare. In fact, disorders that involve this nerve almost invariably affect the nearby vagus, accessory, or hypoglossal nerves. Nevertheless, damage to CN IX can occur as a result of tonsillectomy, bronchoscopy, or laryngoscopy (Donati et al., 1991; Arnhold-Schneider and Bernemann, 1987; Vories, 1999), reflecting the proximity of its lingual branch to the muscle layer of the palatine tonsillar bed. Neoplasms along the course of CN IX only rarely present with isolated impairment of the nerve. Vernet's syndrome – a syndrome consisting of loss of taste in posterior third of tongue, paralysis of the vocal cord, palate, pharynx, trapezius, and sternocleidomastoid muscles – is caused by lesions

of the jugular foramen that affect cranial nerves IX, X, XI. Usually, it is of traumatic origin (e.g., skull base fracture); however, it can occur as a result of internal carotid artery aneurysms, tumors, granulomas, or thrombosis of the jugular bulb (Haerer, 1992).

Glossopharyngeal neuralgia is an important syndrome involving this nerve in which eating, swallowing, or talking may bring on a lancinating pain from one side of the throat, along the course of the eustachian tube to the tympanic membrane and ear. Like trigeminal neuralgia, there can be trigger zones for pain, and with the glossopharyngeal nerve they are usually the base of the tongue, pharyngeal wall, or tonsillar regions. While most cases are considered idiopathic, glossopharyngeal neuralgia has been associated with tongue carcinoma (particularly the posterior third), laryngeal carcinoid, a cerebellopontine angle tumor, and neck trauma (Webb et al., 2000).

On rare occasion there can be a disturbance of taste with increased salivation that accompanies diseases of the middle ear (Haerer, 1992). This owes to the fact that the tympanic plexus is a glossopharyngeal-mediated structure with corresponding visceral fibers in both the inferior salivatory and the gustatory nuclei (Carpenter, 1985).

**39.4.2.3 The Vagus Nerve (CN X).** The vagus (CN X) mediates sensation from the vocal cords, external ear, external auditory canal, and external surface of the tympanic membrane, as well as visceral sensation from the larynx to the gut. It innervates the taste buds on the epiglottis, aryepiglottal folds, and esophagus (via the internal portion of the superior laryngeal branch). Afferents from the superior laryngeal nerve project centrally from their cell bodies in the inferior nodose ganglion. This nerve provides motor function to the smooth muscle of the pharynx, larynx, and viscera, as well as to all striated muscles of the pharynx, larynx, and palate, except the stylopharyngeus (CN IX) and tensor veli palatini (CN V3) muscles.

Clinically important CN X reflexes include: (1) the vomiting reflex (a severe form of the gag reflex involving the vagus nerve), (2) the swallowing reflex (swallowing in response to pharyngeal wall and back of tongue stimulation by a food bolus), (3) the cough reflex (cough in response to stimulation of the pharynx, larynx, trachea, bronchial tree, tympanic membrane or external auditory canal), (4) the sucking reflex (sucking by infants in response to tactile stimulation of the lips near the buccal angle), and (5) the carotid sinus reflex (mentioned above, the efferent limb). In terms of localization, it is important to note that pharyngeal branches separate from the vagus nerve high in the neck; thus, the absence of any sensory changes in the pharynx suggests that the neural lesion is below this level.

While a number of disorders can affect the vagus nerve, such as tumors, vascular lesions, and infections, it is unclear

whether isolated vagal injury can actually result in a subjective impairment or distortion of taste. This is of particular current interest given our understanding, described earlier in the chapter, that gastrointestinal chemosensation exists, and that chemosensory cells in the gut are known to interact with visceral afferents and the secretion of satiation peptides.

#### **39.4.2.4 Other Nerves Relevant to Taste.**

The trigeminal nerve (CN V), largely responsible for somatosensory function of orofacial structures, is important to consider with other gustatory-mediating cranial nerves since (a) tactile, thermal, and spicy sensations are essential to the overall flavor of a tasted substance, and (b) anatomically, the gustatory fibers of the facial nerve (chorda tympani) travel in conjunction with the mandibular-trigeminal fibers of the lingual nerve for a short distance near the tongue – making both of these nerves susceptible to orofacial causes of injury.

Isolated damage to the auriculotemporal nerve (ATN) can produce a rare clinical syndrome of post-traumatic gustatory neuralgia – a taste-initiated, episodic, paroxysmal lancinating facial pain in the cutaneous distribution of the auriculotemporal nerve (Scrivani et al., 1998; Soria et al., 1990; Truax, 1989; Sharav et al., 1991). Post-traumatic abnormalities involving this nerve were originally described by Lucie Frey in 1923, such as sweating and flushing in this same region of the ATN following a taste stimulus (Frey's Syndrome). Although typically provoked by tastants, one report suggests Frey's syndrome can be elicited by the smell of food or even emotional excitement (Scrivani et al., 1998). Reported causes include head trauma, parotid gland surgery, temporomandibular joint (TMJ) surgery, carotid endarterectomy, orthognathic surgery, oncologic surgery, viral illness, and local infection (Scrivani et al., 1998; Truax, 1989; Sharav et al., 1991). A condition known as Collet-Sicard Syndrome is a neuropathy of CN XII due to damage to this nerve and nearby structures near the jugular foramen. Trauma and structural lesions to the lateral neck are common causes. The clinical features of this syndrome include: (1) ipsilateral paralysis of the trapezius and sternocleidomastoid muscles, (2) vocal cord and pharynx weakness, (3) hemiparalysis of the tongue, (4) taste lost on the posterior of the tongue, and (5) hemianesthesia of the palate, pharynx and larynx.

#### **39.4.3 Disorders Involving Parts of the Central Nervous System that Affect Taste**

The anatomy of the taste system is described in detail in Chapters 29, 32, and 33, and is only cursorily mentioned

here to remind the reader of the major brain regions where lesions can influence taste function. Initially, the CN VII, IX and X afferents from the taste receptors enter the brain and synapse within the nucleus tractus solitarius (NTS) of the medulla. From this brain region higher order projections are made to the ventroposteromedial thalamus and then to the parietal operculum and adjacent parainsular cortex, regions that make up the “primary gustatory cortex.” A secondary “gustatory cortex” is located in the caudomedial/caudolateral orbitofrontal cortex, just rostral to the primary taste cortex. Within the NTS visceroviseral and viscerosomatic reflexive connections are also made, via the interneurons of the reticular formation, with cranial nuclei that control (1) the muscles of facial expression, (2) taste-related behaviors, including chewing, licking, salivation and swallowing, and (3) preabsorptive insulin release. The orbitofrontal cortex processes information from several sensory pathways (including olfactory, gustatory, and visual), and has been linked to emotion, feeding and social behaviors in both monkeys and humans (Chapters 32 and 46).

Salivary gland secretion is controlled centrally by the autonomic nervous system and involves multiple structures. While CN IX provides secretomotor function to the lingual glands, as well as to the parotid gland, the fibers of CN VII – in connection with the superior salivatory nucleus – innervate the sublingual and submandibular glands, as well as the buccal glands. Salivation can be produced by electrical stimulation of the brainstem between or adjacent to CN VII and IX (Grovum et al., 2000), the lower Rolandic cortex, the lower precentral gyrus, the postcentral gyrus, the insula, and regions within the frontal cortex (Penfield and Jasper, 1954). Seizures involving the lower Rolandic region are commonly associated with hypersalivation (Penfield and Jasper, 1954).

Damage to brainstem structures that subserve taste may produce dysgeusia, although usually not without significant impairment of other cranial nerves or long tracts (see Table 39.4). Notable brainstem areas involved in taste that are susceptible to injury include the tractus solitarius and its nucleus (where injury produces ipsilateral ageusia) and the pontine tegmentum which involves both gustatory lemnisci (where injury produces bilateral ageusia). Bilateral injury to the thalamus can result in ageusia, although unilateral lesions above the brainstem do not usually cause complete loss of function (likely due to the multiple areas involved in processing taste information). An isolated unilateral lesion to the thalamus or the parietal lobe may cause contralateral taste disturbance.

Taste function is clearly at risk by some central nervous system lesions, as seen in cases of stroke (either ischemic or hemorrhagic) or demyelinating disorders such as multiple sclerosis (Dahlslett et al., 2012; Fleiner et al., 2010; Catalanotto et al., 1984; Onoda and Ikeda, 1999;

Yabe et al., 1995). In a review of 15 reported cases, Onoda and Ikeda (1999) found that unilateral impairment of taste function occurs with injury to any one of several central structures, including: (1) the pons – involved in 8 cases (53.3%), (2) the thalamus – involved in five cases (33.3%), (3) the midbrain – involved in one case (6.7%), and (4) the internal capsule – involved in one case (6.7%). Interestingly, based on the side of the respective central lesion and its effect on either unilateral or contralateral gustatory function, they surmised that the gustatory pathways ascend ipsilaterally from the medulla, cross over in their course from the pons to the midbrain, and synapse within the contralateral thalamus. It should be noted, however, that while this interpretation supports a primarily contralateral projection of taste information to the cerebral cortex in humans, gustatory-evoked potentials suggest that unilateral taste stimulation can evoke contralateral and bilateral cortical responses (Plattig, 1968; Kida, 1974). More recent data in the form of repeated case reports support the notion that bilateral diminished taste responses can occur in patients with unilateral midbrain and unilateral paramedian thalamic infarctions (Tsivgoulis et al., 2011; Nakajima et al., 2010). Pritchard et al. (1999) performed formal gustatory testing in six stroke patients with unilateral lesions of the insular cortex and six patients with brain damage outside the insula and found that, compared to controls, damage to the *right* insula produced ipsilateral taste deficits in recognition and intensity, whereas damage to the *left* insula caused an ipsilateral deficit in taste intensity but a

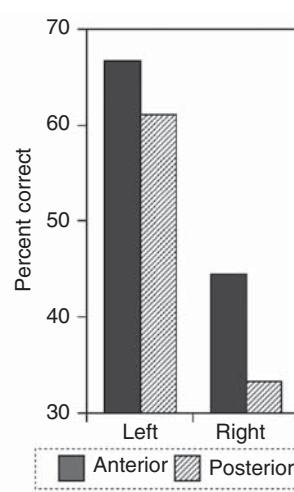

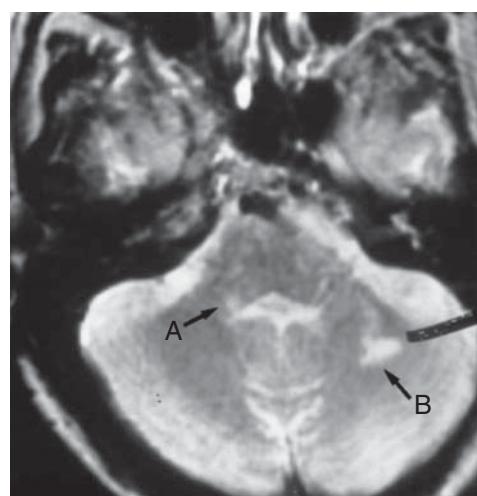

*bilateral* deficit in taste recognition. This suggested that taste information from both sides of the tongue must pass through the left insula for proper recognition to occur. In a case presenting with taste dysfunction to our center (Figure 39.1), the MRI showed increased signal intensity suggestive of ischemia in a region of the upper medulla near the right nucleus tractus solitarius (note that, in this image, the patient's right side is on the left of the picture). Taste dysfunction, as indicated by our taste identification test and a localized complaint of dysgeusia, was greater on the right than on the left side of the tongue. Both CN VII and CN IX seem to be involved. In a case report of two patients with different stroke presentations – one with a minor stroke in the anterior circulation and one with a minor stroke in the posterior circulation – both patients reported both olfactory and gustatory dysfunction immediately following their strokes and subsequently experienced weight loss, diminished energy and strength, and an overall decreased in their nutritional status (Green et al., 2008).

Small et al. (1997) found that patients with *right*, but not left, temporal lobe resections for control of intractable epilepsy had elevated citric acid *recognition* thresholds, but normal *detection* thresholds. In normal subjects, orally-presented citric acid increased regional cerebral blood flow bilaterally in the caudolateral orbitofrontal cortex, as measured by PET. Relatively more blood flow occurred in the right anteromedial temporal lobe and right caudomedial orbitofrontal cortex, suggesting that damage to the latter areas might explain the higher taste recognition thresholds that were observed in the patients with right temporal lobe resections.

Gustatory perception may also be affected by cortical injury to areas of association cortex outside of direct gustatory processing. The concept of left unilateral neglect, typically resulting from *contralateral* injury to the right hemisphere (e.g., parietal lobe, thalamus, basal ganglia),

appears to exist for taste in a manner similar to the visual, auditory, tactile, and olfactory sensory systems (Bellas et al., 1988). In fact, a specific syndrome of buccal hemineglect may exist in which patients neglect mouth and food products in the left half of the mouth and are unable to initiate chewing and swallowing when food is in this location (Andre et al., 2000). This syndrome can result in choking or a socially-embarrassing tendency to drool and regurgitate unnoticed food.

Electrochemical events such as migraine and seizure are presumed to influence taste perception on a central level. With migraine headache, the cortical spreading depression (CSD) associated initiation of aura and early phases of migraine is linked to hypersensitivity to visual (photophobia), auditory (phonophobia) and olfactory (osmophobia) stimuli (Sjostrand et al., 2010; Zanchin et al., 2005; Boulloche et al., 2010; Denuelle et al., 2011). However, it is not clear how gustatory processing changes as a result of migraine. While certain tastes may, in fact, induce a migraine (Blau and Solomon, 1985), central processing of taste information during migraine may actually “mix” with other sensory information in a condition described as synesthesia (Alstadhaug and Benjaminsen, 2010; Beeli et al., 2005). Possibly as a result of CSD temporarily altering networks involved in cross-modal perceptions, taste can be experienced as a co-percept of vision and colors can actually influence the perceptions of odors and tastes (Alstadhaug and Benjaminsen, 2010). For example, there is a well-established association between seeing yellow and the experience of lemon (Osterbauer et al., 2005). Other cross-modal influences on sensory perception include a more recent look at the effects of auditory stimuli on gustation (North, 2012). While auditory stimuli can influence perceptions of freshness of food products, background music may be an influence on taste perception in general, such as with the “tasting” of wine (North, 2012).

**Figure 39.1** L: Axial T2 (2500/90) MR scan through the upper brain stem reveals a hyperintensive infarct lesion (4 x 3 mm) in the right medulla (Arrow A). Note also large infarct (15 x 8 mm) inside the white matter of the left cerebellum (Arrow B). R: Scores on a taste identification test showing a relative decrement on right side of tongue. From a 65-year-old-woman with a history of ministrokes who developed a persistent salty/metallic dysgeusia and soreness on the right side of the tongue following a severe 2-day bout of emesis accompanied by marked dehydration and increased blood pressure but unaccompanied by fever. Copyright © Richard L. Doty, 2001.

With seizure, alteration of taste function through cortical excitation is an area of long-standing interest.

Following in the footsteps of Penfield and Jasper (1954), who explored the function of the brain by observing the effects spontaneous and induced epileptic seizures, Hausser-Hauw and Bancaud (1987) found six specific areas of the brain where gustatory sensations result from electrical stimulation. These areas included the right rolandic operculum, right parietal operculum, right amygdala, right hippocampus, medial aspect of the right T1 gyrus, and the anterior part of the right T2 gyrus. Like olfactory auras, gustatory auras represent seizure activity predominately within the temporal lobes, but they can also be linked on rare occasion to epileptiform activity in the orbitofrontal lobes (Hausser-Hauw and Bancaud, 1987; Acharya et al., 1998; Roper and Gilmore, 1995). Etiologies of the seizures can vary, and identifiable causes include mesial temporal sclerosis, tumors, vascular malformations, infections (e.g., tuberculosis, herpes simplex), and Rasmussen's encephalitis. Examples of taste sensations that have been reported in such cases include "peculiar," "rotten," "sweet," "like a cigarette," "like rotten apples," and "like vomitus" (for review, see West and Doty, 1995). However, some of these "tastes" likely represent smell sensations that are miscategorized as tastes by both the patients and their physicians.

### 39.4.4 Systemic Disorders and Medications

Excessive dryness of the oral cavity and hyperviscosity of saliva accompany several diseases (e.g., Sjogren's syndrome, xerostomia, pandysautonomia, diabetes mellitus) and are common side-effects of a number of medications (e.g., anticholinergics, antidepressants, antihistamines) (see Chapter 40). Although such conditions likely alter taste when they are chronic, acute effects are less well understood. In general, hyposalivation, per se, appears to have little influence on taste sensitivity in the short run (Christensen et al., 1984).

A number of systemic disorders have been associated with taste dysfunction. Both chronic renal failure (Middleton and Allman-Farinelli, 1999; Armstrong et al., 2010) and end-stage liver disease (Bloomfield et al., 1999; Davidson et al., 1998; Musialik et al., 2012) can produce altered taste function, which, in some cases, seems to improve following transplantation (Bloomfield et al., 1999). Apparently the taste dysfunction associated with liver failure is not necessarily associated with a vitamin deficiency, and may be centrally-mediated (Bergasa, 1998), although it is generally believed that poor nutritional states can be related to taste impairment (Davidson et al., 1998). Avitaminosis, particularly of the B group and C, can result in pellagra, sprue, pernicious anemia, scurvy, or

glossitis. Additionally, zinc and copper deficiencies may produce taste disturbances (Mattes and Cowart, 1994). In patients younger than 55 years with uremia, a significant impairment of taste recognition — independent of zinc deficiency—was found by Ciechanover et al. (1980) for salty, sweet, bitter, and sour compared to controls. The impairment for sour and bitter, however, showed improvement immediately after a dialysis session. Interestingly, idiopathic dysgeusia has been reported with blood transfusions (Erick, 1996), and we are familiar with one leukemia patient who could ascertain, by taste, whether transfused blood came from a smoker or a non-smoker.

There is considerable evidence that diabetes is associated with loss of taste function. Thus, there appears to be a progressive loss of taste beginning with glucose and extending to other sweeteners, salty stimuli, and then all stimuli (Hardy et al., 1981). In newly diagnosed non-insulin dependent diabetics (based on plasma glucose concentration and glycosolated hemoglobin percentage), quantifiable taste impairment not only exists, but may be somewhat reversible with correction of the hyperglycemia (Perros et al., 1996). Interestingly, about 10% of first order relatives of late-onset diabetics exhibit decreased suprathreshold taste function that is rather specific to glucose (Settle, 1981). Whether these individuals are more prone to subsequent development of diabetes is not known, but is an intriguing possibility since about 10% of such relatives eventually develop the disease.

Hypothyroidism has been reported to result in significant changes in taste detection thresholds (McConnell et al., 1976); however, the degree of taste dysfunction does not appear to correlate with the severity of the disease (Pittman and Beschi, 1967). Importantly, there is suggestion that replacement of thyroid hormone may normalize threshold sensitivity and suprathreshold performance, although dysgeusias may still be present (Deems et al., 1991).

Pharmacologic agents appear to result in taste disturbances much more frequently than olfactory disturbances (Doty et al., 2008). General anesthesia has been associated with anosmia and hypogeusia, although the mechanisms behind this reported rare complication are unclear (Dhanani and Jiang, 2012). Over 250 medications reportedly alter the sense of taste, including antiproliferative drugs, antirheumatic drugs, antibiotic drugs, psychotropic drugs and drugs, with sulphydryl groups, such as penicillamine and captopril (Table 39.5). Angiotensin-converting enzyme (ACE) inhibitors are considered by many authors to be most commonly associated with taste disturbance, such as hypogeusia, or excessive metallic, bitter, or sour dysgeusic tastes (Suliburska et al., 2012; Ackerman and Kasbekar, 1997). Terbinafine, a commonly used antifungal medication, has been linked to taste disturbance that reportedly can last from two days to three years. In the sole study

beyond a case report that quantitatively examined taste function in patients complaining of terbinafine-related taste loss, all four major qualities were affected. However, smell function was intact (Doty and Haxel, 2005).

As noted earlier, dysgeusia occurs commonly in the context of cancer therapies, with a weighted prevalence from 56–76% depending on the type of cancer treatment (Hovan et al., 2010). In a systematic review of taste disturbances resulting from antiproliferative agents, members of the International Society of Oral Oncology (ISOO)

found that attempts to prevent taste problems from these drugs using prophylactic zinc sulfate or amifostine had minimal benefit and nutritional counseling was helpful in some patients to diminish the symptoms of dygeusia (Hovan et al., 2010). While many antiepileptic medications have been used in the treatment of smell and taste disorders, particularly as they relate to seizures, migraines and other causes of gustatory hallucinosis and dysgeusias, one case report acknowledges that the use of topiramate in a three and a half-year-old boy for his primary generalized seizures resulted in a reversible loss of his ability to detect and recognize tastes and odors during treatment (Ghanizadeh, 2009). Doty and colleagues (2009) ran an independent double-blind study of the influences of eszopiclone (Lunesta<sup>TM</sup>) – a commonly prescribed sleep induction agent – and the influences this medication has on dysgeusia and taste function (Doty et al., 2009). They found that the taste disturbances associated with eszopiclone are more intense and longer lasting in women than in men, stronger in the morning than in the evening, and positively correlated with drug plasma and saliva levels of the same medication (Doty et al., 2009).

In a study of six psychotropic medications, including amitriptyline, clomipramine, desimpramine, imipramine, doxepin, and trifluoperazine, Schiffman et al. (1998) found that these drugs not only have a taste of their own, but they can significantly alter the intensity of other tastants (such as salt and sugar). She also noted that among the medications used in the treatment of HIV and AIDS, the protease inhibitors have a taste themselves, and appear to adversely modify the taste perception of other taste compounds (Schiffman et al., 1999). Repeated oral use of some topical agents, such as hydrogen peroxide or steroids, may affect taste.

It should also be noted that the common antiplatelet therapy — clopidogrel (Plavix<sup>TM</sup>) — used to treat patients with cardiac and stroke-related problems is reported to produce ageusia as a rare side-effect in some cases (Ksouda et al., 2011). Five months after reduction of the clopidogrel dose, researchers note that the ageusia partially improved (Ksouda et al., 2011). Recognizing that this common stroke therapy may result in taste disturbance for some stroke patients needs to be considered when evaluating the effects on gustation in any stroke patient.

### 39.4.5 Psychiatric Disorders

There are multiple psychiatric conditions known to affect taste function. Patients who are clinically depressed may complain of an unpleasant or diminished taste that is not readily explainable by medications or other causes (Miller and Naylor, 1989); however, the problem with taste can be reversible (Gangdev, 1995). When formally

tested, depressed patients demonstrate a higher recognition threshold for sucrose compared to non-depressed controls, a finding that is possibly related to a subtle carbohydrate intolerance observed in many depressed patients (Amsterdam et al., 1987; Steiner et al., 1969).

Gustatory hallucinations are associated, on rare occasion, with schizophrenia, cocaine use, and a number of other organic conditions (Carter, 1992; Siegel, 1978). In a study evaluating a large cohort of patients with schizophrenia, schizoaffective disorder, and bipolar I disorder, researchers discovered that tactile, olfactory, and gustatory hallucinations were common among the patients studied and affected as much as 20% of the total study population (Lewandowski et al., 2009). With regard to olfactory or gustatory hallucinations alone, previous reports suggest that 11% of patients with schizophrenia or schizoaffective disorder have chemosensory-specific experiences (Mueser et al., 1990). Of note, tactile, olfactory and gustatory hallucinations are associated with an earlier age of onset of psychotic illness and an earlier age of onset is considered a marker of more severe illness (Lewandowski et al., 2009). While hallucinations appear to be associated with activation of the same brain regions involved in normal sensory processing, there appears to be a component of shared neurobiology underlying many of experiences. This possibly relates to brain regions involved in patients who report synesthesia-like events during migraine attacks and seizures (Weiss and Heckers, 1999; Alstadhaug and Benjaminsen, 2010).

Patients with bulimia nervosa appear to have impaired satiety responses in response to glucose loads; bulimics, unlike controls, do not find sweet tastes less pleasant under such loads (Rodin et al., 1990). Bulimic patients also appear to have a selective loss of taste on the palate, presumably from the local effect of acidic vomitus during a purging episode (Rodin et al., 1990). In a trial evaluating olfactory and gustatory sensitivities among subjects with anorexia nervosa or bulimia nervosa, anorexic patients exhibited lower smell and taste sensitivities than healthy controls (Aschenbrenner et al., 2008; see also Federoff et al., 1995). More importantly, improving the Body Mass Index (BMI) and decreasing eating pathology in these same patients resulted in better olfactory and gustatory performance (Aschenbrenner et al., 2008).

In the context of litigation or identifiable secondary gain, a physician may need to consider malingering on the part of the patient who is complaining of taste loss or distortion. Conversion disorder involving taste is also a possibility in some psychiatric cases.

### 39.4.6 Genetic Disorders

Familial dysautonomia (also known as Riley-Day syndrome or Hereditary Sensory and Autonomic Neuropathy

Type III), an autosomal recessively inherited disease, is a sensory neuropathy that mostly affects Ashkenazi Jewish patients and results in defective autonomic control, insensitivity to pain, hyporeflexia, impaired lacrimation, the absence of fungiform papillae and taste buds on the tongue, and impairment of taste (Gadoth et al., 1997). A recent assessment of the oro-dental-facial features and dysfunction in children with familial dysautonomia at the Barzilai Medical Center in Israel found these children have a normal sense of smell but decreased numbers of lingual fungiform papillae and a specific dysgeusia (Mass, 2012).

Fukutake et al. (1996) described another inherited disease entity in two Japanese siblings which consists of late-onset progressive ataxia, global thermoanalgesia, sensorineural deafness, mild autonomic disturbances, and ageusia in the context of absent fungiform papillae and taste buds. This particular disease entity may represent a variant of late-onset hereditary spinocerebellar degeneration. A few of the same authors reported a case of a family with a possible new variant of Machado-Joseph Disease (confirmed with genetic testing) associated with a sensory dominant axonal neuropathy, autonomic disturbances, and the absence of fungiform papillae (Uchiyama et al., 2001). Gonadal dysgenesis, particularly Turner's Syndrome, has been reportedly linked to a number of sensory abnormalities, including gustatory dysfunction (Henkin, 1967; Valkov et al. 1975).

In addition to altered taste function associated with genetic diseases, it should be noted that taste receptor genes, such as TAS2R38, have been associated, in healthy cohorts, with food and beverage preferences that potentially influence nutrition and health. For example, the TAS2R38 gene is related to vegetable intake (Sacerdote et al., 2007; Duffy et al., 2010; Negri et al., 2012) and variations in TAS2R13 with differences in alcohol consumption in head and neck cancer patients (Dotson et al., 2012).

### 39.4.7 Special Circumstances

**39.4.7.1 Aging.** Regional tests of taste function demonstrate marked losses in older persons (Matsuda and Doty, 1995). However, such regional deficits need not translate into marked overall whole mouth loss, given the redundancy of the system. Nonetheless, whole mouth taste acuity does decline with age, and the elderly tend to perceive tastes as being less intense than do younger persons (Weiffenbach et al., 1986). Fortunately, the amount of decline is not as marked as that seen for olfaction. Nonetheless, in conjunction with the loss seen with the sense of smell, decrements in taste function — and most significantly age-related dysgeusias — can be very detrimental to some of the elderly, leading to anorexia, weight loss, malnutrition, impaired immunity, and worsening of medical illnesses.

**39.4.7.2 Pregnancy.** Pregnancy proves to be a unique condition with regard to taste function. In one study of 46 pregnant and 41 health women controls, Duffy et al. (1998) noted that sensitivity to quinine hydrochloride (bitter) was highest during the first trimester of pregnancy. The subjects found its taste to be less intense and less disliked as pregnancy progressed. The authors suggest that the increased dislike and intensity of bitter tastes during the first trimester may help to ensure that pregnant women to avoid poisons during a critical phase of fetal development. Similarly, a relative increase in the preference for salt and bitter in the second and third trimesters may support the ingestion of much needed electrolytes to expand fluid volume and support a varied diet (Duffy et al., 1998).

**39.4.7.3 Burning Mouth Syndrome.** Burning Mouth Syndrome (BMS), also referred to as glossodynia or glossalgia, is the subjective sensation of intense “burning” pain within the mouth without obvious physical cause. Often accompanied by dry mouth, thirst, and altered or dysgeusic taste, BMS usually begins by late morning and is continuous once it has started for the day (Gorsky et al., 1987; Grushka and Sessle, 1991). Interestingly, most of the BMS patients who present for treatment are postmenopausal; however, studies vary in terms of the effectiveness of hormone replacement therapy in reducing oral symptoms. Numerous etiologies suggested by researchers, many of them amenable to treatment, include: (1) nutritional deficiencies (e.g., iron, folic acid, B vitamins, zinc), (2) diabetes mellitus (possibly predisposing to oral candidiasis), (3) denture allergy, (4) mechanical irritation from dentures or oral devices, (5) parafunctional habits of the mouth (e.g., tongue thrusting, teeth grinding, jaw clenching), (6) tongue ischemia as a result of temporal arteritis, (7) oral candidiasis, (8) periodontal disease, (9) reflux esophagitis, and (10) geographic tongue (see Tourne and Friction, 1992 for review). Psychological factors are clearly important in the diagnosis and management of BMS, since psychological dysfunction (e.g., anxiety, depression) is common in this population (Gorsky et al., 1991). Both neuropathic and psychiatric factors linked to patients with BMS may help to explain why tricyclic antidepressants (e.g., amitriptyline, desipramine, nortriptyline) and benzodiazepines are reportedly useful as therapy in some cases. It is not clear whether the oral burning pain is a result of central or peripheral mechanisms. In a study of 9 men and 24 women, with an average age of 60 years, Formaker et al. (1998) found that the application of a topical anesthetic (dyclonine HCl) reduced the perceptual intensity of salt and sugar, but had variable affects on the burning sensation — such that 12 patients demonstrated increased burning, 14 patients had burning that did not change, and 7 patients experienced decreased burning.

Topical capsaicin may also be helpful, although clinical trials using this substance are limited. A recent review of randomized trials for the treatment of burning mouth syndrome (2012) found a total of 12 relevant articles suggesting that therapies such as capsaicin,  $\alpha$ -lipoic acid and clonazepam were more efficacious than some other therapies in reducing BMS symptoms (de Moraes et al., 2012).

## 39.5 TREATMENT

As with other sensory systems, prognosis for functional recovery of taste is related to the kind of neural damage that is involved. For example, permanent sensory abnormalities are more likely to result from nerve section of a gustatory-mediating cranial nerve than a crush injury (Robinson et al., 2000). Depending on the underlying disorder affecting taste function, spontaneous recovery can occur and some therapeutic strategies can be effective. Taste impairment secondary to nutritional deficiencies may improve with supplementation and a regular diet. When dysfunction is due to viruses, damaged taste afferents often regenerate. Conditions such as Bell’s Palsy and radiation-induced xerostomia generally improve over time, a fact that, when known in advance to a patient, is very therapeutic. When identified, infection and inflammation of the mouth surfaces and perioral anatomic structures should be treated with antibiotic or anti-inflammatory medications. In the case of taste loss secondary to hypothyroidism, thyroxin replacement therapy may be beneficial (Mattes and Kare, 1986). Nevertheless, strong evidence for efficacy of most hormonal or pharmacologic treatments reported in the literature is lacking, since double-blind studies are rarely performed.

Dysgeusias and phantogeusias are among the most debilitating taste disorders, often leading to inhibition of eating and loss of weight. Fortunately, spontaneous resolution of most dysgeusias occurs, usually within two years (Deems et al., 1996). In some cases, antifungal and antibiotic treatments have been reported to be useful in resolving phantogeusias and dysgeusias. Antidepressants, such as sertraline, venlafaxine, and mirtazapine, reportedly benefit some patients with dysgeusia (Mizoguchi et al., 2012; Landis et al., 2012; Devere 2012). Since vitamin D deficiency is a cofactor of chemotherapy-induced mucocutaneous toxicity and dysgeusia, adding vitamin D3 1000–2000 units daily may benefit some patients (Fink, 2011). Chlorhexidine mouthwash has been suggested as having possible efficacy for some salty or bitter dysgeusias, possible as a result of its strong positive charge (Helms et al., 1995). One open trial of  $\alpha$ -lipoic acid therapy for idiopathic dysgeusia found significant improvements in patients treated with this agent compared to a placebo

(Femiano et al., 2002), leading to the suggestion that the idiopathic form may be a kind of neuropathy “comparable to Burning Mouth Syndrome.” Interestingly, something as simple as transient cooling of the mouth in the form of ice cube stimulation can improve some cases of dysgeusia (Fujiyama et al., 2010).

Several other medications may benefit some cases of taste disturbance. In situations where xerostomia and excessive dryness exists, artificial saliva (e.g., Xerolube) may improve comfort and mucosal function. Pilocarpine (Salagen<sup>TM</sup>) is a prescribed medication that stimulates muscarinic cholinergic receptors and subsequently improves salivation for patients suffering from xerostomia related to such conditions as head and neck cancer therapies and Sjogren Syndrome. Cepacol lozenges with benzocaine, used 3–4 times per day, can improve salivation and contribute to anesthesia of mucosal surfaces. Where pain is more evident, lidocaine (Xylocaine<sup>TM</sup>) mouth gel 0.5%–1%, used 3–4 times per day, may also give relief. Amifostine (Ethylol<sup>TM</sup>) is an agent that presumably acts like a free radical scavenger that prevents oxidative damage associated with radiotherapy. Phase III trials have shown that amifostine may reduce xerostomia when given at the time of radiotherapy (Vissink et al., 2010). Oral steroids may be beneficial in some cases of acute and ongoing inflammatory disease (e.g., a prednisone taper from 60 mg to 0 mg over a 7–10 day period). Zinc gluconate around 140 mg per day is potentially helpful in some cases since zinc is a necessary component to regeneration of taste buds and formation of saliva (Devere, 2011, 2012). Additionally, magnesium oxide in doses ranging from 250 mg to 750 mg daily has shown promise in some cases of oral paresthesias as well as migraine and seizures. Some antiepileptic medications are effective, presumably through stabilization of damaged and hyperactive neural fibers transmitting information from oral structures. Among the most commonly used antiepileptic medications to treat chemosensory disturbance is gabapentin, with dose ranges from 300 to 3600 mg per day (Devere, 2012). Another antiepileptic agent that has been reported to show effectiveness for dysgeusia in an epileptic child is lamotrigine (Yamashita et al., 2011).

Trauma and surgery-related injury to peripheral nerves supplying taste (e.g., lingual nerve, facial nerve) may be amenable to surgical repair, particularly in the early months immediately following injury (Robinson et al., 2000; Zuniga et al., 1994). In a series of 53 patients with prior lingual nerve injury who underwent direct reapposition of the nerve with epineurial sutures, 41% of the patients could detect some taste solutions postoperatively (Robinson et al., 2000). Recovery of sensory function after repair can varied, light touch and pain functions being most improved. In this study, the study group did not appear to regain completely normal taste sensation or get relief from

spontaneous paresthesias or pain syndromes, although many did recover some function and fewer patients were found to bite their tongues by accident (Robinson et al., 2000).

Medication-related changes in taste can, in some instances, be reversed by discontinuance of the offending drug, by employing alternative medications, or by changing drug dosage. The health care professional should be aware of the fact, however, that many pharmacological agents appear to induce long-term alterations in taste that may take months to disappear even after discontinuance of the drug. Although the Physician’s Desk Reference (PDR) can be helpful in identifying medications that may result in drug-related taste dysfunction, there is lack of uniformity and control in the acquisition of this information. Many agents are listed with the potential side effects of “altered taste,” “ageusia,” “dysgeusia,” “bad taste,” “metallic taste,” or “bitter taste” without the benefit of a controlled trial. Therefore, caution should be used in simply attributing a patient’s taste disturbance to his or her medication regimen based on PDR classification alone.

Alternative therapies, such as acupuncture, meditation, cognitive-behavioral therapy, and yoga may not only help a patient manage aberrant experiences associated with taste disturbance and oral pain syndromes, but they can be helpful with allowing patients to cope with the psychosocial stressors surrounding their impairment. Specifically, there is some evidence that acupuncture may also stimulate salivary gland secretion and help to alleviate xerostomia (Vissink et al., 2010). Modification of diet and eating habits is also important. Accentuating the other sensory experiences of a meal — such as food texture, aroma, temperature, and color — can optimize the overall eating experience for a patient. In some cases, a flavor enhancer like monosodium glutamate (MSG) can be added to foods to increase palatability and encourage intake (Devere, 2012; Bellisle, 1998; Schiffman, 1997).

Proper oral hygiene and routine dental care are extremely important ways for patients to protect themselves from disorders of the oral cavity that can ultimately result in taste disturbance. Patients should be warned not to overcompensate for their taste loss by adding excessive amounts of sugar or salt. Smoking cessation and the discontinuance of oral tobacco use are essential in the management of any patient with smell and/or taste disturbance and should be repeatedly emphasized.

## 39.6 CONCLUSIONS

Clinical disorders that influence taste are numerous and may involve multiple organ systems. Because of this, the appropriate diagnosis and management of a patient with gustatory complaints requires a multidisciplinary mind

set on the part of the evaluating physician. A disturbance of taste may represent a spectrum of possible problems from local (e.g., oral cavity) to more generalized (e.g., systemic disorders or agents). The ability to taste reflects the proper function of many systems within the body, and as such, may be considered a marker for good health. Conversely, altered taste function, particularly dygeusias that make food distasteful, can influence nutrition and lead to unhealthy states of being — not to mention adversely affecting a person's ability to enjoy food products and overall quality of life. In this chapter, we have presented multiple disorders, across medical specialties, that can influence taste, described anatomy and physiology relating these disorders to the taste system, and provided basic information for the evaluation and management of patients who complain of taste disturbance.

## Influence of Drugs on Taste Function

SUSAN S. SCHIFFMAN

### 40.1 INTRODUCTION

Medications frequently have objectionable taste-related side-effects that can adversely affect patient compliance with prescribed drug regimens and the successful treatment of disease (al-Shammary et al., 1995; Barbara et al., 1986; Harrison, 1995; Iwai, 1997; Liacouras et al., 1993; Matsui et al., 1996). Hundreds of drugs encompassing all major therapeutic classes have been reported clinically to induce unpleasant and altered taste sensations when administered alone or in combination with other medications (see Table 40.1). These aversive sensations include bitter and metallic tastes, partial or total loss of taste, as well as taste distortions and perversions.

Most of our current knowledge about taste disturbances from medications derives from clinical reports, drug reference books, medication inserts, and chemosensory testing of a small number of patients rather than from comprehensive clinical trials that utilize objective, quantitative tests in conjunction with documentation of medication usage. Thus, neither the incidence nor prevalence of drug-induced taste disturbances in the general population is known (Doty et al., 2008). Estimates of the potential risk of taste disturbances from therapeutic drugs vary widely. An early study of medication use by 4,163 community-dwelling elderly (the Duke Established Populations for Epidemiologic Studies of the Elderly, EPESE) concluded that only 11% of participants took drugs that could alter taste perception (Lewis et al., 1993). A later study of 1,163 persons aged from 32 to 81 years drawn from the San Antonio Longitudinal Study of Aging and the San Antonio Heart study concluded that 389 (or 33%) of the drugs used by this population had the potential to alter the sense of taste (Shinkai et al., 2006). A comparison

of the list of the “Top 200 drugs in the US market by dispensed prescriptions, 2010” (Bartholow, 2011) with the list of drugs in Table 40.1 indicates that 59% of the top 200 drugs have potential taste side-effects. Taste disturbances associated with pharmacological treatments were reported to be the most frequent cause of taste complaints in 2278 patients who visited a Taste and Smell Clinic in Tokyo, Japan during the 10-year period between 1981 and 1990 (Hamada et al., 2002). Drug-induced taste disorders accounted for 21.7% of the diagnoses with a sharp increase in incidence at 50 years of age. In a separate analysis of a portion of the data at the same clinic, Tomita and Yoshikawa (2002) reported that drugs accounted for ~25% of the cases of taste disorders. For specific drugs, the reported incidence of taste disturbances varies widely from less than 5% on average according to drug reference books (PDR, 2005) to as high as 66% for the drug eszopiclone in a clinical study (Doty et al., 2009). The actual incidence and prevalence of drug-related taste disorders for specific drugs awaits quantification with controlled clinical trials because “self-report markedly underestimates chemosensory deficits” (Doty and Haxel, 2005).

Quantification and documentation of taste-related deficits caused by medications present numerous challenges due to several factors. First, standardized taste tests are not routinely utilized by medical practitioners to verify and validate drug-related taste complaints by patients. Second, many taste complaints cannot be classified as standard gustatory sensations such as sweet (sucrose), sour (citric acid), salty (NaCl), bitter (quinine), and umami (monosodium glutamate), or as more controversial tastes such as metallic (iron salts), chalky (calcium salts) or fatty (fatty acids). For example, a patient may complain of a “foul” taste in the mouth that cannot be matched

**Table 40.1** Drugs reported to cause taste disturbances.

Drug Class	Subclass/Indication	
Anesthetics		Amydricaine, Amylocaine, Benzocaine, Cocaine, Dibucaine, Eucaine, Euprocin, Lidocaine, Procaine, Tetracaine, Tropacocaine
Antiepileptics/ anticonvulsants		Acetazolamide, Carbamazepine, Felbamate, Lamotrigine, Phenytoin, Topiramate
Antihistamines and antiallergenic agents	Antihistamines	Azelastine, Chlorpheniramine, Cyproheptadine, Loratadine, Promethazine, Terfenadine
	Steroids	Becлометазоне, Бudesонид, Flunisolide, Fluticasone
Antihypertensives and Cardiovascular agents		Adenosine, Amiloride, Amiodarone, Amlodipine, Amrinone, Antithrombin III, Atropine sulfate, Benazepril HCl, Bepridil, Betaxolol, Bisoprolol, Bretylium, Captopril, Chlorthalidone, Cilazapril, Clonidine, Diazoxide, Diltiazem, Dipyridamole, Doxazosin, Enalapril, Esmolol, Ethacrynic Acid, Flecainide, Flosequinan, Fosinopril, Furosemide, Guanfacine, Hydralazine, Hydrochlorothiazide, Inamrinone, Isosorbide Nitrates, Labetalol, Lisinopril, Losartan, Methyldopa, Metolazone, Metoprolol, Mexiletine, Minoxidil, Moricizine, Nifedipine, Nisoldipine, Nitroglycerin, Nyldidrin, Oxyfendine, Pentoxifylline, Perindopril, Phenindione, Procainamide, Propafenone, Propranolol, Quinapril, Quinidine, Ramapril, Spironolactone, Tocainide, Triamterene, Trichlormethiazide
Anti-infectives	Antibacterials	Amoxicillin, Ampicillin, Azithromycin, Aztreonam, Bacampicillin, Carbenicillin, Cefacetile, Cefadroxil, Cefamandole, Cefodizime, Cefpirome, Cefpodoxime, Ceftriaxone, Cefuroxime, Cephalexin, Chlorhexidine, Cinoxacin, Ciprofloxacin, Clarithromycin, Clindamycin, Clofazimine, Dapsone, Enoxacin, Ethambutol, Ethionamide, Hexetidine, Imipenem, Lincomycin, Lomefloxacin, Mezlocillin, Minocycline, Norfloxacin, Ofloxacin, Penicillins, Piperacillin, Rifabutin, Roxithromycin, Streptomycin, Sulfamethoxazole, Tetracyclines, Ticarcillin, Trimethoprim, Tyrothricin, Vancomycin
	Antivirals	Aцикловир, Амантадин, Фоскарнет, Ганцикловир, Идоуродин, Осельтамивир, Пиорадавир, Рибавирин, Римантадин
	Antifungals	Amphotericin B, Атофуон, Флюконазол, Гризофулвін, Пентамідін, Тербінафін
	HIV/AIDS drugs	Didanosine, Индинавир, Ламивудин, Нелфинавир, Невирапін, Рітонавір, Сақінавір, Ставудін, Залцитабін, Зідовудін
	Antimalarials	Хлорохін, Гідроксихлорохін, Піраметамін
	Other	Антимоній, Левамізол, Метронідазол, Нікосамід, Нірідазол, Стібоглюконат
Anti-inflammatory, anti-pyretic, and/or analgesic agents	NSAIDs	Ацеметацин, Аспірин, Беноксафроен, Селекоцин, Колін магніємум трісаліцилат, Діклофенак, Етодолак, Фенопрофен, Флурбіпрофен, Ібупрофен, Індометацин, Кетопрофен, Кеторолак, Міфенамік Аїд, Набуметон, Наропрен, Оксапроцин, Фенілбутазон, Пірокам, Сульдін, Толметін
	Opioids	Буторфанол, Кодейн, Фентаніл, Гідроморфон, Морфін, Налбупін, Пентазоцин
	Antirheumatic/ Antiarthritic/ Antigout drugs	Алlopурінол, Ауранофін, Ауротіоглюкоз, Колхіцин, Голь компоненти, D-Пеніцилламін, 5-Тіопірідоксін
	Other	Ацетамінофен, Діметил сульфід, Трамадол, Гідрокортизон, Дексаметазон
Antilipidemics		Аторвастатін, Холестірамін, Клофібріт, Флувастатін, Гемфіброзіл, Ловастатін, Правастатін, Пробукол, Сімвастатін

**Table 40.1** (Continued)

Drug Class	Subclass/Indication
Antimigraine drugs	Naratriptan, Rizatriptan, Sumatriptan, Dihydroergotamine mesylate
Antineoplastic and immunosuppressant drugs	Adriamycin, Aldesleukin, Amonafide, Azathioprine, Bleomycin, Busulfan, Carboplatin, Carmustine, Cisplatin, Cyclophosphamide, Dacarbazine, Doxorubicin, 5-Fluorouracil, Lomustine, Methotrexate, Tamoxifen, Tegafur, Vinblastine, Vincristine
CNS drugs/ Sympathomimetics	Amezinium, Amphetamine, Apraclonidine, Benzphetamine, Dexamphetamine, Methamphetamine, Methylphenidate, Phenmetrazine
Dental agents	Mercury, Nickel, Sodium lauryl sulfate, Sodium fluoride
Dermatologic agents	Etretinate, Isotretinoin, Zinc Oxide
Endocrine and diabetes drugs	Carbimazole, Methimazole, Methylthiouracil, Propylthiouracil, Thiouracil
	Acarbose, Glipizide, Glyburide, Insulin, Metformin, Phenformin, Tolazamide, Tolbutamide
	Alendronate, Calcitonin, Etidronate, Pamidronate
Gastrointestinal drugs	Levothyroxine, Protirelin
	Clindinium, Dicyclomine, Glycopyrrolate, Hyoscymine, Oxbutynin, Propantheline, Tridihexethyl Chloride
	Cimetidine, Famotidine, Isopropamide, Lansoprazole, Mesalamine, Methscopolamine, Metoclopramide, Misoprostol, Omeprazole, Ranitidine, Sucralfate, Sulfasalazine
	Dinitrophenol, Fenfluramine, Mazindol, Phendimetrazine, Phentermine
Muscle relaxants and antiparkinsonism drugs	Bismuth, Granisetron, Ursodiol, Monoctanoin, Prochlorperazine
	Apomorphine, Baclofen, Benztropine, Bromocriptine, Cyclobenzaprine, Dantrolene, Levodopa, Methocarbamol, Pergolide, Selegiline, Trihexyphenidyl HCl
Nose, throat, and pulmonary agents	Albuterol, Bamifylline, Bitolterol, Cromolyn, Metaproterenol, Nedocromil, Pirbuterol, Pseudoephedrine, Terbutaline
Psychopharmacologic agents	Amitriptyline, Bupropion, Citalopram, Clomipramine, Desipramine, Doxepin, Fluoxetine, Fluvoxamine, Imipramine, Lithium, Maprotiline, Nortriptyline, Paroxetine, Protriptyline, Sertraline, Tranylcypromine, Trazodone, Trimipramine, Venlafaxine
	Clozapine, Fluphenazine, Olanzapine, Pimozide, Prochlorperazine, Risperidone, Trifluoperazine
	Alprazolam, Buspirone, Chlormezanone, Clonazepam, Diazepam, Estazolam, Flurazepam, Midazolam, Oxazepam, Triazolam
	Donepezil, Rivastigmine, Tacrine
Vitamins, minerals, nutrients and related compounds	Eszopiclone, Ethchlorvynol, Propofol, Quazepam, Zolpidem, Zopiclone
	Calcifediol, Calcitriol, Calcium Salts, Ergocalciferol, Omega Fatty Acids, Phytonadione, Potassium Iodide, Selenium
Miscellaneous	Anti-glaucoma drugs
	Dorzolamide, Pilocarpine, Timolol
	Biotechnology drugs
	Filgrastim, Interferon-Alpha, Interferon-Gamma, Interleukin-2
	Diagnostics
	Gallium, Thallium, Gadodiamide
	Other
	Decitabine, Deferoxamine, Dinoprostone, Disulfiram, Leuprolide, Nicotine, Riluzole, Tiopronin

<sup>1</sup>GERD: Gastroesophageal reflux disease

Sources: Micromedex®, 2012; Physicians Desk Reference, 2005; Schiffman, 1983, 1991; Schiffman and Zervakis, 2002; Schiffman et al., 2003; Johnell and Klarin, 2007

by representative chemosensory stimuli. Third, patients with taste disturbances are frequently taking drugs for a medical condition such as cancer that also causes taste disorders. Thus, the taste disorder may be medication-related, disease-related, or an interaction between the medication and the disease. Fourth, most persons with drug-related taste disorders are taking multiple medications concurrently so it is difficult to determine if a taste disturbance is due to a single medication or to an interaction between several drugs. Fifth, adverse taste effects typically affect only a proportion but not all of the patients who use a drug. Groups that are particularly vulnerable include (1) the elderly who use a disproportionate number of drugs (Qato et al., 2008) and who have reduced drug clearance (Shi and Klotz, 2011), and (2) persons with certain genetic polymorphisms related to bitter taste perception (Hamor and Lafdjian, 1967; Kim et al., 2005; Sandell and Breslin, 2008; Woodling et al., 2004) and the metabolism of drugs (Lee et al., 2005).

Prior reviews on the topic of drug-related taste disorders have summarized information from case reports, quantitative studies of a limited number of persons with taste disturbances, and/or drug reference material supplied by manufacturers (Schiffman, 1983, 1991, 1997; Schiffman and Zervakis, 2002; Schiffman et al., 2003; Ackerman and Kasbekar, 1997; Doty et al., 2008). This review will focus on six topics relevant to understanding the biological bases of drug-induced taste disorders. These include: (1) interaction of drugs with taste receptors on the apical side of the tongue in the oral cavity, (2) genetic differences among individuals that affect taste perception of drugs, (3) taste sensations caused by injectable drugs, (4) drug interactions that result from use of multiple medications, (5) potential biochemical and pharmacological mechanisms by which therapeutic drugs can cause taste disorders, and (6) other factors to consider when assessing the cause of a taste disturbance.

## 40.2 TASTE COMPLAINTS DUE TO THE SENSORY PROPERTIES OF THE DRUG ITSELF

The majority of active drugs in oral pharmaceutical products are bitter in taste (Szejtli and Szente, 2005), and some chemosensory complaints are directly related to the unpleasant taste properties of the active drugs themselves rather than alteration or distortion of taste sensations. Orally ingested drugs reach taste receptors and channels located on the microvilli of taste buds either during ingestion or alternatively after leaving the general circulation subsequent to absorption from the gut. After exiting the

capillaries adjacent to taste buds, drugs diffuse or are transported across salivary gland membranes into the saliva (Kaufman and Lamster, 2002). Drugs that leave the bloodstream can also permeate paracellular pathways (tight junctions) between taste cells in papillae to reach taste receptors embedded in microvilli (Holland et al., 1991).

### 40.2.1 Bitter Taste

The fact that drugs typically have bitter tastes is not unexpected because they are xenobiotic compounds with pharmacological and even toxic effects that alter the biochemistry of the body. Many poisonous and potentially harmful compounds in the natural environment of plant and animal origin have bitter, aversive tastes that serve as warning signals to reject and prevent ingestion (Brockhoff et al., 2010; Drewnowski and Gomez-Carneros, 2000; Lindemann, 2001; Meyerhof et al., 2010). Bitter taste sensations are mediated by G-protein coupled taste receptors (Margolskee, 2002) that are encoded by the taste 2 receptor gene family (*TAS2R*) with at least 25 members in humans (Meyerhof et al., 2010, 2011). The human *TAS2R* genes are located at four chromosomal loci including two loci on chromosome 7, a cluster on chromosome 12, and a single gene on chromosome 5 (Adler et al., 2000; Meyerhof et al., 2010; Reed et al., 1999). Tens of thousands of structurally diverse bitter-tasting compounds including drugs are detected by the combinatorial pattern of hTAS2R activation (Meyerhof et al., 2010). A single compound can activate one or multiple TAS2Rs, and conversely a given TAS2R can recognize multiple compounds. Overall, receptors vary in their breath of tuning, and the most broadly tuned receptors (hTAS2R10, hTAS2R14, and hTAS2R46) respond collectively to ~50% of bitter tastants (Meyerhof et al., 2010). The specific subsets of hTAS2R repertoire that encode bitter taste for the vast majority of therapeutic drugs have not yet been characterized. However, the hTAS2R activation patterns for 12 drugs that engender taste complaints are given in Table 40.2; these data show that three drugs activated only one hTAS2R subtype while seven activated multiple subtypes; two drugs (doxepin and metronidazole) did not activate any receptor at the maximal concentrations employed. The finding that some bitter compounds do not activate the hTAS2R subtypes tested suggests that additional (as yet unidentified receptors) may mediate bitterness. Furthermore, mechanisms that do not involve activation of a G-protein coupled taste receptors may also play a role in bitter taste perception of drugs including blockage of potassium channels and permeation of cell membranes with activation of downstream signaling mechanisms (Lindemann, 2001; Naim et al., 2008).

**Table 40.2** Activation pattern of hT2R subtypes by drugs associated with taste complaints. NR=Number of hT2R Subtypes Activated.

Drug	hT2R subtype												NR
	3	4	7	10	14	38	39	40	43	44	46	49	
Azathioprine		×		×	×		×				×		5

### 40.2.2 Genetic Differences in Bitter Taste Perception of Drugs

Variation in bitter taste sensitivity as a consequence of genetic polymorphisms in *hTAS2R* genes (Kim et al., 2005; Woodling et al., 2004; Drayna, 2005) is one factor that contributes to inter-individual differences in the perceived aversiveness of drugs. Surveys of 25 *hTAS2R* genes have reported an average of 4.2 single nucleotide polymorphisms (SNPs) per *hTAS2R* gene and at least 151 different haplotypes that occur at a frequency >10% in the population studied (Kim et al., 2005; Drayna, 2005). Widely divergent alleles of the *hTAS2R38* gene (also called the *PTC* gene), for example, govern taste sensitivity to the bitterness of thiourea compounds including the chemical phenylthiocarbamide (PTC); the allele for tasters of PTC differs from the nontaster allele at three locations. “Tasters” are persons who are sensitive to the bitter taste of PTC while “nontasters” are those who find the taste of PTC to be bland. Individuals who were homozygous for the taster form of the *hTAS2R38* gene have been reported to be more sensitive to the bitterness of numerous thiourea compounds including the antithyroid drug methimazole (Hamor and Lafdjian, 1967; Sandell and Breslin, 2008). Genetic polymorphisms of other biochemical components associated with the taste system including gustin and the TRPM5 channel may also contribute to the variation in the perceived aversive taste of the drugs. Gustin (CA6), a zinc metalloprotein secreted by salivary and von Ebner glands, is a taste bud trophic factor (Calò et al., 2011). Polymorphism of the gustin (CA6) gene at rs2274333 (A/G) has been associated with variability in the perception of bitterness of the thiourea compound 6-n-propylthiouracil

(PROP) (Padiglia et al., 2010). Genetic polymorphisms in the gene that encodes for a calcium-sensitive, nonselective cation channel TRPM5 expressed in taste buds have been identified (Ketterer et al., 2011); TRPM5 plays a role in downstream signaling of bitter (as well as sweet and umami) taste transduction. Overall, genetic variations that increase the sensitivity to strong bitter tastes are potential contributing factors to taste complaints from drugs.

### 40.2.3 Metallic Taste

Some therapeutic drugs, such as enoxacin, fenoprofen, and baclofen, produce unpleasant metallic sensations (with or without accompanying bitterness) that occur upon direct contact of the medication with the lingual surface (Schiffman et al., 2002). Artificial sweeteners used as excipients in pharmaceutical products including sodium saccharin and acesulfame-K also have metallic components for some individuals (Schiffman et al., 1979). Medicinal mixtures of traditional herbs such as the hemostatic Ankaferd Blood Stopper (ABS) used during dental procedures produce a metallic taste lasting 3–5 minutes when applied topically (Ercetin et al., 2010). Mineral supplements containing iron, zinc and copper salts also induce metallic tastes upon contact with the lingual surface (Schiffman, 2000). While the transduction mechanisms responsible for metallic sensations induced by drugs are not fully characterized, recent data suggest that the metallic component of artificial sweeteners and mineral salts is mediated in part by TRPV1 (the transient receptor potential cation channel subfamily V member 1) located in sensory nerve endings in the mouth (Riera et al., 2007, 2009). Variants in the *TRPV1* gene that affect its function (Xu et al., 2007) may play a role in

inter-individual differences in the perception of metallic taste.

#### 40.2.4 Intravascular Taste

Taste complaints frequently occur when drugs are administered by the intravascular route. For over 80 years, it has been known that injection of a chemical solution into the peripheral vascular system can produce a taste response within seconds. Weiss et al. (1929) reported that injection of histamine into a vein in the arm produced a sensation on the tongue described as “salty, metallic, electric” in approximately 23 seconds. Fishberg et al. (1933) found that injection of saccharin into an arm vein produced a sweet taste within 16 seconds that rapidly passed from the base to the tip of the tongue. Tarr et al. (1933) reported that injection of sodium dehydrocholate into the arm produced a bitter taste within 16 seconds. Since these early studies, there have been many reports of taste sensations from drugs and nutrients, predominantly metallic and/or bitter tastes, that occur within seconds after injection. Intravenous injections of lidocaine (Owen et al., 2004), ropivacaine (McCartney et al., 2003), iron preparations (Breymann et al., 2001; Macdougall and Roche, 2005), galanin (McDonald et al., 1994), thyrotropin-releasing hormone (TRH) (Callahan et al., 1997), nicotinic acid (Phillips and Lightman, 1981), and arginine (Weldhuis et al., 2006) all elicit metallic taste complaints. The finding that arginine is perceived as metallic when injected but bitter when tasted orally (Schiffman et al., 1981) suggests that the sensory properties of drugs differ depending on whether they contact the apical tongue surface or the basolateral side of taste cells. On the apical surface, drugs directly activate taste receptors on the microvilli. However, activation from the basolateral side must involve downstream signaling mechanisms because G-protein-coupled receptors (GPCRs) that mediate the tastes of bitter, sweet, and umami are presumed to be absent basolaterally. However, amiloride-sensitive sodium channels that serve as receptors for salty taste are present on both the apical and basolateral membranes (Mierson et al., 1996). Some taste disturbances that occur almost instantaneously upon injection are unlikely due to chemical stimulation by a drug but rather a neural response associated with intravascular pressure (Schiffman, 2007).

### 40.3 MODIFICATION OF NORMAL TASTE SENSATIONS BY DRUGS

Drugs not only have bitter, metallic, or unpleasant tastes of their own but can also modify the sensations of other taste stimuli. While the mechanisms by which medications alter normal taste perception are not well-understood,

modulation or disruption of taste signals can occur at multiple levels including the apical and basolateral side of taste cells, chemosensory neural pathways, and/or the brain. Blood plasma and saliva concentrations also play a role because plasma and salivary levels have been positively correlated with taste distortions (Doty et al., 2009).

#### 40.3.1 Taste Alterations from Interactions of Drugs at the Apical Taste Cell Level

Drugs can modulate taste signals by direct interactions with channels and receptors or by penetrating, accumulating, and/or disrupting taste cell membranes. Antidepressant drugs such as the sertraline have been shown to accumulate in cellular membranes and transform the biochemical properties of the cell (Chen et al., 2012). Permeation of the apical taste cell membrane by drugs to reach the cytosolic side of the membrane can alter signals by interacting with downstream signaling mechanisms including G-proteins and TRPM5 (Naim et al., 2008; Gao et al., 2009). Alteration of taste signals may occur within minutes of exposure to drugs at the apical level. For example, application of the diuretic amiloride, a potent inhibitor of sodium transport, to the tongue surface for five minutes reduced the taste intensity of sodium and lithium salts as well as sweeteners including saccharides, glycosides, dipeptides, proteins, and amino acids. However, amiloride had no effect on the perception of potassium or calcium salts, bitter and sour tastes, or amino acids without a sweet or salty component (Schiffman et al., 1983). Adaptation of the tongue to the antifibrillary drug bretylium tosylate was found to potentiate the taste of NaCl and LiCl with no effect on other salts, sweeteners, bitter or sour compounds (Schiffman et al., 1986a). Adaptation of the tongue for several minutes to methyl xanthines (caffeine, theobromine, and theophylline), which are potent antagonists of the adenosine receptor, potentiated the taste of bitter-tasting quinine and artificial sweeteners with a bitter component such as acesulfame-K with little or no effect on sucrose and urea. (Schiffman et al., 1985, 1986b).

Schiffman and colleagues performed a series of experiments to determine if a four-minute lingual application of drugs reported clinically to cause taste disturbances altered the perception of nine suprathreshold oral stimuli (summarized in Schiffman et al., 2002). Table 40.3 is a representative list of the some of the drugs tested along with the taste quality of each drug, taste detection thresholds (DT), and alterations in taste intensity caused by the topical drug exposure. All of these drugs are amphipathic compounds (they contain both hydrophobic and hydrophilic domains) and are membrane permeant. Each of the drugs had sufficient aqueous solubility to determine a taste threshold. The nine stimuli that were evaluated included NaCl, KCl,

$\text{CaCl}_2$ , sucrose, quinine HCl (QHCl), citric acid, capsaicin (pungent), WS-3 (n-ethyl-p-menthane-3-carboxamide) which has a menthol-like “taste,” and  $\text{FeSO}_4$  (metallic). The main finding was that topical application of a given drug at a level slightly above the taste DT led to some changes in the perceived intensity of the nine test stimuli. (A single arrow indicates that the change in intensity was less than 20% while a double arrow indicates that the change was greater than 20%). Distortions in taste quality of the nine oral stimuli often accompanied these intensity changes. These data show that a short lingual exposure to a drug can alter the taste of subsequent taste stimuli. Alteration of taste perception at the apical surface may be more likely from direct exposure to a drug at the time of ingestion rather than access to apical receptors from the bloodstream because the drug concentration at the apical receptors is typically higher in the former case. It is not yet known if drugs that leave the systemic circulation can accumulate over time in apical taste cell membranes at concentrations high enough to cause the taste alterations reported in Table 40.3.

### 40.3.2 Taste Alterations Resulting from Drug-Drug Interactions and Polypharmacy

Drug-drug interactions occur when one drug alters the bioavailability and/or pharmacological effect of a co-administered drug (Huang et al., 2008). Polypharmacy increases the risk of toxicity and adverse effects from drug-drug interactions (Johnell and Klarin, 2007) including taste disorders (Schiffman, 2009). Over the last several decades, the rates of prescription drug use and prevalence of polypharmacy have increased significantly in many countries in the world (Rumble and Morgan, 1994; Hovstadius et al., 2010; Hajjar et al., 2007; Gorard, 2006). In a nationally representative sample of community-residing individuals in the United States, 29% of individuals aged 57 through 85 used at least 5 prescription medications concurrently (Qato et al., 2008). A study of elderly cardiovascular patients found that taste losses at the threshold level as well as complaints of altered taste were most prevalent among those who used the greatest number of medications (Schiffman, 2007). Orally administered drugs arrive at the small intestine where they permeate the intestinal membranes and are transported by the hepatic portal vein to the liver and ultimately the systemic bloodstream. During their transit in the intestine and liver, drugs come in contact with metabolic enzymes including cytochromes P450 (CYP) and transporters (e.g., P-glycoprotein) that normally limit the fraction of the dose before it reaches the systemic circulation (van Herwaarden et al., 2009). CYP metabolism promotes the elimination of drugs via chemical reactions that render drugs more polar and water-soluble.

P-glycoprotein (P-gp) is an energy-dependent efflux “pump” that extrudes drugs from the apical surface of intestinal and liver cells back into the intestinal lumen and bile respectively leading to decreased drug accumulation. The combined effect of multiple co-administered drugs on CYP enzymes and transporters can alter normal metabolic processes and trigger significant adverse side effects including taste disorders (Schiffman, 2009). The elderly are at higher risk from drug interactions due to numerous age-related changes in pharmacokinetics including reduced effectiveness of drug metabolism and impaired renal excretion (Corsonello et al., 2010).

Drug-drug interactions that result from inhibition of two CYP isozymes, CYP3A4 and CYP2D6, contribute disproportionately to adverse drug-drug interactions including taste disorders (Schiffman, 2009) because these two isozymes are involved collectively in the metabolism of over 70% of prescription medications (Dantzig et al., 1999; Felmlee et al., 2008; Ingelman-Sundberg, 2005). In Table 40.4, representative drugs from Table 40.1 are presented along with their interactions with CYP3A4, CYP2D6, and/or P-gp (Preissner et al., 2010; Drugbank, 2012; Pubchem, 2012; Flockhart, 2012). The three columns under the label “Substrates” indicate that a drug is either metabolized by CYP3A4 or CYP2D6 or is effluxed by P-gp. The three columns under the label “Inhibitors” indicate that a drug is an inhibitor of CYP3A4 or CYP2D6 metabolism or an inhibitor of P-gp efflux. (Note: a drug can be both a substrate as well as an inhibitor depending upon numerous variables such as the plasma concentration or length of exposure.) Drugs that are substrates of CYP3A4 are frequently substrates of P-gp as well. When a drug that is a substrate of CYP3A4, CYP2D6, or P-gp is coadministered with a drug that is inhibitor of the analogous CYP isozyme or transporter, elevated plasma drug concentrations can occur. Drugs that are strong inhibitors of CYP3A4 such as clarithromycin, indinavir, nelfinavir, ritonavir, and saquinavir, cause a >5-fold increase in the plasma AUC values of co-administered CYP3A4 substrates (Flockhart, 2012). AUC (area under the plasma concentration time curve) has many of important uses in pharmacokinetics. Drugs that are strong inhibitors of CYP2D6 such as bupropion, fluoxetine, paroxetine, and quinidine cause a >5-fold increase in the plasma AUC values of co-administered CYP2D6 substrates. Moderate CYP inhibitors cause a 2-fold to 5-fold increase in the plasma AUC values and weak inhibitors, a >1.25-fold but <2-fold increase. Clarithromycin, a potent inhibitor of CYP3A4 and P-gp, elicited the most taste complaints in a study of over 600,000 elderly patients from the Swedish Prescribed Drug Register (Johnell and Klarin, 2007). The column in Table 40.4 labeled T/N (the ratio of the toxic blood-plasma levels to normal therapeutic blood-plasma levels calculated from Schulz et al., 2012) indicates that

**Table 40.3** Taste quality, mean taste detection thresholds (DT), and alterations in perceived intensity of nine oral stimuli after a 4-minute topical exposure of the tongue to drugs.

many drugs when co-administered with CYP or P-gp inhibitor can be elevated to toxic levels in the blood. For example, the pharmacologic agents diazepam, donepezil, fentanyl, pimozide, sertraline, and trazodone become toxic when blood-plasma levels are only 1.1 to 1.2 times greater than normal therapeutic blood levels. Drug-drug interactions that elevate blood-plasma levels of a medication beyond therapeutic concentrations play a major role in inducing taste disorders (Schiffman, 2009).

An illustration of a toxic effect caused by a drug-drug interaction with a CYP3A4 inhibitor involves the antihistamine terfenadine. In the absence of a CYP3A4 inhibitor, the parent compound terfenadine is nearly completely metabolized presystemically to fexofenadine which is the active form. However, when the parent terfenadine is co-administered with a potent CYP3A4 inhibitor, the parent compound does not undergo metabolism by CYP3A4 to fexofenadine but rather is itself absorbed. Terfenadine, a potent blocker of delayed rectifier potassium channels, can cause cardiac arrhythmias and has been implicated in approximately 125 deaths (Rampe et al., 1993; Flockhart, 1996). Furthermore, terfenadine also causes taste aberrations by a similar action (Schiffman, 2009). Terfenadine was ultimately removed from the United States, Canadian, and UK markets. A second example of a toxic effect caused by a drug-drug interaction involves the P-gp substrate digoxin that inhibits Na/K-ATPase and is used in the treatment of congestive heart failure and atrial fibrillation (Physicians Desk Reference, 2005). Over 30 years ago, Leahey et al. (1978) first reported a drug-drug interaction between digoxin and the antiarrhythmic drug quinidine that is an inhibitor of P-gp. When digoxin and quinidine were co-administered, digoxin levels were more than doubled resulting in ventricular tachycardias and one death. Many other P-gp inhibitors, such as amiodarone and spironolactone, can also elevate digoxin levels beyond therapeutic levels with adverse effects. Taste alterations frequently accompany adverse reactions involving digoxin

and may involve modulation of Na/K-ATPase in the taste system (Schiffman, 2009). Inhibition of CYP2D6 can also cause drug-drug interactions with toxic results, but the degree of the effect is determined by genetic polymorphisms in the CYP2D6 gene that renders a person an “extensive metaboliser” or a “poor metaboliser” of CYP2D6 substrates (Lee et al., 2005). The magnitude of inhibitory drug interactions is greater in extensive metabolisers of CYP2D6 than poor metabolisers.

### 40.3.3 Pharmacokinetic Factors that may be Causative Factors in Taste Disorders

The potential pharmacokinetic factors that contribute to adverse side effects and toxicity of drugs including taste disorders are very extensive and are in part illustrated by the three columns in Table 40.4 below the title “Number of known pharmacokinetic factors” and subtitles labeled “Targets,” “Enzymes,” and “Transporters.” A single drug such as the psychopharmacologic agent amitriptyline interacts with 21 targets, 9 enzymes, and 1 transporter including: the sodium-dependent noradrenaline transporter (inhibitor), sodium-dependent serotonin transporter (inhibitor), 5-hydroxytryptamine 2A receptor (antagonist), 5-hydroxytryptamine 1A receptor (pharmacological interaction unknown), delta- and kappa-type opioid receptors (agonist), high affinity nerve growth factor receptor (agonist), brain-derived neurotrophic factor (BDNF)/neurotrophin-3 growth factor receptors (agonist), alpha-1A, 1D, and 2A adrenergic receptors (antagonist), histamine H1 receptor (antagonist), muscarinic acetylcholine receptors M1, M2, M3, M4, and M5 (antagonist), potassium voltage-gated channels subfamily KQT member 2, subfamily A member 1, subfamily D member 2, and subfamily D member 3 (inhibitor), cytochrome P450 2D6 (substrate, inhibitor), cytochrome P450 1A2 (substrate), cytochrome P450 2C19 (substrate, inhibitor),

cytochrome P450 2C9 (substrate), cytochrome P450 3A4 (substrate), cytochrome P450 3A5 (substrate), cytochrome P450 2B6 (substrate), cytochrome P450 2C8 (substrate, inhibitor), cytochrome P450 2E1 (substrate, inhibitor), and P-gp/multidrug resistance protein 1 (substrate, inhibitor). Furthermore, amitriptyline also interacts with two carriers, serum albumin and alpha-1-acid glycoprotein. It is not yet known which one or combination of these 33 targets, enzymes, transporter, and carriers are responsible for the taste aberrations caused by amitriptyline. The representative drugs in Table 40.4 interact with over different 175 targets, enzymes, and transporters (PubChem, 2012; Drugbank, 2012) which illustrates the magnitude of the difficulty of determining the precise mechanism by which a particular drug or drug combination causes taste aberrations. Furthermore a drug can have toxic consequences that are unrelated to their pharmacokinetic effects involving targets, enzymes, and transporters. Experimental studies are needed to obtain empirical data regarding the mechanisms by which drugs alone and in combination disrupt taste perception.

#### 40.3.4 Reductions in Drug Bioavailability Due to Induction of Drug Metabolism Exacerbate Disease States

Drugs not only serve as substrates and inhibitors but can also be inducers of drug metabolism as well. Increased expression or induction of metabolizing enzymes such as CYP3A4 and transporters such as P-gp by one drug can significantly reduce the plasma concentration of a co-administered drug that is a substrate of CYP3A4 and/or P-gp. Clinical studies have found that expression of CYP3A4 and P-gp is inducible by certain drugs, and that these drugs are frequently associated with taste complaints. Examples of drugs in Table 40.4 that are inducers of CYP3A4 under certain conditions include terfenadine, atorvastatin, nifedipine, quinidine, simvastatin, clarithromycin, ritonavir, terbinafine, dexamethasone, and tamoxifen (Pubchem, 2012). Examples of drugs that are inducers of P-gp include amiodarone, nifedipine, indinavir, nelfinavir, ritonavir, saquinavir, dexamethasone, doxorubicin, tamoxifen, vincristine, cimetidine, midazolam, and trazodone. Dexamethasone has been reported to be an inducer of CYP2D6 (Flockhart, 2012); however, CYP2D6, in general, is difficult to induce. Because induction of CYP3A4 and P-gp by one drug will lead to increased metabolism and efflux respectively of a co-administered drug, the bioavailability of the co-administered drug may be reduced below therapeutic levels. For cancer drugs as an example, induction of CYP3A4 and P-gp can reduce the bioavailability of the CYP3A4 substrate etoposide and the P-gp substrate methotrexate to subtherapeutic levels.

In this case, taste complaints may be a consequence of exacerbation of the disease state (cancer) rather than the CYP3A4 or P-gp inducing drug. Cancer is well-known to cause disturbances in taste (Epstein and Barasch, 2010).

#### 40.3.5 Potential Side-Effects of Drugs Initiated by Interaction with Extra-Oral TAS2Rs

Another potential contributor to taste complaints is the alteration of physiological processes subsequent to interaction of drugs with extra-oral bitter taste receptors. In addition to their presence in the oral cavity, TAS2Rs are expressed in: (1) nasal and laryngeal solitary chemosensory cells (SCCs) (Finger et al., 2003; Tizzano et al., 2011), (2) the respiratory system (Deshpande et al., 2010), (3) the gastrointestinal tract and enteroendocrine STC-1 cells (Wu et al., 2002; Chen et al., 2006), (4) the brain (Singh et al., 2011) and (5) the heart (Foster et al., 2012). Interaction of bitter compounds with TAS2Rs throughout the respiratory system mediates protective airway reflexes (Tizzano et al., 2011) along with the unanticipated effect of relaxation of airway smooth muscle (Deshpande et al., 2010). In the GIT, interaction of bitter compounds with TAS2Rs can impact the motility, GIT hormone release, glucose and insulin homeostasis, and pancreaticobiliary secretion (Wu et al., 2002; Dotson et al., 2008). In the brain, activation of TAS2Rs increases intracellular calcium and has been hypothesized to impact the secretion of regulatory peptides involved in the regulation of food intake (such as cholecystokinin) and other biological processes (Singh et al., 2011). The effect of interaction of bitter-tasting compounds with TAS2Rs in the heart is not yet known. Conditioned taste aversions associated with the bitter taste of drugs may in some cases be a consequence of physiological effects produced by interaction of drugs with extra-oral TAS2R receptors; taste aversions serve as an innate response designed to protect an organism against toxic bitter compounds. Conversely, desirable physiological effects produced by interaction of bitter drugs with TAS2Rs, e.g. bronchodilation in asthma, may explain learned tolerance or even preference for some bitter drugs.

### 40.4 TREATMENT AND PROGNOSIS

At present, there are standard no methods for the treatment of adverse taste disturbances caused by medications. If a taste disturbance is simply due to the taste of the drug during ingestion, numerous taste-masking strategies have been developed to reduce unwanted tastes (Ayenew et al., 2009; Szejtli and Szente, 2005). A frequently employed method is

the addition of sweeteners and flavoring agents (Schiffman et al., 1994; Mennella and Beauchamp, 2008). Additional taste masking methods utilize amino acids, salts, microencapsulation, particulate coatings, chemical bitter blockers, and ion exchange resins (Ayene et al., 2009; Schiffman et al., 2002; Breslin and Beauchamp, 1995; Brockhoff et al., 2011; Lavasanifar et al., 1997; Lorenzo-Lamosa et al., 1997; Ndesendo et al., 1996). Bitter receptor antagonists have recently been identified that reportedly block activation at specific TAS2Rs (Slack et al., 2010; Greene et al., 2011; Brockhoff et al., 2011). The efficacy of taste-masking strategies is influenced by genetic factors. Allelic variation at bitter taste receptors (Kim et al., 2005; Woodling et al., 2004; Drayna, 2005) that elevates bitter sensitivity or at sweet taste receptors (Fushan et al. 2009, 2010) that reduces sweet sensitivity can influence the likelihood of sensory complaints from drugs and affect medication choices (Lipchock et al., 2012; Mennella et al., 2012).

In most (but not all) cases, a taste disorder will resolve within a period of 4 to 10 months after removal of the offending drug or drug combination (Schiffman, 1983; Deems et al., 1996). Taste disorders typically persist for prolonged periods after an offending drug (or drug combination) is withdrawn for numerous reasons. First, the levels and functioning of drug targets, enzymes, and transporters do not return to baseline immediately after cessation of medication use; pharmacokinetic parameters require a period of recovery to return to non-medicated levels after drug withdrawal. Second, most drugs are lipophilic, and can potentially bioaccumulate in tissues. For example, amiodarone, which is deposited and stored in fat, has an elimination half-life of 47 days (Schiffman, 2009). This prolonged half-life is due to the slow release of amiodarone from lipid-rich tissues. The half-life of 47 days specifies the period of time required for the drug level of amiodarone to fall to 50%; at the end of 7 half-lives (329 days), over 99% of amiodarone will be eliminated from the body. Third, some cases of taste loss are due to impaired turnover and replacement of taste cells. Taste cells undergo continuous turnover with a half-life of approximately 10 days (Beidler and Smith, 1991), and disruption of turnover, for example, by chemotherapeutic agents including vinblastine, bleomycin, cisplatin, and methotrexate, are associated with taste loss and alterations.

It is likely that the incidence and prevalence of taste disorders will grow in the coming decades as the number of persons (particularly the elderly) being treated with multiple medications continues to increase globally. Thus, development of effective treatments for taste disorders is necessary to reduce the probability of therapeutic failure due to noncompliance. To achieve this end, experimental studies are required to determine the physiological and pharmacological parameters that are responsible for taste

disturbances caused by specific drugs and/or drug combinations. This knowledge can then be employed in the rational development of treatments for drug-related taste disorders.

## Taste Processing in Insects

JOHN I. GLENDINNING

### 41.1 INTRODUCTION

The sense of taste is essential for the survival of insects. It helps them evaluate the chemical composition of foods (White and Chapman, 1990; Schoonhoven et al., 1992; Glendinning, 2002), select host plants for oviposition (Ma and Schoonhoven, 1973; Städler et al., 1995) and self-medicate themselves against endoparasite infections (Bernays and Singer, 2005). Taste also facilitates digestion by stimulating salivation (Watanabe and Mizunami, 2006) and determining whether ingested food is directed to the mid-gut for digestion or to the crop for storage (Schmidt and Friend, 1991). Below, I review five topics: (a) organization of the taste system, (b) peripheral taste function, (c) taste-mixture interactions, (d) taste processing in the central nervous system, and (d) factors that modulate taste responses. Whenever possible, I highlight significant gaps in our understanding of insect taste. I also emphasize commonalities between the taste systems of insects and mammals.

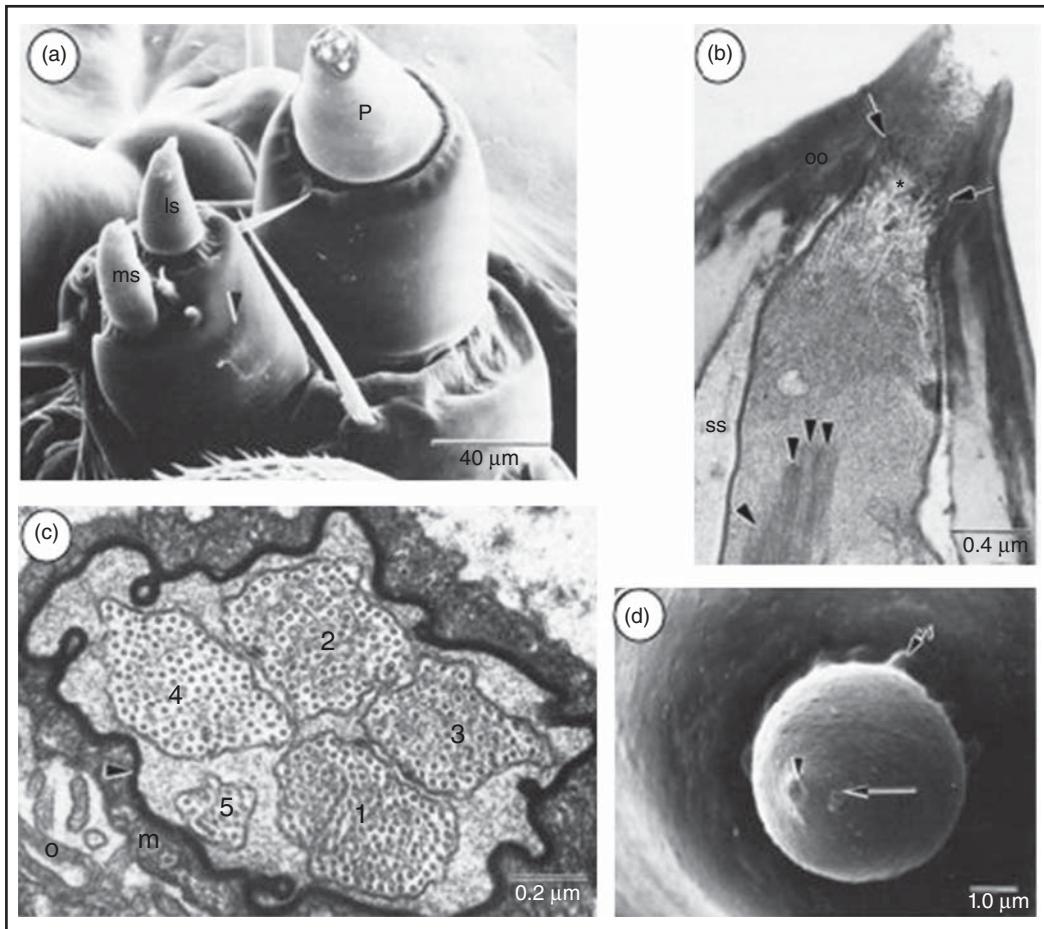

Before I begin, two caveats are in order. First, the class Insecta contains about 900,000 described species, many of which eat different types of foods. At this point, investigators have studied the taste systems of only a fraction of these species, and have a detailed knowledge of only one species (the fruit fly, *Drosophila melanogaster*). Thus, any generalizations about insect taste must be tempered by our rather myopic view. Second, I cannot possibly cover all of the new information on insect taste in this review. Thus, I have decided to focus on how taste information is processed both peripherally and centrally. For a more detailed review of the molecular and cellular mechanisms of insect taste, I refer the reader to several excellent reviews (Montell, 2009; Isono and Morita, 2010; Kwon et al., 2011).

### 41.2 ORGANIZATION OF THE TASTE SYSTEM

In contrast to vertebrates, insects can sense foods without actually ingesting them. This was established in the 1920s by Dwight Minnich, who elicited an appetitive response (i.e., extension of the feeding proboscis) in flies and butterflies simply by immersing their “feet” (i.e., tarsi) in a sugar solution (Minnich, 1921; Minnich, 1929). Several years later, Minnich identified the peripheral taste structures that mediated this appetitive response: small hair-like structures protruding from the tarsi (henceforth, taste sensilla). He found that stimulation of a single taste sensillum with sugar water was sufficient to elicit proboscis extension in flies (Minnich, 1931). Remarkably, the significance of this observation—that is, the discovery of the primary organ of taste in insects – was not appreciated until over two decades later (Grabowski and Dethier, 1954; Lewis, 1954).

Subsequent research established that taste sensilla are uniporous structures (Figure 41.1a) that are innervated by the single, unbranched dendrites of 2–6 gustatory receptor neurons (GRNs) (Chapman, 1982). The dendrites terminate near the distal tip of the sensillum (Figure 41.1b). The cell body of each GRN occurs at the base of the taste sensillum, and the axon extends directly to the central nervous system (Dethier, 1976). Because the GRNs within a taste sensillum lie in close proximity to one another (Figure 41.1c), there is the opportunity for activity in one GRN to influence activity in another (see *Taste-Mixture Interactions* below). Taste sensilla are also innervated by a fifth mechanosensory neuron, which provides proprioceptive feedback about when the sensillum is contacting foods (Figure 41.1c).

In some insects, the taste sensilla are restricted to external appendages associated with the oral cavity

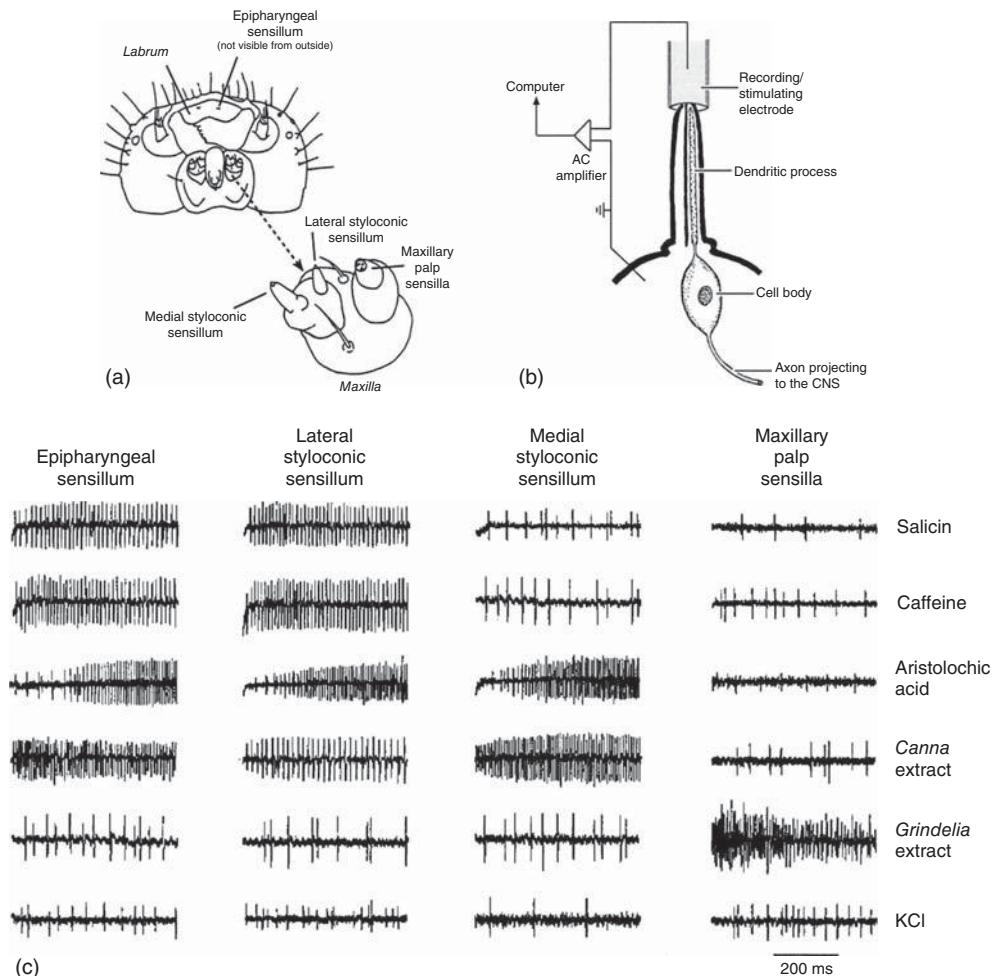

**Figure 41.1** SEM micrographs of a taste sensillum from a caterpillar (*Mamestra configurata*, Lepidoptera: Noctuidae). (a) Left maxilla of caterpillar with lateral (*ls*) and medial (*ms*) styloconic sensilla, and a maxillary palp (*P*). (b) Longitudinal section of a lateral styloconic sensillum. At the top of the image, one can see the tip of the pore, which contains a plug of fenestrated fibrils (asterisk), and the dendritic sheath (arrows), which is fused with the cuticular wall of the sensillum. Four distal dendrites, each from a different GRNs (arrowheads), can be seen near the bottom of the image; they are enclosed by the dendritic sheath. *cu*, cuticle; *ss*, sensillar sinus. (c) Proximal cross-section of a medial styloconic sensillum, showing GRNs (1–4) and a mechanosensory neuron (5). All GRNs are enclosed by a dendritic sheath (arrowhead), which is surrounded by a densely granulated intermediate sheath cell (m). *o*, outer sheath cell. (d) Apical view of the tip of a lateral styloconic sensillum with the terminal pore (arrowhead). These micrographs are from Shields (1994).

(e.g., see Figure 41.2a), whereas in other insects they are distributed across the body surface (Chapman, 1982). In flies, for example, taste sensilla occur on the proboscis, wing margins, feet and distal tip of the abdomen (Vosshall and Stocker, 2007). The total number of taste sensilla per insect varies greatly across species (i.e., from 30 to over 3000) (Chapman, 1982). Little is known, however, about the functional significance of this variation – for example, whether large numbers of sensilla confer greater sensitivity or discriminatory abilities.

For taste transduction to occur, a chemical stimulus must first diffuse through a mucopolysaccharide substance in the pore at the tip of a taste sensillum and then dissolve into the fluid (or receptor lymph) surrounding the dendrites

(Figure 41.1b) (Shields, 1996). Once the chemical stimulus encounters the distal dendritic membrane of a GRN, it is thought to interact with cell-surface receptors and activate transduction mechanisms that lead to the generation of action potentials (Dethier, 1976; Morita, 1992). The nature of the cell-surface gustatory receptors (Grs) was not known until 2000, when Peter Clyne, Coral Warr and John Carlson discovered a family of 19 highly divergent Grs in *Drosophila* (Clyne et al., 2000). Subsequent studies expanded the number of *Drosophila* Grs to 68 (see review in Isono and Morita, 2010) and examined the pattern of expression of the Grs, both within specific GRNs and across the entire population of taste sensilla (see below for details). Although Grs have been discovered in other insect

**Figure 41.2** (a) Cartoon of the head of a *Manduca sexta* caterpillar, as viewed from below. An enlargement of the maxilla (indicated with an arrow) is provided to clarify the location of the medial and lateral styloconic sensilla. The epipharyngeal sensilla are located underneath the labrum, and thus are not visible in this diagram. This cartoon was adapted from Bernays and Chapman (1994; their Fig. 3.4). (b) Illustration of the tip recording method, which was used to record excitatory responses of individual GRNs located within a taste sensillum. During a tip recording (Hodgson et al., 1955), the tip of a taste sensillum is inserted into the end of a glass recording/stimulating electrode, which is filled with a taste stimulus dissolved in an electrolyte solution (0.1 M KCl in deionized water). The taste stimulus solution diffuses through a pore in the tip of the sensillum and activates transduction mechanism(s) on the distal end of a GRN's dendritic process; the electrode detects the ensuing action potentials. For clarity, only one GRN is indicated. Note that the GRN's axonal process projects directly to the central nervous system without synapsing. (c) Typical excitatory responses of the four different classes of taste sensilla to five aversive taste stimuli: salicin, caffeine, aristolochic acid, *Canna* extract, and *Grindelia* extract (see Glendinning et al., 2002, for exact concentrations of each taste stimulus). The onset of stimulation occurred at the beginning of each trace, and each vertical line reflects the occurrence of an action potential. In most of the traces containing a large number of action potentials, there is a single bitter-sensitive GRN firing regularly, and another GRN (the salt-sensitive taste cell) firing sporadically. The only exception is the multi-unit response of the maxillary palp sensilla to the *Grindelia* extract, which probably contains action potentials from several bitter-sensitive GRNs. Because all aversive taste stimuli were presented in a 0.1 M KCl solution, I also show representative responses of each sensillum to the electrolyte solution alone for comparison. Note that each aversive taste stimulus selectively activates bitter-sensitive GRNs in only a subset of the taste sensilla (e.g., the *Grindelia* extract only stimulated bitter-sensitive GRNs in the maxillary palp). These traces are from Glendinning et al. (2002).

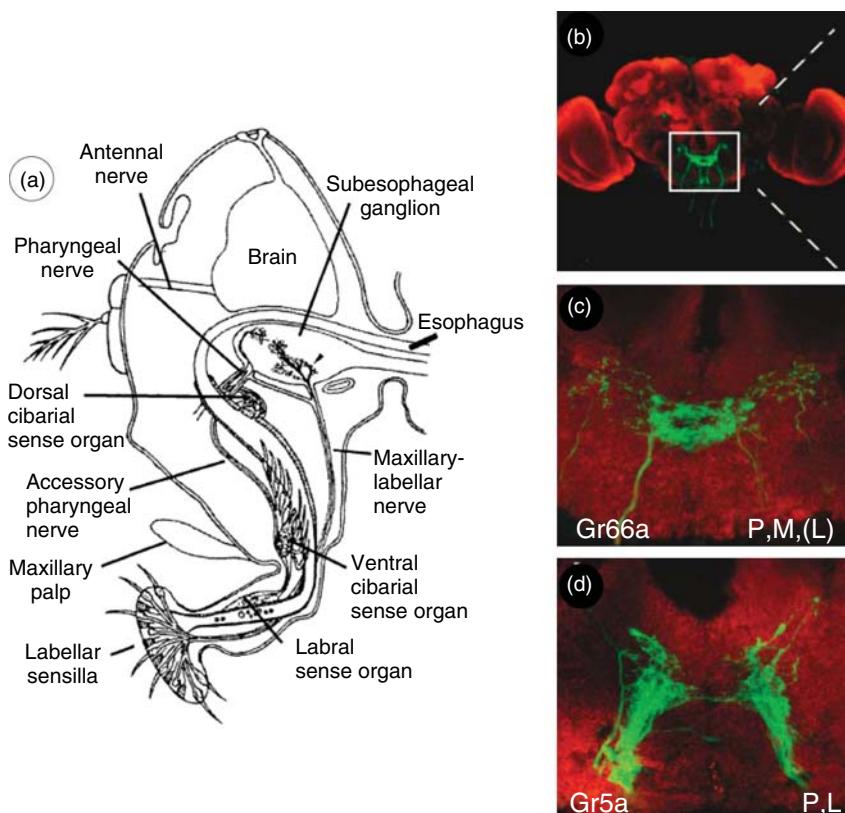

taxa – Lepidoptera (Wanner and Robertson, 2008; Howlett et al., 2012), Hymenoptera (Kent and Roberston, 2009) and Coleoptera (Kent and Roberston, 2009) – progress has been comparatively slow, owing to a paucity of genomic information and molecular tools.

Insect Grs were originally hypothesized to function as G protein-coupled receptors (GPCRs), based on amino acid sequences specifying seven transmembrane domains, a feature typical of GPCRs (Clyne et al., 2000). However, functional studies have produced equivocal support for this hypothesis. On the one hand, there are reports that pharmacological (or genetic) manipulation of metabotropic signaling pathways (i.e., G protein subunits, cAMP, cGMP, calmodulin, protein kinase C, nitric oxide and inositol 1,4,5-trisphosphate) alters taste-mediated responses of insects to chemical stimuli (Amakawa and Ozaki, 1989; Amakawa et al., 1990; Ishimoto et al., 2005; Nakamura et al., 2005; Seno et al., 2005a, 2005b; Kan et al., 2008; Ouyang et al., 2009; Bredendieck et al., 2011; Kan et al., 2011; Vermehren-Schmaedick et al., 2011). On the other hand, there are reports that sugar receptors are ligand-gated ion channels in flies (Murakami and Kijima, 2000) and moths (Sato et al., 2011). At this point, more work is needed to resolve these contradictory findings. It is notable that in insect olfactory receptor neurons (ORNs), odor stimuli are thought to be transduced primarily by

ionotropic mechanisms; the metabotropic mechanisms are thought to serve a modulatory role (Silbering and Benton, 2010). This may be the case for insect GRNs as well.

Recent molecular studies in adult *Drosophila* indicate that Grs function as part of heteromeric complexes. For instance, mutation of *Gr66a*, *Gr93a*, or *Gr33a* attenuates responsiveness to caffeine, indicating that the Grs encoded by these genes are necessary for normal caffeine detection (Lee et al., 2009). However, misexpression of two or all three of these Grs in a sugar-sensitive GRN fails to confer caffeine responsiveness, indicating that functional “bitter” receptors consist of four or more Grs (Moon et al., 2009).

Most GRNs terminate in the subesophageal ganglion (SOG; Figure 41.3a) and tritocerebrum; these sites are widely considered to be the primary taste processing centers (Kent and Hildebrand, 1987; Mitchell and Itagaki, 1992; Stocker, 1994; Thorne et al., 2004; Wang et al., 2004; Ignell and Hansson, 2005; Colomb et al., 2007). In some species, GRNs from tarsal taste sensilla terminate in the metathoracic ganglia (Rogers and Newland, 2002). Based on three lines of evidence, Input from GRNs is thought to modulate oromotor feeding circuits in the SOG/tritocerebrum: (a) GRN axons intermingle with (or occur in close apposition to) arborizations from the mouthpart motor neurons (Altman and Kien, 1987); (b) some SOG interneurons have branches that occur in

**Figure 41.3** (a) Ultrastructure of the head, feeding apparatus and central nervous system of an adult fruit fly *Drosophila melanogaster* (from Stocker and Schorderet, 1981). (b) A whole-mount of the brain of *D. melanogaster*, showing axonal projects from taste cells (labeled with anti-GFP immunohistochemistry). The white box indicates the region of the SOG depicted in panels (c-d). The green axons in panel C are from GRNs expressing the bitter-sensitive *Gr66a*, and those in panel D are from GRNs expressing the sugar-sensitive *Gr5a*. It is notable that the projection sites for GRNs expressing *Gr66a* are spatially distinct from those expressing *Gr5a*. Panels (b-d) are from Wang et al. (2004). (See plate section for color version.)

neuropil with both sensory and motor terminals (Altman and Kien, 1987); and (c) stimulating GRNs with plant extracts modulates the output of the mouthpart motor neurons (Griss et al., 1991). The ability of GRN input to modify oromotor feeding circuits does not appear to involve direct connections between GRNs and mouthpart motor neurons (Gordon and Scott, 2009). Instead, there appear to be intermediary taste circuits within the SOG and/or higher brain centers. One such higher brain center could be the calyces of the mushroom body (a neuropil important for learning and memory), which receives taste input from the SOG via the subesophageal-calycal tract (Schröter and Menzel, 2003). Indeed, there is evidence that disruption of the mushroom body impairs taste-associated learning in adult *Drosophila* (Masek and Scott, 2010).

### 41.3 PERIPHERAL TASTE FUNCTION

In this section I discuss what is known about peripheral taste responses to chemical stimuli, and how recent studies of *Drosophila* have provided insight into the molecular basis of these responses.

To measure responses of individual GRNs to chemical stimuli, investigators typically make “tip recordings,” which involve contacting the pore at the tip of a taste sensillum with a solution containing a taste stimulus dissolved in an electrolyte solution (Hodgson et al., 1955) (Figure 41.2b). Because tip recordings usually contain responses from multiple GRNs, investigators use spike-sorting methods (based on shape, amplitude and/or temporal pattern) to assign spikes to individual GRNs (Schnuch and Hansen, 1990; Smith et al., 1990; Meunier et al., 2003; Glendinning et al., 2006). The GRNs are classified according to their “best” stimulus – that is, the stimulus that generates the strongest excitatory response. Accordingly, a GRN that responds best to sugars is referred to as sugar-sensitive. It should be noted, however, that because most insect GRNs have been tested with only a limited number of taste stimuli, the “best” stimulus for a specific GRN may still be unknown. For the sake of simplicity, I will use best stimulus terminology for labeling GRNs, keeping in mind this caveat.

#### 41.3.1 Aversive Compounds

Many of the compounds that taste bitter to humans also elicit aversive responses (i.e., rapidly inhibit feeding) in insects. Because virtually all naturally occurring poisons taste bitter to humans, the rejection of aversive compounds is thought to represent an evolved mechanism for avoiding poisonous foods (Bate-Smith, 1972; Garcia and Hankins, 1975; Brower, 1984; Brieskorn, 1990). The

effectiveness of this taste-mediated poison detection system is limited by the fact that there is no straightforward relationship between taste and toxicity. Indeed, many aversive compounds are harmless (Bernays and Chapman, 1987; Bernays, 1990; Rouseff, 1990; Bernays, 1991; Glendinning, 1994).

All insects studied to date – for example, Orthopterans (locusts and grasshoppers), Dipterans (flies), Lepidopterans (butterflies and moths), and Coleopterans (beetles) – possess GRNs that respond selectively to aversive and potentially toxic compounds (Schoonhoven and van Loon, 2002; Meunier et al., 2003; Thorne et al., 2004; Marella et al., 2006; Weiss et al., 2011). These GRNs are referred to as “deterrent” or “bitter-sensitive” (Schoonhoven and van Loon, 2002). Importantly, activation of bitter-sensitive GRNs strongly inhibits feeding in insects (Schoonhoven and van Loon, 2002). One study reported that stimulation of as few as two bitter-sensitive GRNs can inhibit feeding (Glendinning et al., 1999b).

The studies cited in the previous paragraph reveal four notable features of bitter-sensitive GRNs. First, the response (i.e., firing rate) increases with stimulus concentration; this indicates that taste intensity is coded, at least in part, in the periphery. Second, many bitter-sensitive GRNs respond to a structurally diverse range of compounds. In *Drosophila*, this capacity stems from the fact that bitter-sensitive GRNs express a diversity of Grs. Third, comparisons across sensilla within the same insect reveal that many GRNs display different molecular receptive ranges (MRRs) (Figure 41.2c). This attribute can be explained in *Drosophila* by the fact that different classes of bitter-sensitive GRNs express different combinations of Grs. Fourth, taste responses to aversive compounds are not mediated exclusively by Grs. For instance, TrpA1 channels are expressed in bitter-sensitive GRNs, and disrupting expression of TrpA1 selectively attenuates the aversive response of *Drosophila* to aristolochic acid (Kim et al., 2010).

#### 41.3.2 Sugars

Most insects show concentration-dependent increases in intake of simple sugars. For instance, the probability that bees, butterflies, and flies will extend their proboscis in response to taste stimulation increases with sugar concentration (Dethier, 1976; Schoonhoven and van Loon, 2002; Omura and Honda, 2003; de Brito Sanchez et al., 2005; Dahanukar et al., 2007; Gordon and Scott, 2009; Zhang et al., 2010). Likewise, the rate at which Lepidopteran caterpillars either bite from disks (Ma, 1972) or swallow solutions (Sasaki and Asaoka, 2006) increases with sugar concentration. *Manduca sexta* caterpillars (Sphingidae; Lepidoptera) are a notable exception to this pattern. They exhibit a strong peripheral taste response to sugars, but

nevertheless fail to show immediate appetitive responses to them – for example, they bite at the same rate from disks treated with sugar solutions as from disks treated with water alone (Glendinning et al., 2007).

All insects studied to date possess GRNs that respond robustly to sugars (e.g., glucose, sucrose, fructose, and trehalose) and sugar alcohols (e.g., sorbitol, mannitol, and *myo*-inositol). Whereas Dipterans have sugar-sensitive GRNs that respond to sugars and sugar alcohols, most Lepidopterans have separate GRNs for sugars and sugar alcohols (Dethier, 1976; Schoonhoven and van Loon, 2002; Dahanukar et al., 2007). As in the bitter-sensitive GRNs, the firing rate of carbohydrate-sensitive GRNs increases with stimulus concentration (Dethier, 1976; Glendinning et al., 2007). Second, carbohydrate-sensitive GRNs usually respond to a structurally diverse range of sugars (Dethier, 1976; Schoonhoven and van Loon, 2002; Dahanukar et al., 2007; Glendinning et al., 2007; Jiao et al., 2007). In *Drosophila*, this capacity appears to stem from two factors. The two best characterized sugar receptors – Gr5a and 64a – are not only broadly tuned, but they each respond to a large number of sugars (Dahanukar et al., 2007; Jiao et al., 2007; Slone et al., 2007). It is important to keep in mind that sugars can stimulate feeding by mechanisms other than taste. For instance, *Drosophila* possess post-oral mechanisms for sensing ingested sugars, and that they use input from these mechanisms to learn which foods are most nutritious (Burke and Waddell, 2011; Dus et al., 2011; Fujita and Tanimura, 2011). This post-oral chemosensation may be mediated in part by the cluster of Gr28 receptors in the abdominal multi-dendritic neurons (Thorne and Amrein, 2008).

### 41.3.3 Salts

All insects studied to date have salt-sensitive GRNs. In flies, monovalent inorganic cations are the most effective stimulants for these GRNs (Dethier, 1976). Cations differ, however, in their stimulatory effectiveness (e.g., in the fleshfly, *Boettcherisca peregrina*,  $\text{Li}^+ < \text{Na}^+ < \text{Cs}^+ < \text{Rb}^+ < \text{K}^+$ ; (den Otter, 1972).

Flies show an appetitive response to low NaCl concentrations (5–10 mM) and aversive response to high NaCl concentrations ( $\geq 500$  mM; Dethier, 1968; Hiroi et al., 2004). This concentration-dependent change in hedonic response to salts is thought to have evolved because low concentrations of salts satisfy nutritional needs, whereas higher concentrations threaten osmotic equilibrium. To explain the mechanistic basis of this behavior, investigators have silenced the sugar-sensitive GRNs of *Drosophila* that express Gr5a (Wang et al., 2004). When these flies were offered a range of NaCl concentrations, they exhibited an attenuated appetitive response to a low (5 mM) concentration, but a normal aversive response to high

concentrations ( $\geq 500$  mM). These latter findings, together with those of Hiroi et al. (2004), indicate that NaCl stimulates two different classes of GRN – low concentrations stimulate Gr5a-expressing (i.e., sugar-sensitive) GRNs, and high concentrations stimulate a different (presumably salt-sensitive) population of GRNs.

In adult *Drosophila*, the aversive response to high NaCl concentrations is thought to be mediated in part by the *dpr* gene (Nakamura et al., 2002). This inference is based on the observation that the proboscis extension reflex was strongly inhibited by high NaCl concentrations in wildtype flies, but not in *dpr*-knockout flies. The *dpr* gene is thought to encode a protein with a single transmembrane domain, and to be expressed in a subset of GRNs (Nakamura et al., 2002).

An important, but unexplained, observation is that some insects can discriminate between different types of salts (Arms et al., 1974; Maes and Bijpost, 1979; Miyakawa, 1981; Miyakawa, 1982). In laboratory rats, the ability to discriminate  $\text{Na}^+$  and  $\text{K}^+$  salts appears to be mediated by differential input from  $\text{Na}^+$ -specific (amiloride-sensitive) and  $\text{Na}^+$ -nonspecific (amiloride-insensitive) cation channels (Spector and Grill, 1992; Smith et al., 2000). The question of whether insects use a similar mechanism is unresolved. One study reported that *Drosophila* expresses two amiloride-sensitive degenerin/epithelial  $\text{Na}^+$  (DEG/ENaC) channels – Ppk11 and Ppk19 – in GRNs within the gustatory terminal organ of larvae and taste sensilla on the labellum, legs and wing margins of adults (Liu et al., 2003). One concern about the latter study is that 5 mM amiloride was required to inhibit the response of Ppk11 and Ppk19 to NaCl. In mammalian GRNs, one can effectively inhibit the response to  $\text{Na}^+$  in mammals with concentrations as low as 30  $\mu\text{M}$  (Vandenbeuch et al., 2008). The need for such a high amiloride concentration in *Drosophila* may reflect a low binding affinity of amiloride for Ppk11 or Ppk19 channels, or non-specific effects of amiloride on insect GRNs.

### 41.3.4 Amino Acids

Free amino acids stimulate feeding in many insect species, but the behavioral responsiveness to any given amino acid varies considerably across species (Bernays, 1985; Albert and Parisella, 1988; Hirao and Ariai, 1990; Kim and Mullin, 1998; Schoonhoven and van Loon, 2002). Appetitive responses to amino acids are considered adaptive because plant tissues with relatively high protein concentrations should, on average, have correspondingly high concentrations of free amino acids. If so, then amino acid-sensitive GRNs could help insects identify protein-rich plant tissues. Likewise, because some amino acids (e.g., phenylalanine) are considered limiting nutrients for plant feeding insects (Bernays, 1982),

amino acid-sensitive GRNs could help the insect maintain nutritional homeostasis.

In caterpillars, amino acids often stimulate specific GRNs (Dethier, 1973; Schoonhoven and van Loon, 2002). For example, two closely related species of *Pieris* caterpillars have an amino acid-sensitive GRN that exhibits concentration-dependent increases in response to ecologically relevant concentrations of 12 L-amino acids (Dethier, 1973; van Loon and van Eeuwijk, 1989). Other caterpillar species (e.g., *Grammia geneura*) detect amino acids with multiple GRNs (Bernays and Chapman, 2001). One of the amino acid sensitive GRNs in *G. geneura* is unusual in that it responds to a diverse array of phagostimulants present in the insect's preferred foodplants, including seven amino acids, three sugars, and a secondary plant compound (catalpol, an iridoid glycoside) (Bernays et al., 2000).

Dipterans use a variety of gustatory mechanisms for detecting amino acids. On the one hand, the tsetse fly (*Flossina fuscipes fuscipes*) has an amino acid-sensitive GRN that responds to 11 out of the 20 L-amino acids present in animal proteins (van der Goes van Naters and den Otter, 1998). On the other hand, the blowfly (*Phormia regina*), fleshfly (*Boettcherisca peregrina*) and hoverfly (*Eristalis tenax*) all lack GRNs that respond to amino acids (Wolbarsht and Hanson, 1965; Shiraishi and Kuwabara, 1970; Goldrich, 1973; Wacht et al., 2000). Instead, these flies detect amino acids in other ways. For instance, the neural responses to 19 amino acids of the labellar sensilla in blowflies and fleshflies fall into one of four categories. The amino acids (1) inhibit the excitatory response of all GRNs (aspartic acid, glutamic acid, histidine, arginine, lysine); (2) stimulate the salt-sensitive GRNs (proline, hydroxyproline); (3) stimulate the sugar-sensitive GRN (valine, leucine, isoleucine, methionine, phenylalanine, tryptophan); or (4) fail to stimulate or inhibit any GRN (glycine, alanine, serine, threonine, cysteine, tyrosine) (Shiraishi and Kuwabara, 1970; Goldrich, 1973). The impact of these four different effects of amino acids on feeding is unclear, however, because none of them elicit proboscis extension in the blowfly (Wolbarsht and Hanson, 1965).

Adult *Drosophila* appear to possess a heterodimeric receptor (Gr8a + Gr66a) which responds to L-canavanine, a naturally occurring a non-proteinogenic amino acid present in leguminous plants (Lee et al., 2012). Activation of this receptor elicits behavioral avoidance. Additional studies are needed to determine whether Gr8a + Gr66a responds to amino acids other than L-canavanine.

### 41.3.5 Acids

In humans, acids elicit the perception of sourness. Little is known about the behavioral responses of insects to low pH

foods. There is one report showing that ascorbic acid stimulates feeding in *Pieris brassicae* caterpillars, but only when it is presented in binary mixture with sucrose (Ma, 1972).

Ascorbic acid occurs in plant tissues at concentrations of 1–10 mM (Schultz and Lechowicz, 1986). The fact that ascorbic acid is an essential vitamin for most herbivorous insects may explain why caterpillars show an appetitive response to ascorbic acid when it co-occurs with sugars. On the other hand, the fact that acidic substances can be toxic and/or depress the pH of the midgut may explain why many insects display aversive responses to highly acidic foods.

Ground beetles (Coleoptera, Carabidae) are the only known taxon of insects with GRNs that show robust pH-dependent changes in firing rate – the higher the pH, the higher the firing rate (Millius et al., 2006). In other taxa of insects, acids appear to play a modulatory role – that is, alter the responsiveness of specific GRNs to their best stimuli. For example, at low concentrations, acids inhibit the responsiveness of salt-sensitive GRNs, whereas at higher concentrations, they inhibit the responsiveness of sugar- and inositol-sensitive GRNs and stimulate bitter-sensitive GRNs (Dethier and Kuch, 1971; Bernays et al., 1998).

### 41.3.6 Water

The ability to detect and regulate intake of water is essential, particularly for small terrestrial animals like insects that desiccate easily (Dethier, 1976). In 1957, Myson Wolbarscht discovered a GRN in flies that responds specifically to water (Wolbarsht, 1957); this observation was soon replicated and extended (Evans and Mellon, 1962). Around the same time, investigators demonstrated that stimulation of this water-sensitive GRN stimulates proboscis extension and ingestion in thirsty flies (Dethier and Evans, 1961; Evans, 1961; Dethier, 1976). Subsequent studies have reported similar water-sensitive GRNs in other insects (review in (Schoonhoven and van Loon, 2002). It was not until recently that investigators identified the molecular basis of water taste. Two labs independently reported that Ppk28, a member of the DEG/eNaC family, is the water receptor (Cameron et al., 2010; Chen et al., 2010). There are still questions, however, about the downstream events in water taste transduction. For instance, one study inferred a role of aquaporins in water taste (Solari et al., 2010), and another found evidence for a modulatory role of calmodulin in water taste (Meunier et al., 2009).

### 41.3.7 Species-Specific Taste Stimuli

Many insect species possess GRNs that are narrowly tuned to chemical stimuli in their diet. Below are a few examples. First, the sugar-sensitive GRNs of blood-feeding insects (e.g., the fleshfly, *Boettcherisca peregrina*) discharge in

response to nucleotides in blood (e.g., ADP and GDP) (Furuyama et al., 1999). Second, several herbivorous insects possess GRNs that respond to phytoecdysteroids in plant tissues (Ma, 1969; Tanaka et al., 1994; Marion-Poll and Descoins, 2002; Calas et al., 2007). Stimulation of these GRNs elicits an aversive response. This response is thought to have evolved because phytoecdysteroids are found in about 6% of all land plant species, and their consumption can interfere with ecdysis. Third, several insect species depend on pyrrolizidine alkaloids (PAs) for reproduction and chemical defense against predators. These species possess GRNs, which are narrowly tuned to PAs and stimulate intake of PA-containing foods (Bernays et al., 2002; Bernays et al., 2003). Fourth, some butterflies utilize food sources (e.g., tree sap and rotting fruits) that contain fermentation products like ethanol. Some (e.g., *Vanessa indica*), but not all (*Argyreus hyperbius*) of these butterflies show a stronger peripheral taste response and appetitive feeding response to sugar solutions containing ecologically relevant concentrations of ethanol (Ômura et al., 2008). Fifth, adult *Drosophila* have a population of GRNs that detects CO<sub>2</sub>. When activated, they elicit an appetitive feeding response. This CO<sub>2</sub>-specific response pathway is thought to help *Drosophila* locate growing yeast, an important food source (Fischler et al., 2007).

## 41.4 TASTE-MIXTURE INTERACTIONS

### 41.4.1 Peripheral Taste System

Based on evidence presented above, it is apparent that many insect GRNs are “tuned” to specific classes of taste stimuli (e.g., sugars or salts). These findings were based on studies in which insects were presented with single-component stimuli. What happens when insects encounter real foods, which invariably contain complex mixtures of taste stimuli? Does each class of GRN (e.g., sugar- versus salt-sensitive) function as an independent processing unit (i.e., “silo”), relaying its responses to the central gustatory system with high fidelity? Alternatively, does activation of one GRN influence the response of other GRNs in the same sensillum? If the latter is the case, then this would indicate that taste sensilla serve as a peripheral taste processing unit, much like what has been proposed for vertebrate taste buds (Herness and Zhao, 2009; Chaudhari and Roper, 2010).

It turns out that there is widespread evidence that taste sensilla process the peripheral taste signal. For instance, when two taste stimuli (e.g., S<sub>1</sub> and S<sub>2</sub>) that activate different GRNs (e.g., GRN<sub>1</sub> and GRN<sub>2</sub>) are presented in a mixture, insect taste sensilla usually generate fewer action potentials than would be predicted based on the

sum of the action potentials elicited by each stimulus alone (i.e., they exhibit mixture suppression). Two different types of mixture suppression have been reported. In one type (reciprocal inhibition), S<sub>1</sub> stimulates GRN<sub>1</sub> and S<sub>2</sub> stimulates GRN<sub>2</sub>; but when S<sub>1</sub> and S<sub>2</sub> are presented together, the excitatory responses of both GRN<sub>1</sub> and GRN<sub>2</sub> are diminished (Ishikawa, 1963; White et al., 1990; Shields and Mitchell, 1995; Bernays and Chapman, 2001; Glendinning et al., 2007; Wright et al., 2010). In the other type of mixture suppression (non-reciprocal inhibition), S<sub>1</sub> stimulates GRN<sub>1</sub> and S<sub>2</sub> fails to stimulate any GRN; nevertheless, when S<sub>1</sub> and S<sub>2</sub> are presented together, the excitatory response of GRN<sub>1</sub> is diminished (Dethier and Bowdan, 1989; Bernays and Chapman, 2000; Bernays and Chapman, 2001; de Brito Sanchez et al., 2005).

Recent work in my laboratory indicates that peripheral taste processing may be even more complex than hitherto appreciated (Cocco and Glendinning, 2012). The caterpillar *Manduca sexta* (Sphingidae) possesses two classes of sugar-sensitive GRNs – one responds to glucose and inositol (a sugar alcohol) and the other to sucrose. It also possesses a bitter-sensitive GRN, which responds to several aversive compounds including aristolochic acid (AA). While all sugars modulated peripheral taste responses to AA, sucrose had the greatest impact, despite eliciting fewer action potentials per unit time. For instance, when we mixed a single sugar (i.e., sucrose, glucose or inositol) with AA, sucrose (but none of the other sugars) partially blocked the response to AA. When we mixed binary mixtures of sugars with AA, the binary mixtures containing sucrose (i.e., sucrose+inositol or sucrose+glucose) produced the greatest mixture suppression. It follows that activation of the sucrose-sensitive GRN produced greater mixture suppression than activation of the glucose/inositol-sensitive GRN. Additional studies are needed to explain why the taste system of *M. sexta* caterpillars pays particular attention to input from the sucrose-sensitive GRNs.

Little is known about the nature of mixture suppression in insect taste sensilla. While it may involve direct electrical communication via gap junctions (Steinbrecht, 1989; Isidoro et al., 1993) or ephaptic interactions among adjacent GRNs (Jefferys, 1995; Bokil et al., 2001), the most likely explanation is that activation of one GRN elicits paracrine release into the sensillar lumen, which modulates the response of neighboring GRNs. This speculation is based on the existence of extensive paracrine signaling within mammalian taste buds (Herness and Zhao, 2009).

### 41.4.2 Mixture Interactions in the Central Nervous System

Taste-mixture interactions have also been observed in the central gustatory system. For instance, caffeine normally elicits a taste-mediated aversive response in *Manduca sexta*

caterpillars (Glendinning et al., 1999b). However, when caffeine is presented in binary mixture with *myo*-inositol (a sugar alcohol), the aversive response is completely attenuated (Glendinning et al., 2000). Recordings from the peripheral taste system of this insect revealed that the bitter-sensitive GRNs exhibited the same response to caffeine, irrespective of whether the caffeine was presented alone or in binary mixture with *myo*-inositol; likewise, the inositol-sensitive GRNs exhibited the same response to *myo*-inositol, irrespective of whether the *myo*-inositol was presented alone or in binary mixture with caffeine (Glendinning et al., 2000). The most parsimonious interpretation of these findings is that input from the inositol-sensitive GRNs inhibited a neural circuit in the central nervous system that mediates the aversive response to caffeine.

## 41.5 TASTE PROCESSING IN THE CENTRAL NERVOUS SYSTEM

In mammals, the brain rapidly processes taste input according to three orthogonal dimensions: intensity, hedonics and quality (Grill and Berridge, 1985; Spector, 2000). Do insects use the same three taste dimensions? With regard to intensity, there are several reports of insects (a) exhibiting concentration-dependent changes in taste-mediated behavioral responsiveness to specific taste stimuli (Dethier, 1968; Bowdan, 1995; Glendinning and Gonzalez, 1995; Glendinning et al., 1999b; Wang et al., 2004), and (b) discriminating different intensities (i.e., concentrations) of taste stimuli (Maes and Bijpost, 1979; Masek and Scott, 2010). With regard to hedonics (a measure of stimulus palatability), there are reports of insects showing taste-mediated preferences or aversions to chemical stimuli (Harley and Thorsteinson, 1967; Dethier, 1968; Dethier, 1976; Bernays and Chapman, 1994; Bowdan, 1995; Glendinning and Gonzalez, 1995; Glendinning et al., 1999b; Wang et al., 2004). Little is known, however, about where in the brain these two taste dimensions are coded (e.g., the SOG or higher brain areas).

The question of whether insects categorize taste stimuli into different qualities (e.g., sweet, salty, sour, bitter and umami) has not been examined. To address this core issue, one cannot simply measure unconditioned behavioral responses (i.e., whether an insect exhibits a preference or aversion to a stimulus). This is because some taste stimuli that are functionally distinct from one another (e.g., high concentrations of NaCl and quinine) elicit similar behavioral responses (i.e., avoidance), but nevertheless stimulate difference classes of GRNs. In the mammal literature, the most commonly used paradigm for determining whether two stimuli elicit distinct taste

qualities is the conditioned taste aversion task (CTA) (Frank and Nowlis, 1989; Wiggins et al., 1989). In brief, one creates a CTA to one taste stimulus (e.g., NaCl), and then asks whether the CTA generalizes to an isostimulatory concentration of another taste stimulus (e.g., quinine). If the animal does *not* generalize the CTA, then one infers that the two taste stimuli have distinct taste qualities. On the other hand, if the animal does generalize the CTA, then one infers that the animal could not distinguish the two taste stimuli because they produce a common taste quality. While this CTA-generalization procedure has been used successfully in mammals, I am unaware of its application to insects. Given that insects are capable of forming CTAs (Gelperin, 1968; Lee and Bernays, 1990; Ayrton and Morgan, 2001; Ayestaran et al., 2010; Salloum et al., 2011), the CTA-generalization paradigm should provide a powerful tool for analyzing taste qualities in insects. Alternatively, one could generate a conditioned taste preference (CTP) to one taste stimulus (Gerber et al., 2004), and then test for generalization of the CTP to another taste stimulus.

The CTA approach was used to determine whether adult *Drosophila* could discriminate among different concentrations and types of sugars (glucose, fructose and maltose), or different types of aversive compounds (caffeine, quinine and berberine). Although the flies readily discriminated stimuli based on sugar intensity (e.g., 100 versus 250 mM fructose), they could not readily discriminate based on sugar type (Masek and Scott, 2010).

### 41.5.1 Taste Processing in the SOG

There have been several important advances in our understanding of how the SOG processes taste input. One is that GRNs from different gustatory organs and taste sensilla appear to project to spatially distinct regions of the SOG (Kent and Hildebrand, 1987; Shanbhag and Singh, 1992; Stocker, 1994; Pollack and Balakrishnan, 1997; Wang et al., 2004; Jørgensen et al., 2006). Further, these axonal projections are segregated spatially according to GRN type (e.g., whether they respond to sugars, aversive compounds or water) (Figure 41.3) (Thorne et al., 2004; Wang et al., 2004; Inoshita and Tanimura, 2006; Cameron et al., 2010). Accordingly, the spatial pattern of activation of the SOG would provide information to the brain about hedonic features of the taste stimulus (appetitive versus aversive) and its location on the body (mouthparts or legs). It has been proposed that an analogous gustotopic organization exists in the taste cortex of mice (Chen et al., 2011).

Two studies have begun to dissect the circuits controlling ingestive behavior in adult *Drosophila*. One study identified a motor neuron (E49) in the SOG that appears to influence proboscis extension by integrating inputs from bitter-sensitive and sweet-sensitive GRNs (Gordon and Scott, 2009). Another study examined neural control of

the cibarial pump, which controls fluid ingestion, via two motor neurons (MN11 and MN12). This study found that MN11 and MN12 exhibit longer patterns of activation in response to taste stimulation with palatable (sucrose) than with unpalatable (caffeine) chemicals (Manzo et al., 2012).

### 41.5.2 Coding Mechanisms

The nature of the sensory code for insect taste is unresolved. As in mammalian systems, there is debate over the relative importance of three different coding frameworks: labeled-lines, ensemble (i.e., across-fiber) patterns, and temporal patterns of spiking. The labeled-line framework hypothesizes that tastant identity is represented by neural activity in a specific subset of gustatory neurons. According to this model, activation of the sugar-sensitive GRNs would stimulate neural circuits within the SOG that initiate biting, whereas activation of the bitter-sensitive GRNs would inhibit the same neural circuits. Further, the behavioral response to a mixture of sugars and bitter taste stimuli should reflect the algebraic sum of the inputs from the sugar- and bitter-sensitive GRNs, respectively (Schoonhoven and Blom, 1988; Simmonds and Blaney, 1991). One study provided fairly definitive evidence for labeled-line coding in adult *Drosophila* (Marella et al., 2006). The investigators genetically engineered two types of flies (e.g., A and B). In type A flies, they misexpressed a capsaicin receptor (VR1E600K) in the GRNs that express Gr5a (i.e., sugar-sensitive GRNs); whereas in type B flies, they misexpressed VR1E600K in the GRNs that express Gr66a (i.e., bitter-sensitive GRNs). In subsequent behavioral studies, they found that type A flies exhibited an appetitive response to capsaicin, while the type B flies exhibited an aversive response to capsaicin. This result indicates that the hedonic response of an insect is determined by the specific class of GRN (or labeled-line) that is activated. An analogous experiment was performed in mice, and produced similar results (Zhao et al., 2003; Mueller et al., 2005).

The ensemble coding framework hypothesizes that tastant identity is represented by the spatial pattern of activity across large populations of GRNs (Schoonhoven et al., 1992; Smith et al., 2000). Accordingly, discriminable taste stimuli should each elicit different ensemble patterns (i.e., different magnitudes of discharge across the population of GRNs). Ensemble coding was evaluated in a study that sought to identify the framework that best explained how *M. sexta* caterpillars discriminate the taste of three different host plants (Dethier and Crnjar, 1982). After evaluating the three coding frameworks, the authors concluded that ensemble pattern provided the most parsimonious discrimination mechanism. Another study has demonstrated that *M. sexta* uses ensemble coding to discriminate between two aversive taste stimuli (salicin and

*Grindelia* leaf extract), which activate different classes of bitter-sensitive GRN (Glendinning et al., 2002).

While the labeled-line and ensemble coding frameworks focus on *which* neurons are activated within the gustatory neuraxis, the temporal coding framework focuses on *how* neurons are activated. This latter framework hypothesizes that tastant identity is represented by the precise temporal pattern of spiking within a neuron or across populations of neurons (Dethier and Crnjar, 1982; Katz et al., 2002; Katz, 2005). Support for this hypothesis comes from a recent study of *Manduca sexta* caterpillars from our laboratory (Glendinning et al., 2006). Several of the bitter-sensitive GRNs in this caterpillar generate a decelerating temporal pattern of spiking when stimulated by caffeine and salicin, and an accelerating temporal pattern of spiking when stimulated by aristolochic acid. We showed that the caterpillars use the distinct temporal patterns of spiking generated by salicin versus aristolochic acid as a basis for discrimination.

It is important to emphasize two caveats associated with the coding frameworks discussed above. First, the three frameworks are not mutually exclusive. In fact, they probably function in a complimentary manner within the same insect (Dethier and Crnjar, 1982). Second, given the profound effects of taste-mixture interactions, physiological state, and experience on responsiveness of individual GRNs to their respective ligands (see below), central processing of the taste input is probably more dynamic and complex than hitherto appreciated.

## 41.6 FACTORS THAT MODULATE TASTE RESPONSIVENESS

One of the remarkable features of the insect taste system is its plasticity. To illustrate this point, I discuss below several factors known to increase (or decrease) the responsiveness of the gustatory system to specific taste stimuli.

### 41.6.1 Physical Changes in Taste Sensilla

For a chemical to stimulate a GRN, it must first diffuse through the pore at the tip of a taste sensillum (see Figure 41.1d). Although this terminal pore remains permanently open in many insect species, it opens and closes in Orthopterans (Bernays et al., 1972). The functional significance of terminal pore closure was revealed by a series of experiments in locusts, *Locusta migratoria* (Bernays and Chapman, 1972). When the foregut of the locust becomes distended (e.g., after a meal), stretch receptors in the wall of the foregut are activated and send afferent signals to the brain via the posterior pharyngeal nerves and frontal connectives. These afferent signals stimulate the

release of a diuretic hormone from the corpora cardiaca, which in turn cause pore closure in many of the taste sensilla. The functional effect of terminal pore closure is that it contributes to meal termination by eliminating phagostimulatory input from the peripheral taste system.

### 41.6.2 Nutrient Levels in Hemolymph

Several investigators have discovered that changes in the concentration of specific nutrients (e.g., amino acids or trehalose) in the hemolymph directly modulate the responsiveness of GRNs in grasshoppers and caterpillars to the same chemicals (Simmonds et al., 1992; Simpson and Simpson, 1992; Bernays et al., 2004). For example, in locusts, when hemolymph levels of amino acids are low and sugars high, the responsiveness of the GRNs to amino acids is high and that to sugars low (Simpson and Simpson, 1992). On the other hand, when hemolymph levels of amino acids are high and sugars low, the responsiveness of the GRNs to amino acids is low and to that to sugars is high. Because the modulatory effects of hemolymph composition on GRN responsiveness occurred in the absence of neural or humoral links between the central nervous system and GRNs, they were assumed to be mediated peripherally.

### 41.6.3 Dopaminergic Signaling

There is evidence that dopamine modulates the proboscis extension reflex in adult *Drosophila*, and that the extent of modulation varies as a function of physiological state (i.e., whether the fly is hungry or sated) (Marella et al., 2012). Accordingly, when the fly is hungry, there appears to be an increase in both the activity of its dopaminergic neurons and the probability of proboscis extension. Importantly, this result was observed following taste stimulation with sugars but not aversive compounds or water, implicating a selective role of dopamine in sugar appetite.

### 41.6.4 Dietary Exposure

When insects are exposed repeatedly to the same taste stimulus (e.g., within and across successive meals), the responsiveness of their gustatory system to these stimuli can increase or decrease. The time-scale over which these changes occur varies from seconds to days. Below, I discuss a four ways that dietary experience modifies taste.

#### 41.6.4.1 Short-Term Sensory Adaptation.

A common feature of all sensory receptor cells is that their firing rate diminishes over time (i.e., adapts) in response to continuous stimulation, but recovers rapidly (i.e., disadapts) upon removal of the stimulus. Adaptation

and disadaptation occur over a period of milliseconds to seconds.

Bitter-sensitive GRNs appear to be more resistant to adaptation than nutrient-sensitive GRNs, a phenomenon that has been reported for a number of species of insects (e.g., Schoonhoven, 1977; Cocco and Glendinning, 2012). From a functional standpoint, this suggests that the amount of afferent input from different GRNs during a meal may not be constant, with the relative amount of input from the bitter-sensitive GRNs increasing over time. The extent to which these adaptation processes contribute to feeding during a meal is unclear, however, because insect taste sensilla do not remain in continuous contact with foods throughout a meal. Some gustatory organs make a series of drumming movements, resulting in intermittent contacts lasting only 100 to 200 ms (Blaney and Duckett, 1975; Devitt and Smith, 1985). These drumming movements could serve to minimize the effects of short-term adaptation in the GRNs, effectively increasing the level of sensory input from GRNs over time (Blaney and Duckett, 1975).

#### 41.6.4.2 Habituation.

When an animal is presented with a stimulus repeatedly across a series of discrete trials, its responsiveness to that stimulus usually wanes (Hinde, 1970). This phenomenon is referred to as habituation if it meets several criteria – for example, it must be mediated centrally, recover spontaneously, generalize to related stimuli, and develop more readily in response to weak than intense stimuli (Thompson and Spencer, 1966). For instance, fruit flies and bees normally exhibit a proboscis extension reflex for 5% sucrose, but this reflex extinguishes following 20 consecutive stimulations within a 5 min period (Duerr and Quinn, 1982; Braun and Bicker, 1992; Scheiner, 2004; Scheiner et al., 2004). This exposure-induced response decrement for sucrose was considered habituation because it met at least two of Thompson and Spencer's habituation criteria.

#### 41.6.4.3 Long-Term Adaptation.

When herbivorous insects are offered a diet containing an unpalatable but harmless compound as their only source of water and nutrients, they will usually sample the diet repeatedly. After ~24 hr of such sampling, the insects eventually adapt their aversive response. This long-term adaptation phenomenon has been reported in several species of herbivorous insect (Jermy et al., 1982; Simmonds and Blaney, 1983; Szentesi and Bernays, 1984; Blaney and Simmonds, 1987; Usher et al., 1988; Glendinning and Gonzalez, 1995; Bernays et al., 2004), but has been examined most extensively in caterpillars of *M. sexta* (Schoonhoven, 1969; Schoonhoven, 1978; Glendinning et al., 1999a, 2001a, 2001b, 2002). For example, 24 hr of dietary exposure to a caffeine diet

eliminates the aversive response to caffeine. The long-term adaptation phenomenon is mediated peripherally (at least in part) because the dietary exposure regime profoundly desensitizes all of the bitter-sensitive GRNs to caffeine. Twenty-four hr of dietary exposure to a salicin diet also eliminates the aversive response to salicin. However, because there is no associated reduction in responsiveness of the bitter-sensitive GRNs, this latter adaptation phenomenon must be mediated centrally. Taken together, these results indicate that the peripheral and central gustatory system of *M. sexta* each have independent mechanisms for overcoming the aversive response to harmless aversive compounds.

Because the long-term adaptation to salicin is mediated by the central gustatory system, and because it generalizes to related taste stimuli (Glendinning et al., 2001b; Glendinning et al., 2002), it can be viewed as a type of habituation. It is important to note, however, that the onset latency for the habituation to salicin (in *M. sexta*) is about 24 hr, whereas that to sucrose (in flies and bees) is  $\leq 5$  min (Duerr and Quinn, 1982; Braun and Bicker, 1992; Scheiner, 2004; Scheiner et al., 2004). Further work is needed to determine whether these different onset latencies reflect (a) species differences, (b) greater difficulty habituating to aversive taste stimuli, and/or (c) the existence of multiple habituation mechanisms.

**41.6.4.4 Induced Food Preferences.** After feeding on a particular plant species for one to two days, many species of herbivorous insect induce a strong preference for that plant species (review in Szentesi and Jermy, 1990). Despite the widespread occurrence of this phenomenon, the underlying physiological mechanisms are poorly understood. In all likelihood, a variety of mechanisms are activated, depending on the chemical constituents of the plant tissue and the insect species – for example, induction of detoxification enzymes, changes in gustatory and/or olfactory responsiveness, and conditioned preferences (Bernays and Weiss, 1996).

That taste contributes to induced food preferences was established in a study of *M. sexta* caterpillars, which are facultative specialists on plants in the family Solanaceae. When these caterpillars were reared on solanaceous foliage, they induced a strong and exclusive preference for the same foliage (Hanson and Dethier, 1973; Yamamoto, 1974; de Boer and Hanson, 1987; del Campo and Renwick, 2000; Glendinning et al., 2009). A team of investigators discovered that indoside D (a steroid glycoside) is one of the chemicals in solanaceous foliage to which the caterpillars induce their preference (del Campo et al., 2001). These investigators also presented evidence that GRNs in the caterpillar's styloconic sensilla become “tuned” to indoside D over the course of the induction process, and that

this chemosensory tuning process is sufficient to explain the induced preference for solanaceous leaves (del Campo et al., 2001; del Campo and Miles, 2003). According to the chemosensory tuning hypothesis, the GRNs sensitive to indoside D maintain their normal responsiveness, while those sensitive to other plant chemicals (e.g., sugars, salts and bitter taste stimuli) become less responsive.

**41.6.4.5 Health Status.** There is evidence that the peripheral gustatory response of some caterpillar species increases in response to endoparasitic infection (Bernays and Singer, 2005). More specifically, the endoparasitic infections caused specific GRNs to respond more vigorously to specific host plant compounds (i.e., pyrrolizidine alkaloids, PAs). The elevated responsiveness of the PA-sensitive GRNs in turn promoted greater intake of PA-containing plant tissues. This elevated intake was subsequently shown to be adaptive because the PAs were toxic to the endoparasites, and thus helped control (or even eliminate) the infection (Singer et al., 2009).

## 41.7 CONCLUSION

The discovery of the Grs in *Drosophila* represented a turning point in insect gustation. Investigators were able to use the Grs, together with existing molecular tools, to gain deep insight into how taste input is processed in *Drosophila*. Future work is needed to determine the extent to which the logic of taste processing in *Drosophila* generalizes to other insect species. Given that the genomes of insect species spanning 23 different genera have already been sequenced ([http://en.wikipedia.org/wiki/List\\_of\\_sequenced\\_animal\\_genomes#Insects](http://en.wikipedia.org/wiki/List_of_sequenced_animal_genomes#Insects)), it should soon be possible to address fundamental questions about how lifestyle, diet, sex, life stage, and phylogeny all influence taste processing in insects. These advances will not only enrich our understanding of insect feeding biology and evolution, but they may also reveal strategies for controlling insects that transmit disease and cause agricultural damage.

Throughout this review, I have tried to emphasize that despite the many differences between insects and mammals, the taste systems of both taxa appear to share important features. For instance, their taste cells can be grouped into distinct populations based on Gr expression patterns (e.g., some express sugar-sensitive Grs and others bitter-sensitive Grs). Second, both taxa have peripheral taste organs that contain multiple taste receptor cells (taste sensilla in insects and taste buds in mammals), and there is evidence for extensive processing of taste signals within these organs. Third, both taxa appear to display varying degrees of chemotopic organization in their central taste processing areas. By focusing on similarities (rather

than differences), we may gain deeper insight into taste processing mechanisms that are universal across species. Such insights should provide valuable clues for future investigations of taste function.

## Taste in Aquatic Vertebrates

TOSHIAKI J. HARA

*“Our head may look incredibly complicated, but it is built from a simple and elegant blueprint. There is a pattern common to every skull on earth, whether it belongs to a shark, a bony fish, a salamander, or a human.”*

NEIL SHUBIN (2008)

### 42.1 INTRODUCTION

Some of the earliest vertebrates, derived from ancestral chordates, were adapted to life as filter feeders in an aquatic environment, probably very much the way that larval lampreys and some jawed fishes survive today. Some fishes suck up mouthfuls of bottom sediments, and some predatory fishes suck in mouthfuls of water carrying the prey into their mouths. All of these methods of feeding require mechanisms for differentiating between edible and the inedible, or between the favorable and unfavorable. These mechanisms are the chemical senses of gustation (taste) and olfaction (smell). The relation of gustation to food intake is manifested in all vertebrates including humans, but many aspects of the complex integration of chemosensory input with antecedent or concomitant physiological activities remain mostly unclear. The evolutionary development of the chemosensory system associated with feeding in vertebrates followed the course in which gustatory perception is responsible for basic food appraisal and bestows the animals with valuable discriminatory power.

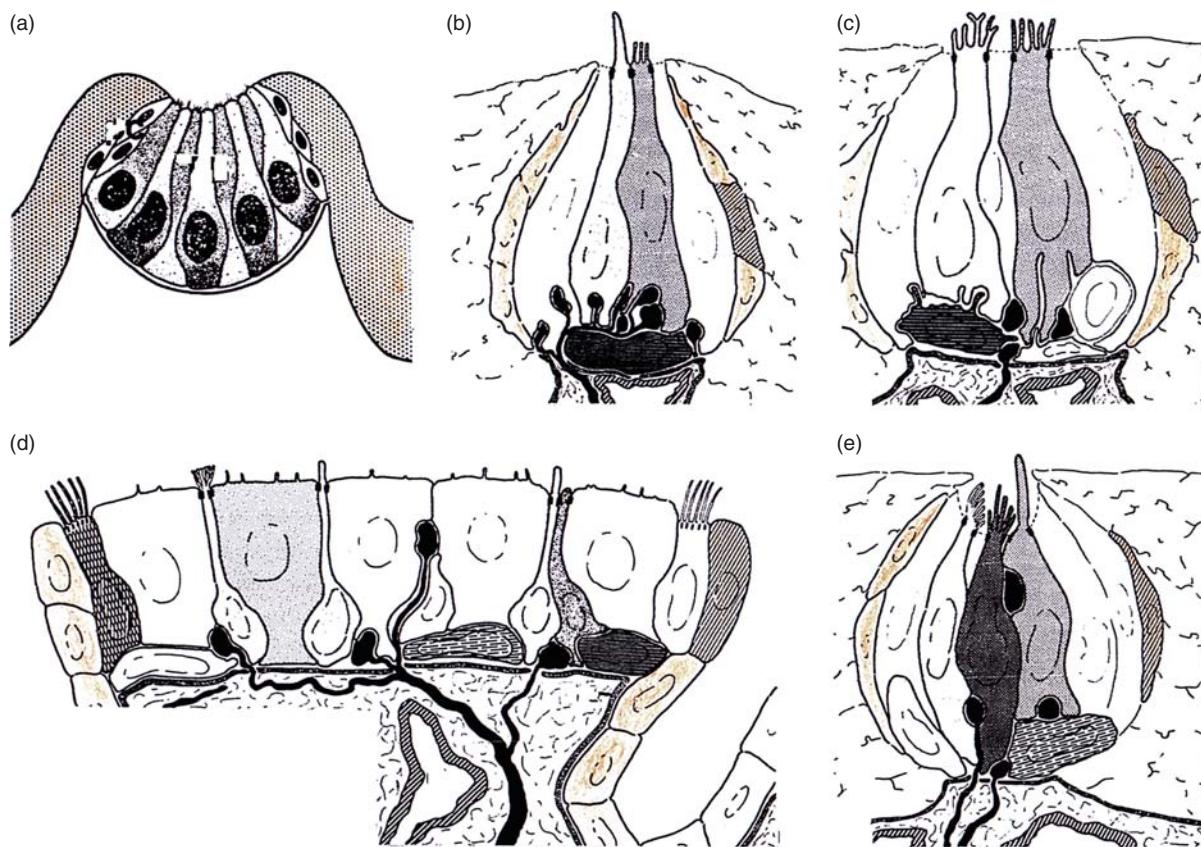

Fish, constituting slightly more than one-half of the total number of about 50,000 recognized living vertebrate species, are a pivotal group that has served as a vertebrate model for the study of the gustatory system. Taste buds were first described in fish in early 1800s, and by the turn

of the century the peripheral and central gustatory neural organization had been clearly illustrated (Herrick, 1904, 1905). Further elaboration has since made focusing on topographic representation of the gustatory and motor roots in the fish brains (Finger, 1987; Kanwal and Finger, 1992). The gustatory receptor systems in aquatic vertebrates are unique in that, unlike those of the terrestrial, receptors are stimulated by dilute solutions, or “distance chemical receptors”. However, there exists a broad line of similarity between both the peripheral and the central gustatory paths in all vertebrate types (Hara, 2007, 2011a), and fishes with enormous hypertrophy/specialization of the gustatory centers may serve as a guide to point the way for researches on the gustatory pathways of higher vertebrates where the system is less accessible. Thus, this chapter is concerned with aspects of the gustatory systems of aquatic vertebrates in perspective of those of all vertebrates, with an emphasis on new insights into the taste bud development, central neural pathways, and physiological as well as behavioral implications.

### 42.2 STRUCTURAL ORGANIZATION

#### 42.2.1 Peripheral Gustatory Systems

**42.2.1.1 Taste Buds.** Taste buds, also termed terminal buds, end buds, or cutaneous buds, constitute the structural basis of the peripheral gustatory organ (Figure 42.1). Taste buds occur in virtually all extant vertebrates. Taste (terminal) buds were first described in lampreys; their histology and central connections in larval and adult forms are comparable to those of the gnathostome vertebrates (Baatrup, 1983). The lamprey terminal buds show strong similarity to the taste buds of

**Figure 42.1** Schematic drawings of terminal bud, taste bud, or taste disc, typical of aquatic vertebrates, with the mammalian for comparison. (a) lamprey (b) teleost fish (c) urodelan amphibian and juvenile anuran (d) frog, a salientian amphibian (e) mammal. Modified from Baatrup (1983) and Reutter and Witt (1993).

higher vertebrates, despite the fact that the ciliated cells instead of the microvillar are believed to be the receptor. The presence of cilia may be a specialized character, but is more likely to be another example of the phylogenetic originality of ciliated receptors (Gans and Northcutt, 1983). In teleosts, taste buds are distributed in five subpopulations, reflecting feeding habits, strategies, and habitats of fishes: (1) oral, (2) palatal and laryngeal, (3) branchial (gills), (4) cutaneous, and (5) barbels. Most teleosts lack external taste buds, although some have independently evolved external taste buds on specialized parts of the body, such as barbels, elongated fin rays, and the lips of the mouth. Yellow bullhead catfish (*Ictalurus natalis*), for example, have more than 175,000 taste buds on the entire body surface alone (Atema, 1971). Carp (*Cyprinus carpio*) and goldfish (*Carassius auratus*) have evolved a highly sophisticated food separation system on the roof of the mouth, i.e., palatal organ. Freshwater fish species generally have well-developed taste buds in the oropharyngeal cavity and gill arches/rakers, which is thought to be an adaptation to freshwater habitats where a wider range of physical and

chemical changes exist than in sea water (Iwai, 1964; Hara et al., 1993).

Amphibians exhibit the most complex taste bud features of any vertebrates. Juvenile anurans (tadpoles), and larval salamanders (urodeles) have ovoid taste buds which are encased in small processes termed pre-metamorphic papillae resemble the taste buds of fishes. During metamorphosis they undergo transformation to develop large taste organs called taste disks (Figure 42.1d). Despite extensive histological and physiological studies, however, functional significance of the two morphological types developed in the amphibian taste organ is not well understood (Osculati and Sbarbati, 1995).

Generally, a taste bud is buried in the epithelial layers or sits on a dermal papilla without being partitioned by membranes or any other tissues from the surrounding epithelial cells. Thus, the taste bud, while maintaining its entity, is a constituent of the epithelium without partition from the surrounding epithelial cells. In fish, three gustatory cell types constitute a taste bud: (1) rod, or light cell, (2) microvillar, or dark cell, and (3) basal cell. The total number of gustatory cell in a taste bud varies greatly,

from 5 to as many as 100 cells. The taste bud evolved while fish took possession of their own distinct ecological niche, thus, resulting in considerable variation in their micro-morphology. The rod cell, most likely a receptor cell, is cylindrical to spindle shaped. Its supra-nuclear portion is characterized by the presence of abundant vesicles. Microvillar cells, often believed to be a supporting cell, but, could well be a receptor cell, are characterized by fine filaments, running through the entire cytoplasm. Junctional complexes exist between microvillar cells and between the rod and microvillar cells. The basal cells, typically one to five per taste bud, are situated at the bottom of the taste bud in depression of the basal lamina. They attach to both receptor and supporting cells by desmosomes (Jakubowski and Whitear, 1990). Basal cells contain many lucent vesicles, rich in serotonin, and possess synaptic connections with both cell types as well as with nerve fibers, suggesting that they might act as modulators of gustatory activity (Toyoshima et al., 1984). Unlike those of mammalian taste bud, the basal cells of fish are not the precursors of other cell types within the taste buds.

Gustatory cells of vertebrates, unlike all other type of sensory receptor cells and neurons, are unique in that they originate from local epithelial tissue elements of primarily endoderms, and not from neurogenic ectoderm (neural tube, neural crest or ectodermal placodes). Nevertheless, gustatory cells form synapses and are capable of generating receptor potentials, and even action potentials, and like epithelial cells they have a limited life span and regularly replace themselves (Stone et al., 1995; Vandenbeuch and Kinnamon, 2009). Ontogenetically, taste buds generally develop later than their counterpart the olfactory.

Taste buds are innervated by bundles of unmyelinated nerve fibers that enter from below into their basal portion. Generally, one to three nerve bundles supply each taste bud. Upon entering a taste bud, they further branch out and make an intricate intragemminal nerve plexus, some components of which make synaptic contacts either with the rod cells or with the microvillar cells. However, the synaptic specialization at these nerve-ending receptor junctions is not always clear (Reutter and Witt, 1993).

**42.2.1.2 Palatal Organs and Barbels.** Although the gustatory system is generally well developed throughout fishes, two fish groups, cyprinids (e. g., goldfishes) and ictalurids (e. g., catfishes), have become highly specialized for the use of sophisticated food-handling apparatuses, i.e., the palatal organ and the barbel. Both groups of fishes are bottom feeders, and have evolved complex mechanisms of food detection and separation. They evolved thousands of extra taste buds, which is a result of the independent evolutions occurred a number of times among teleosts (Northcutt, 2005). The palatal organ, which is a muscular

structure attached to the roof of the mouth, combined with the surface of the gill arches, manipulate to separate palatable food materials from the unpalatable. Barbels, by contrast, densely populated with taste buds, are used for food search and sorting, whereas their intra-oral gustatory system is used for selective food ingestion. Unlike the palatal organs in cyprinids, no muscular structure exists within the barbels (Kiyohara et al., 2002).

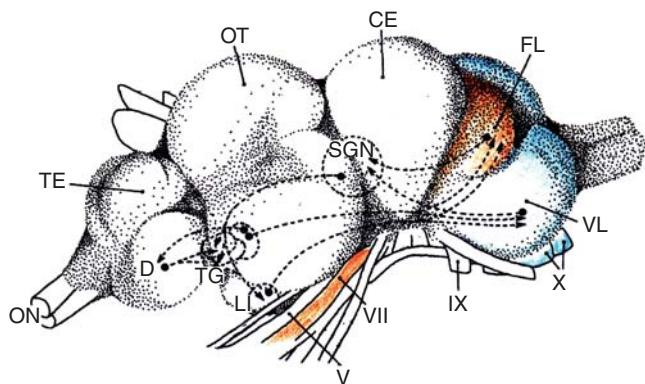

#### 42.2.1.3 Facial and Trigeminal Nerve

**Complication.** The facial nerve is closely allied with the trigeminal nerve, and thus strong tactile component exists in the gustatory sensory signal. In vertebrates, the trigeminal nerve generally carries the sensory nerves from the jaw muscles, which is responsible for sensation including pain, temperature, touch, and proprioception. The sensory part of the trigeminal is exclusively of tactile-carrying stimuli from the same region innervated by the facial nerve (Herrick, 1905; Luitjen, 1975). Catfish barbels, for example, are heavily innervated by trigeminal nerves mixed with the facial, both of which project to the facial lobe by three branches-ophthalmic, maxillary, and mandibular. Trigeminal fibers are coarser than those of the facial which terminate within the same structural loci, and its input to the primary gustatory complex is restricted to those portions of the nucleus receiving sensory inputs from the face and barbels.

Virtually nothing is known about the peripheral termination of the trigeminal nerve, except for the observations that in sea catfish and goatfish some nerve fibers terminate inside taste buds perigemmally without ending on gustatory cells. It thus appears as if the trigeminal fibers have failed to locate their target cells, that is, they become orphaned gustatory nerves. Thus, the relationship between gustatory and tactile sensibility is well recognized but its implications are not fully understood. It seems there may be no pure gustatory area at any level of the gustatory neuraxis (Kiyohara et al., 2002). In rainbow trout, none of single palatine nerve fibers sensitive to tactile stimulation respond to chemical stimulation, and vice versa (Hara, 2011b).

## 42.3 CENTRAL GUSTATORY PATHWAYS

The gustatory system is the only vertebrate sensory system in which three cranial nerves carry all peripheral gustatory information. Depending upon the location of the taste buds, either the facial (cranial nerve VII), glossopharyngeal (IX), or vagal (X) gustatory nerves innervate the gustatory cells. Generally, all cutaneous taste buds on the body surface and rostral oral regions are innervated by the facial nerve, while taste buds within the posterior

**Figure 42.2** Diagram showing dorsolateral view of the brain of a cyprinid fish showing the entrance of trigeminal (V), facial (VII), glossopharyngeal (IX), and vagal (X) nerves, and the main central gustatory connections. CE, cerebellum; D, dorsal telencephalic area; FL, facial lobe; LI, hypothalamic inferior lobe; ON, olfactory nerve; OT, optic tectum; SGN, secondary fustatory nucleus; TE, telencephalon; and TG, tertiary gustatory nucleus. Modified from Luiten (1975). (See plate section for color version.)

oral cavity and pharyngo-branchial region are innervated by the glossopharyngeal and vagal nerves. Somatotopic organization generally exists in the termination of axons in the primary gustatory nucleus (PGN), the mammalian equivalent of the solitary tract (NST). The gustatory nerves from the different regions of the body thus enter the nucleus in approximately the same order as they are located in the body, that is, axons from more rostral regions of the mouth (or body) enter the more rostral portions of the nucleus (Figure 42.2). In fact, this distribution pattern is common to every skull on earth, whether it belongs to a shark, a bony fish, a salamander, or a human (Shubin, 2008).

As Herrick (1905) pointed out with regard to the major importance of the relation of gustation and olfaction, the secondary center is the *area olfactoria* of the forebrain, whose commissure bears the same relation to the secondary tracts as do those of the secondary gustatory nuclei. The main tertiary tract passes to the inferior lobe, which is, in fishes, the central correlation station for all sensory impression. The olfactory and gustatory tertiary tracts end together throughout the inferior lobe and they have a common descending conduction path, the *tractus lobobulbaris* (Figure 42.2). The ascending fiber connections of the central gustatory system in teleosts are essentially similar to those of mammals. The mammalian SGN projects directly to the amygdala, which receives direct projections from the olfactory bulb.

The inferior lobe and lobobulbar lobe develop extensive descending fiber projections to the primary gustatory centers in the facial (cyprinids) and vagal (catfishes) lobes as well as in the viscerosensory column (salmonids). The vagal lobe projects to motoneurons that innervate

the oropharyngeal musculature, which controls swallowing or intraoral food handling in cyprinids. The facial lobe of catfishes, by contrast, projects to somatosensory nuclei in the caudal medulla, which may provide a means to correlate gustatory and somatosensory inputs from a single locus on the body surface.

## 42.4 FUNCTIONAL PROPERTIES OF THE GUSTATORY SYSTEMS

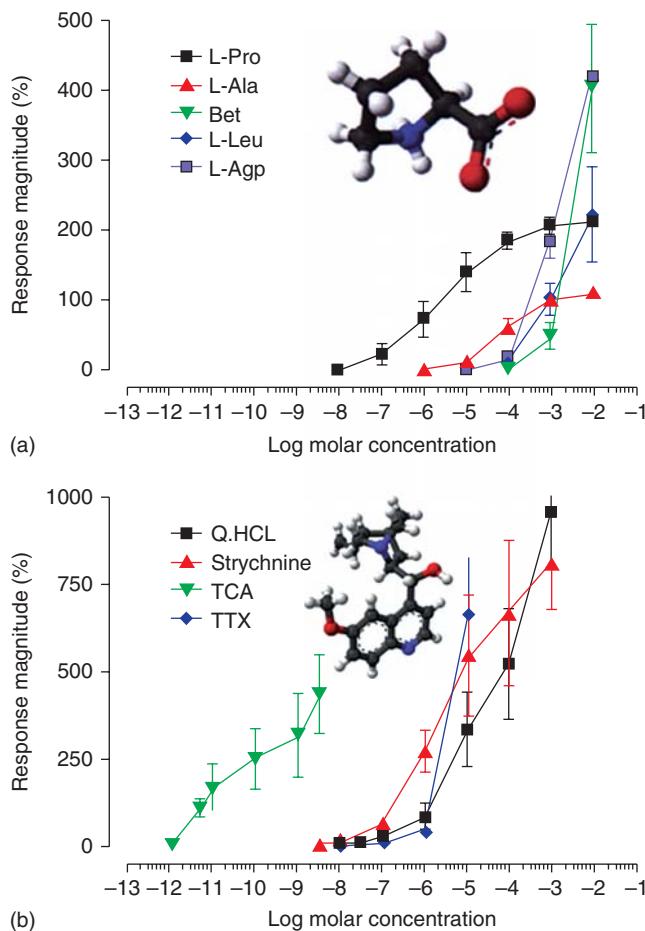

### 42.4.1 Signal Transduction and Molecular Basis of Receptors

Chemical stimuli enter the apical portion of the taste bud and bind to receptor molecules located within the membrane of the apical cilia or microvilli of gustatory cells. This interaction leads to a membrane conductance change and depolarization of the cell. Since the discovery that the gustatory cells, but not surface epithelial cells, of salamander *Necturus* are electrically excitable and generate action potentials in response to membrane depolarization (Roper, 1983), gustatory cells of most, if not all, vertebrate species regularly generate action potentials on electrical and chemical stimulation (Takeuchi et al., 2001; Sato et al., 2008). In mammals, three genes encoding the tetrodotoxin (TTX)-sensitive  $\text{Na}^+$  currents responsible for the action potentials have been identified (Gao et al., 2009). Gustatory cells are thus only non-neuronal sensory receptor cells to generate action potentials. As mentioned, the taste bud, while maintaining its entity, is a constituent of the epithelium without partition from the surrounding epithelial cells. They replace themselves every few weeks; unlike the olfactory, epithelial cells surrounding the taste buds divide and some of their daughter cells migrate into taste buds to form new gustatory cells. Gustatory cells and epithelial cells arise from a common progenitor, and gustatory receptor cells originate local tissue elements (Stone et al., 1995). Amazingly, how the newly created receptor cells acquire the capability to generate action potentials? The acquisition of receptor phenotype is likely to be the consequence of local tissue interactions.

### 42.4.2 Responses to Chemical Stimuli

#### 42.4.2.1 Amino Acids.

In vertebrates, olfaction is generally recognized as a distance chemical sense with high sensitivity and specificity, while gustation is primarily a contact or close-range sense with moderate sensitivity. However, the gustation in fish is unique in that the receptors are equally sensitive to the same chemical stimuli or even more sensitive than the olfactory, making the distinction between the two sensory modalities blurred.

**Figure 42.3** Concentration-response (C-R) relationships of gustatory responses recorded from the rainbow trout palatine nerve bundles. L-Pro, L-proline; L-Ala, L-alanine; Bet, betaine; L-Leu, L-leucine; L-Agp, L- $\alpha$ -amino- $\beta$ -guanidinopropionic acid; Q-HCl, quinine-HCl; TCA, taurocholic acid; and TTX, tetrodotoxin. Insets: molecular structures of L-Pro (a) and Q-HCl (b). Modified from Hara (2011b). (See plate section for color version.)

Furthermore, the gustatory system is no longer the sole player in feeding in fish. In fact, recent studies demonstrate that feeding behavior in fish is primarily triggered by olfaction, and complimented by gustation. Electrophysiological studies show that the fish gustatory receptors are specifically stimulated by dilute aqueous solution of low-molecular-weight-chemicals of two main groups: (1) amino acids and (2) primarily aversive chemicals (Figure 42.3; Marui et al., 1983; Hara, 2007, 2011b).

Electrical responses to amino acids are generally characterized by a fast adapting, rapidly returning to the baseline activity even with continuous stimulation, which contrasts with the slow-adapting olfactory response (Hara, 2011b). Threshold concentrations for the more stimulatory amino acids range between the micromolar and nanomolar. Threshold determinations, however, are highly sensitive

to the background water in studies when the receptors are perfused with water containing varying levels of natural amino acids. Interestingly, natural water is likely to be essential for response generation; replacing natural perfusing water with distilled water eliminates responses to stimulant chemicals, and artificial water only partially restores it. Thus, unknown factor(s) beyond cations in the natural water plays an essential role in maintaining maximal gustatory reception (Kitada and Hara, 1994).

Not all fish are in unison with regard to the chemical response spectra; of the 27 teleost species (comprising 14 families and 29 genera) whose gustatory amino acid specificities have been examined systematically, two general types have been identified: type 1 that are highly selective and respond to only a few amino acids (limited response range), and type 2 whose gustatory systems respond to many amino acids (wide response range) (Hara, 1994a, b). All fish species in type 1, typically salmonids, respond to L-proline (L-Pro), L-alanine (L-Ala), and several other amino acids and related compounds. In rainbow trout, for example, only L-Pro, L-Ala and L-hydroxy-proline (L-Hpr) are stimulatory, with thresholds  $10^{-8}$ – $10^{-5}$  M. Both carp and goldfish may also be placed in this group. A structure–activity study indicates that heterocyclic-imino acids with four, five, or six-membered ring are effective (Marui et al., 1983). The most characteristic feature common to all species of this group is that L-Pro is the dominant stimulant amino acid and it is the only naturally occurring amino acid that is not detected by the counterpart olfactory system (Hara, 2007). These data suggest that the gustatory and olfactory systems detect distinct portions of amino acid spectra, consequently minimizing the redundancy. Further pharmacological characterization of the data indicate that possibly three receptor types are involved in the detection of these amino acids: (1) proline-receptor (L-Pro, L-Hpr, and L-Ala), (2) betaine-receptor (Bet and L-Arg), and (3) leucine-receptor (L-Leu, L-Phe) (Yamashita et al., 2006). Type 2 fishes, by contrast, detect virtually all natural amino acids by gustation, with the sensitivities higher than those of the olfactory counterpart. In channel catfish, for example, responses of the facial nerves innervating extra-oral taste buds to Ala and Arg show thresholds averaging  $10^{-11}$  M, while those of the vagal nerves innervating oropharyngeal taste buds, dominated by the responsiveness to Pro, are less sensitive than the facial (Ogawa and Caprio, 2010). Cross-adaptation results further indicate that all amino acids are detected mainly by L-Ala and L-Arg receptors, supplemented by D-Ala, L-Pro, D-Pro, D-Arg receptors. Japanese eels and some marine fishes are characterized by high sensitivities to Gly, in addition to Ala and Arg (Yoshii et al., 1979; Ishida and Hidaka, 1987).

In larval and adult lampreys, pharyngeal terminal buds are sensitive to several amino acids including Ala and Arg, with the thresholds ranging from  $10^{-7}$  to  $10^{-5}$  M, suggesting

the functional relationship between lamprey terminal buds and the taste buds of the gnathostome vertebrates (Baatrup, 1995). Similarly, aquatic toad and frog are sensitive to wide ranges of amino acids and bitter substances with the thresholds ranging from  $10^{-9}$ – $10^{-6}$  M (Yoshii et al., 1982; Gordon and Caprio, 1985).

#### 42.4.2.2 Aversive and/or Toxic Chemicals.

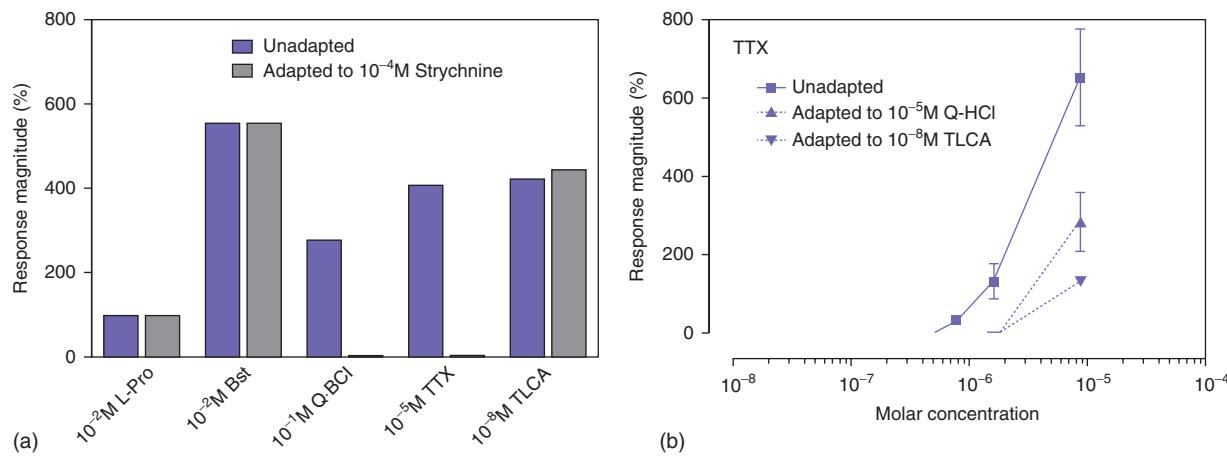

**BILE ACIDS** To date, only salmonid (*Oncorhynchus* and *Salvelinus* sp.) gustatory systems are known to be extremely sensitive to bile acids. In rainbow trout, both taurine- and glycine-conjugated forms are generally more stimulatory than the free, and taurocholic acid (TCA), one of the most potent chemicals tested, in either the olfactory or gustatory, is detected at  $10^{-12}$  M, with the maximum response magnitude double that of the Pro (cf. Figure 42.3; Yamashita et al., 2006). The response pattern to bile acids is characterized by its slow adapting, tonic response. Contrary to the olfactory, where multiple bile acid receptors exist capable of detecting and discriminating different bile acids (Zhang et al., 2001; Giaquinto and Hara, 2008), gustatory responses to all bile acids are inhibited by pre-treatment (cross-adaptation) with taurolithocholic acid (TLC), suggesting that all bile acids may share the one single receptor/transduction system. The gustatory systems of carp, sea catfish, and tilapia are not sensitive to bile acids up to a concentration of  $10^{-4}$  M.

#### QUININE, STRYCHNINE, AND TETRODOTOXIN

Quinine hydrochloride (Q-HCl), strychnine, and TTX stimulate the salmonid gustatory receptors; rainbow trout and three char species (*Salvelinus* sp.) detect these chemicals at thresholds  $10^{-8}$ – $10^{-7}$  M, with extremely

high-response magnitudes (cf. Figure 42.3; Yamamori et al., 1988; Yamashita et al., 1989). Cross-adaptation to strychnine in rainbow trout inhibits responses to Q-HCl and TTX, but without any effect on amino acid and bile acid responses, suggesting that all three groups of chemicals might share the same receptor and transduction mechanisms, or a receptor family with the wide response diversity coexists in a single gustatory cell (Figure 42.4). Aquatic toad *Xenopus* and leopard frog *Rana sphenocephala* also detect Q-HCl, but with much higher thresholds (Yoshii et al., 1982; Gordon and Caprio, 1985).

A paralytic shellfish toxin, saxitoxin (STX), is also potent gustatory stimuli for salmonids. Rainbow trout detect TTX at  $2 \times 10^{-7}$  M, and at  $10^{-5}$  M, it evokes a response magnitude 4 times that of  $10^{-3}$  M Pro (cf. Figure 42.3). These two toxins are vastly different structurally, do not cross-adapt each other, and are therefore unlikely to share the same receptor type. The TTX-sensitive, voltage-dependent  $\text{Na}^+$ -current is present in most vertebrate gustatory cells (Kinnamon and Cummings, 1992). In frog, the transient inward  $\text{Na}^+$ -current in a patch-clamp gustatory cell is completely blocked by TTX (Avenet and Lindemann, 1987). However, *in vivo* experiments the generation of a receptor potential in response to gustatory stimuli is not inhibited by TTX (Ozeki and Noma, 1972). Also, in fish perfusion of the palate with TTX had no effect on gustatory responses to amino acids, suggesting that the amino acid-activated TTX-sensitive cation channel(s) is not present in the apical membrane of the gustatory cells, and that TTX does not penetrate the tight junctions known to present at the top of the gustatory cells (Kitada and Hara, 1994). It is noteworthy that either strychnine or bile acid TLC inhibits gustatory responses to TTX in a competitive fashion (Hara, 2011d).

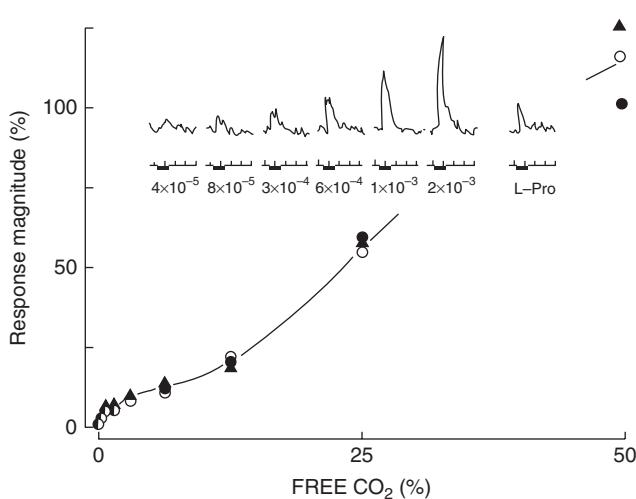

**Figure 42.4** Interactions between strychnine, Q-HCl, bile acid (TLCA), and snf TTX in rainbow trout, demonstrating that Q-HCl and TTX are inhibited by strychnine, but L-Pro, betaine (Bet) and TLC are unaffected (a); TTX is suppressed by either Q-HCl or TLC (b). Adapted from Hara (2011d).

### **CO<sub>2</sub>/PH – GUSTATION IS NOT JUST FOR TASTE**

**BUDS** The fish gustatory receptors are known to be sensitive to CO<sub>2</sub> (Hara, 2007). In pH-controlled decarbonated natural water, rainbow trout detect CO<sub>2</sub> with a threshold  $4 \times 10^{-5}$  M, which is slightly higher than the CO<sub>2</sub> level found in natural water ( $1.8 \times 10^{-5}$  M) equilibrated with air, while the threshold for H<sup>+</sup> is approximately  $4 \times 10^{-5}$  M (Figure 42.5; Yamashita et al., 1989). Responses to CO<sub>2</sub> are independent of pH, and little affected by pretreatment with amino acids or bile acid, and none of the single gustatory fibers responsive to CO<sub>2</sub> responds to other stimuli. The rainbow trout gustatory receptors are thus capable of distinguishing between CO<sub>2</sub> and H<sup>+</sup>, and CO<sub>2</sub> receptors are distinct from those that detect other gustatory stimuli. Experimental evidence suggests that a significant CO<sub>2</sub>/H<sup>+</sup>-driven ventilatory action exists in fishes. The bradycardia and hyperventilation associated with hypercarbia are triggered largely by external CO<sub>2</sub> chemoreceptors on the gills (Gilmour and Perry, 2007).

Similarly, in the gustatory system of the mice, the chorda tympani nerves display robust, dose-dependent, and saturable electrical responses to CO<sub>2</sub> stimulation of the tongue (Chandrashekhar et al., 2009). Also in humans, the superior laryngeal nerves detect CO<sub>2</sub> in the larynx (Nishijima and Atoji, 2004). Why do animals need CO<sub>2</sub> sensing? The ancestral fish from which both modern fish and land vertebrates evolved had lungs that enabled them to live in stagnant, poorly aerated water, they may have participated in a series of reflexes that function to modulate respiration or to block the air way.

**Figure 42.5** Concentration-response curves show the effects of pretreatment with  $10^{-3}$  M Pro (open circles) and  $10^{-8}$  M taurolithocholic acid (solid triangles) on CO<sub>2</sub> responses in rainbow trout. Control responses to CO<sub>2</sub> before adaptation are shown by solid circles. Inset: Typical gustatory responses to CO<sub>2</sub>. Modified from Yamashita et al. (1989).

### **42.4.3 Molecular Basis of Gustatory Receptors and Transduction**

Morphological and neurophysiological studies show that the fish gustatory systems are capable of detecting two groups of chemicals via specific receptor mechanisms: (1) generally attractive chemicals represented by amino acids, and (2) generally aversive chemicals including quinine, bile acids and marine toxins. Supporting evidence came from analyses of genomic sequences encoding proteins homologous to mammalian T1Rs and T2Rs, in which two families of G-protein-coupled gustatory receptors identified in several fish species. Two families of G-protein-coupled gustatory receptors fT1Rs and fT2Rs homologous to mammalian T1Rs and T2Rs exist in puffer fish, medaka fish, and zebrafish (Ishimaru et al., 2005). These receptor genes show 60–70% similarities to those of mammals. The former consists of three subtypes, and are expressed in different gustatory cell populations, while the latter, consisting of two to three subtypes, show low degree of similarities to those of mammals, and expressed in different cell groups from those for T1R genes. Calcium imaging analyses of T1Rs in zebrafish and medaka fish using an HEK293T heterologous expression system further demonstrated that both T1R1/3 and a series of T1R2/3 respond to amino acids and denatonium, but not to sugar. However, the kinetics of Ca imaging (ligand concentrations and response time, etc.) is not in accord with values expected of sensory receptors. Thus, inconsistencies between the various aspects of imaging and electrophysiological response characteristics preclude unequivocal classification of the imaging as representing gustatory receptors in question (Oike et al., 2007). In mammals, T1R1 and T1R3 combine to function as a broadly tuned L-amino acid sensors responding to most amino acids, but not to their D-enantiomers (Nelson et al., 2002). Although some inconsistencies exist between receptor activity and gustatory perception, high degrees of T1Rs identity between fish and mammals suggest that the divergence in these gustatory receptor genes occurred prior to that of fish and mammals.

### **42.4.4 Behavioral Implications**

Contrary to the general belief, the gustatory system is no longer the sole player in feeding in fish, and at the same time, not limited to it. Recent studies demonstrate that feeding behavior is initiated primarily by olfaction, and complemented by gustation in many species (Hara, 2007, 2011c). Feeding, one of the two most fundamental processes for the survival of individuals and species, is not operated exclusively by a single sensory system. This is not limited to fishes; as noted by Brillat-Savarin (Fisher, 2011) in 1826,

"smell and taste are in fact but a single sense, whose laboratory is the mouth and whose chimney is the nose" in us humans. Identifying the active ingredients in fish food has attracted the interest of many investigators from scientific curiosity or for its potential practical applications. All studies examining different aspects of feeding behaviors elicited by natural and/or food extract in diverse fish species have shown conclusively that amino acids act either singly or in combination to play a major role in stimulating feeding behavior. Upon detection of stimuli, fish trigger appetitive behaviors followed by species-specific search behavior patterns. It is important to note that olfactory receptors, and the gustatory for that matter, are genetically fixed, by which their response capacity is determined. However, subsequent behavioral responses to stimuli may be learned by experience, and stored in temporary memory; consequently the correlation does not always exist between electrophysiological and behavioral observations.

Cysteine (Cys), the most potent olfactory stimulating amino acid, enhances locomotor activity, an initial arousal behavior, in all fish species examined, in exactly the same fashion as do food extracts. The increased locomotor (appetitive) activity is followed by distinct species-specific search behavioral patterns. Importantly, behavioral responses exhibited by each species are stereotypic, eliciting the same behavioral patterns regardless of the type of stimuli, and in a concentration-dependent fashion in all species examined, with thresholds  $10^{-9}$ – $10^{-8}$  M, which approximates the physiological values (Hara, 2006). In channel catfish, by contrast, the entire sequence of feeding behavior patterns in response to food extracts and single amino acids are nearly the same in both the intact and anosmic, implying that gustatory stimuli alone are sufficient to control feeding behavior in this species (Valentinčič and Caprio, 1994).

Q-HCl, strychnine and caffeine induce avoidance behavior and suppress locomotor activities in salmonids and goldfish. When food pellets soaked in Q-HCl solution are sprinkled on the surface of an aquarium, both rainbow trout and goldfish pick off, apparently by vision; the former ingest them immediately, but the latter spit them out after a brief mastication. Salmonids are able to avoid the noxious at a distance, but not once they are taken into the mouth (Jones and Hara, 1985), while, goldfish have the specialized palatal organ that enable them to sort food particles from un-palatable particles. They suck up the mixture, if mixed with gravel, sand, or mud, and manipulate the mix in the mouth, then finally spit out. The well-developed reflex system in the vagal lobes activates the musculature of the palatal organ to effect the sorting operation (Lamb and Finger, 1995; Hara, 2005). Surprisingly, the palatal organs are little sensitive to chemical stimuli.

## 42.5 CONCLUDING REMARKS

Taste buds, constituting the structural and functional bases of the peripheral gustatory organs, occur in virtually all extant vertebrates. They are onion-shaped clusters of 50–100 neuroepithelial cells including receptor cells. These features prevail throughout the classes of aquatic vertebrates, except for frogs and urodeles that develop large taste organs called taste disks instead. Despite their experimental advantages and extensive investigations, information on their physiological properties and function has been limited. In fish, by contrast, coupled with expansive peripheral receptors, they all have developed elaborate central structures, probably the most complex neural organization found in any vertebrate central nervous system. Contrary to the general understanding in mammals, electrical recording from individual fibers shows that a single gustatory fiber responds best to one type of stimulus (e.g., amino acids, bitter substances, or tactile). Thus, in fish individual sensory fibers may be establishing synaptic contact with only one type of stimulus. Behaviorally, feeding is triggered by single amino acids primarily through olfaction, and complemented or interchangeably by gustation, in naïve fishes. Feeding, one of the two most fundamental processes for the survival of individuals and species, thus is not operated exclusively by a single sensory system. It is also important to note that the behavioral responses are stereotypic, eliciting the same behavioral patterns regardless of the type of stimulus, and concentration-dependent in all species, with thresholds approximating the physiological ones. Pro is the only natural amino acid that is specifically detected by the fish gustatory receptor *ProR*. These amino acid receptors are specifically activated by their primary ligands, recognizing the characteristic structural feature or epitope of an amino acid including (1) length of hydrocarbon chain, (2) difference in functional group, and (3) position of the functional group within the molecule. This is consistent with Ikeda's stereochemical concept of the "UMAMI" taste; "ionic glutamic acid is related first to the characteristics of an amino acid and second to the fact that its amino group occupies the alpha position for the one carboxyl group and the gamma position for the other carboxyl group ... the location of every residue is relevant for the taste" (Ikeda, 1909).

## Comparative Taste Biology with Special Focus on Birds and Reptiles

HANNAH M. ROWLAND, M. ROCKWELL PARKER, PEIHUA JIANG,  
DANIELLE R. REED, and GARY K. BEAUCHAMP

*Real taste [in] the mouth, according to my theory must be acquired by certain foods being habitual – [and] hence become hereditary.*

CHARLES DARWIN'S Notebooks 1836–1844

### 43.1 INTRODUCTION TO COMPARATIVE TASTE BIOLOGY

Perhaps with the exception of young children, most modern humans are unfamiliar with experimenting with novel and potentially poisonous foods. Thus, our consciously appreciated sense of taste is valuable primarily only inasmuch as it adds pleasure (or displeasure) to dining. We no longer depend upon taste to be the nutrient sensor and early-warning system as it originally served. And if we pause to contemplate the gustatory experience of other animals, we may assume that it is much like our own or perhaps, for some species, like birds, that it is nonexistent. However, this assumption is incorrect. New discoveries from molecular biology and genetics describe the genes and proteins that contribute to taste as a sensory system, and together with mounting evidence from behavioral studies, we have a different story – every organism lives not only in its own dietary niche but, within that niche, also in its own unique world of taste perception and preference. This point was made by Morley Kare more than half a century ago (see Kare, 1970) and is implied by Darwin in the epigraph above.

A striking example of this species variation is the response of animals to sweet fruits. For humans, ripe fruit

produces a sensation of pleasure and motivates consumption; it also invokes consumption in nonhuman primates, fruit-eating bats, and rodents, but cats and chickens are indifferent to sweet foods. We ask why – sugar is a source of energy and a signal of nutrients, so why would some animals not like sugar? Cats and chickens both have diets mostly devoid of sugar, which is associated with the evolutionary loss of a gene involved in sweet perception, a gene that humans and most other vertebrates that consume plants still possess. This type of example has inspired the burgeoning integrative field called *comparative taste biology*, which draws on genetics, anatomy, physiology, behavior, and psychology. As comparative taste researchers, we aim to understand the adaptations of animal taste system by examining their feeding behavior, taste preferences, and the underlying molecular and physiological processes that mediate them.

So far, studies of comparative taste biology have focused on traditional animal model species, such as mice and rats, and have often ignored the biological diversity of sensory form and function in most other vertebrates. But recently, research has shown a link between molecular adaptations and a meat-only diet in carnivores (see Box 43.1). The taste biology of birds and reptiles has been particularly neglected. This in part is due to the belief that species in these groups rely more on sight or olfaction than on taste for feeding. This is a notable oversight because both birds and reptiles can provide novel insights into the evolutionary biology of taste perception and food selection. Birds are components of terrestrial food webs and contributors to the evolution of bitter-tasting insect defenses and sweet, sucrose-rich flower nectars, both of

### BOX 43.1: Examples of Comparative Taste Biology

The study of taste genes is a way to examine how animals adapt to changes in food availability over evolutionary time. New taste receptor genes may be born through genetic duplication and diversification and may proliferate in the population if they are useful, for instance, to warn an animal about new poisons or to provide a cue for a new nutrient. If new mutations result in a new but weak secondary gene function, its duplicated copies can diversify and strengthen that function. If the main function of the original gene becomes less important over time, it can become a pseudogene, while the newly duplicated copies remain functional (Näsvall et al., 2012). This is one model that accounts for the loss of *TAS1R2* (a gene which codes for a part of the sweet receptor) in carnivorous mammals. Below we provide several examples of these types of genetic changes and their relation to taste ecology.

#### Molecular Changes to the Sweet Taste Receptor

Domestic and wild cats (family Felidae) are obligate carnivores, feeding exclusively on meat. Consistent with their preferences for protein- and fat-rich food but not for carbohydrate-rich food, cats are behaviorally insensitive to sweet carbohydrates or noncaloric sweeteners (Bartoshuk et al., 1975; Beauchamp et al., 1977). This insensitivity is best explained by a lack of a functional T1r2 protein in the sweet taste receptor in cats, caused by the pseudogenization of the *TAS1R2* gene (Li et al., 2005). Apparently this gene has become nonfunctional over time in cats, perhaps as their diet became devoid of gustatory sugars.

Like cats, many other species in the order Carnivora are also exclusive meat eaters – have they also lost the sweet taste receptor? A recent study found that 7 of the 12 nonfeline species from the order Carnivora – those that feed exclusively on meat or fish – had pseudogenized *TAS1R2* genes, as predicted (Jiang et al., 2012). These seven species belong to different families within Carnivora: Pinnipedia (sea lion, fur seal, Pacific harbor seal), Mustelidae (Asian small-clawed otter), Hyaenidae (spotted hyena), Eupleridae (fossa), and Prionodontidae (banded linsang). These changes represent six separate mutations – only the sea lion and fur seal, two closely related sister species, share the same mutation. These independent pseudogenizing mutations indicate that the loss of *TAS1R2* occurred independently many times during evolution in the order Carnivora, arguing for convergent evolution of this trait. Apparently, the selective pressure for maintaining *TAS1R2* to detect sweet carbohydrates is relaxed in these meat-eating species.

The loss of the sweet receptor suggests that cats are unable to perceive its taste quality under any circumstance, and this supposition has been tested experimentally using two-bowl choice tests. Species with an intact *TAS1R2* gene, such as lesser panda (*Ailurus fulgens*), ferret (*Mustela putorius furo*), genet (*Genetta thomasi*), meerkat (*Suricata suricatta*), yellow mongoose (*Cynictis penicillata*), domestic dog (*Canis lupus familiaris*), and spectacled bear (*Tremarctos ornatus*), show positive responses to sugars (Jiang et al., 2012; Li et al., 2009). Most have a unique acceptance profile when tested with a variety of sugars, perhaps reflecting differences in the amino acid sequences of the T1R2 and T1R3 proteins that make up the sweet taste receptor (Jiang et al., 2012; Li et al., 2009). In contrast, species with a pseudogenized *TAS1R2*, such as the Asian otter (*Amblonyx cinereus*), appear to be insensitive to sweet carbohydrates (Jiang et al., 2012). Other behavioral taste tests showed that the California sea lion (*Zalophus californianus*) cannot detect sucrose at concentrations up to 2 M (Friedl et al., 1990).

Taken together, these behavioral data agree with genetic data that insensitivity to sweet carbohydrates is due to a lack of a functional sweet taste receptor, which is caused by the pseudogenization of the sweet taste receptor gene *TAS1R2*. We favor the hypothesis that the dietary switch to meat relaxes the selective pressure for maintaining *TAS1R2*, because pseudogenizing events occurred independently during evolution. However, whether the dietary switch to meat caused the pseudogenization of *TAS1R2* or, rather, the pseudogenization of *TAS1R2* gradually drove these species to a meat-based diet remains to be determined.

The bottlenose dolphin (order Cetacea), which displays dietary habitats similar to those of carnivores, also has a pseudogenized *TAS1R2*, based on the draft genome sequence (Jiang et al., 2012). From limited behavioral taste detection data, dolphins show no response or greatly reduced response to sucrose (Friedl et al., 1990; Kuznetsov, 1974), largely agreeing with a lack of a functional T1r2. Together, these findings reinforce the concept of convergent evolution of *TAS1R2* pseudogenization.

#### Swallowing Foods Whole

Some animals, such as those that swallow their foods without chewing and without sampling its chemical composition, may have a weak or missing taste system. Based on anatomical studies, it is likely that some aquatic mammals, such as sea lions (order Carnivora) and dolphins (Cetacea), have lost some or most taste function (Jiang et al., 2012). Sea lions have taste buds only on the tongue tip and tongue root (Yoshimura et al., 2002). Sea lions use a cranovertical feeding action: food grasped in the mouth is thrown backward into the throat for swallowing. This feeding technique similar to that of birds and reptiles, so it is perhaps not surprising that their taste buds have a distribution more akin to that of some birds and reptiles (Yoshimura et al., 2002). Dolphins lack conventional taste tissues (fungiform, foliate, vallate papillae) altogether – only a very small number of taste buds are detected at the root of tongue (Yoshimura and Kobayashi, 1997). Thus, both lineages of aquatic mammals appear to have an atrophied taste system.

Morphological changes also appear to correlate with the degree of adaptation to the aquatic environment (Yoshimura et al., 2002): dolphins, which live a completely aquatic life, show drastic loss of taste structure, whereas sea lions, which are amphibious, retain some residual taste structures found in related land mammals (Yoshimura et al., 2002). These morphological changes mirror the genetic and functional changes of their taste system.

In addition to morphological changes that suggest these species have a greatly reduced sense of taste, the genomic data suggest this conclusion, too. In dolphins, all three Tas1r genes are inactivated, and no intact bitter taste receptor genes have been detected in the draft genome sequence of the bottlenose dolphin (Jiang et al., 2012) – the 10 bitter receptors found are all pseudogenes. Although other bitter receptor genes may yet be found with a completed dolphin genome, the fact that 10 out of 10 receptors identified so far are pseudogenes suggests that bitter taste function is either completely lost or greatly compromised in bottlenose dolphins (Jiang et al., 2012). Thus, sea lions and dolphins appear not to rely on taste for their particular food choices.

which rely on a sense of taste. Reptiles represent the first fully terrestrial group in the evolution of land vertebrates and provide a modern window on the taste biology of more ancient sensory systems (see Figure 43.1).

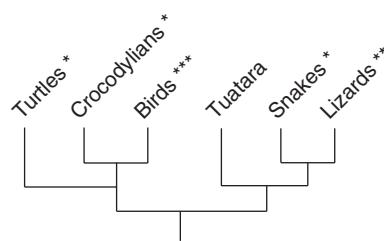

The goal of this chapter is to comprehensively review and consolidate taste research on birds and reptiles. We review what is known about their taste anatomy, physiology, and molecular biology. This provides a basis for understanding taste preferences and feeding behavior. It can also provide insights into broader issues concerning the coevolution of taste and feeding behavior among vertebrates.

We begin by introducing the concept of *taste*, based on research from humans and animal model systems, where information is more complete. We describe the nature of taste as a stimulus, the organization of receptor cells, and how taste perception is evaluated.

### 43.1.1 Definition and Function

Taste stimuli are structurally diverse chemicals that range from small compounds, such as sodium, to large proteins, such as monellin (a sweet protein found in serendipity berries, *Dioscoreophyllum volkensii*). These stimuli elicit a perceptual response because chemical signals are converted (within special cells) to electrical signals, which travel to brain areas where conscious sensation arise. It is generally agreed by researchers that taste consists of a few distinct qualities: sweet, salty, sour, bitter, and umami (Bachmanov and Beauchamp, 2007); however, other perceptual taste qualities may also exist, such as those associated with calcium (Tordoff et al., 2012) and lipids (Fernelius, 1581).

The best-known biological function of taste is to inform animals about the risks (poisons) and benefits (nutrients) of food. Many plants and animals contain chemical defenses that serve to protect them from consumption (Fahey et al., 2001), and for our ancestors, plants that tasted bitter meant “do not eat” (VanEtten, 1969). Modern humans are inclined to discount taste as a means to find calories. We no longer forage among plants, tasting them and rejecting those that are not nutritious.

**Figure 43.1** Representative phylogeny for the major reptilian lineages. Asterisks represent relative abundances of taste behavior studies in the surveyed literature. Adapted from Chiari et al. 2012.

Furthermore, sweet taste is no longer a proxy for calories since the rise of high-potency, noncaloric sweeteners like aspartame. But for our ancestors, the sweetness of a piece of fruit was a signal that useful calories were available and the food source should be consumed. And taste can act as a measuring sensor, helping animals to get just the right amount of a nutrient, such as salt, which can kill if ingested at high doses (Boyd, 1973; Ofran et al., 2004). Taste is also a majordomo: once the decision to ingest a food has been made, taste signals other parts of the body (e.g., the digestive system) to prepare for nutrient arrival (Teff, 2000). A final function of taste is to provide pleasure, a feature not much studied in nonhuman animals but currently in the spotlight for humans because of the contribution of hyperpalatable foods to obesity, diabetes, hypertension, and other diseases of excess.

### 43.1.2 Anatomy

The sensation of taste is initiated by responses of specialized cells in the mouth of mammals that in humans are clustered on the tongue and soft palate, but in many other animals they can be found in other parts of the oral cavity. Chemicals such as capsaicin from hot peppers or menthol from peppermint oil, which stimulate another sensory system, *chemesthesia*, or the common chemical sense, can create a sensation when applied to other areas of the body instead of or in addition to stimulating taste receptors. But for most mammalian species taste perception arises solely from specialized taste cells in the oral cavity. These cells are the reason that sugar tastes sweet only in the mouth and not, for instance, when rubbed on skin. In humans, oral taste cells are organized in *taste buds*, structures that contain many taste receptor cells, as well as cells with other functions. Each taste cell is oriented like a segment of an orange, with microvilli on the surface of the cell pointing inward to the taste pore. Not all cells within the taste bud are of the same type – cells specialize by taste quality and type of taste receptor, and there may be other types of specialization as well (see Chapters 29–31). On the tongue, taste buds can exist either as solitary, fungiform papillae (raised protrusions on the surface of the tongue) or clustered in groups around a cleft, as with foliate and circumvallate papillae, all of which are located in specific subregions of the tongue. Taste cells can also be found in the palate and epiglottis. Taste cells are distinct from solitary chemoreceptors, which are found in some cells in the airways (Finger et al., 2003). The morphology of these solitary cells differs from that of taste cells, although they share some of the same chemical receptors (Finger et al., 2003).

In humans, impulses created from the cells in the taste buds are conveyed to the brain by cranial nerves V, VII, IX, and X. Information from the VII (facial) cranial nerve travels via the chorda tympani to innervate the taste buds

located on the fungiform papillae of the anterior tongue. The lingual branch of the IX (glossopharyngeal) cranial nerve carries information from the posterior regions of the tongue, including the circumvallate papillae, while the X (vagus) cranial nerve carries information from a patch of the tongue just before the epiglottis. The V (trigeminal) cranial nerve carries information about touch, temperature, and chemesthesia. The primary taste nerves carry information to the nucleus of the solitary tract and thalamus, which radiates to brain areas involved in processing, integration, decision making, and pleasure, such as the primary taste cortex in the anterior insula and orbitofrontal cortex (Rolls, 2012). All of these processes arise from the first step in the taste process: interaction with taste stimuli.

### 43.1.3 Receptors and Signaling Molecules

Taste perception is initiated when chemicals contact receptors and other membrane-bound channel proteins that are located on the taste cell surface. Bitter taste receptors, the largest group of receptors, are coded by a multigene family identified in humans by two research groups in 2000 (for a recent review, see Boughter and Bachmanov, 2008). This gene family, termed TAS2R (taste type 2 receptor) genes (Adler et al., 2000; Matsunami et al., 2000), includes a group of genes that are each approximately 900 base pairs long. Data-mining approaches against genomes have identified TAS2R gene repertoires that vary greatly in number in a diverse range of taxa, from humans (25 genes) and mice (34 genes) to western clawed frogs (49 genes). Tallies of taste receptor and other genes from different species are available in online databases, such as Ensembl ([www.ensembl.org](http://www.ensembl.org)).

A smaller family of genes is involved in sweet and umami reception. This gene family, known as the TAS1R (taste type 1 receptor) family, has just three known members, T1R1, T1R2, and T1R3 (coded by the genes *TAS1R1*, *TAS1R2*, and *TAS1R3*, respectively). These receptors combine to form receptor complexes that sense either sweet (T1R2 + T1R3) or umami (T1R3 + T1R1) in several mammals studied. In addition to these receptor proteins, other proteins previously known for their role in glucose sensing in the pancreas may also be present in taste receptor cells and may provide a secondary system for sweet sensing (Yee et al., 2011) for some species.

Sour and salt receptor(s) are presumed to be ion channels, rather than G-protein-coupled receptors like the T1Rs (sweet) and the T2Rs (bitter). Recent evidence strongly implicates an epithelial sodium channel (ENaC) as one receptor type mediating salt (sodium) taste (Chandrashekar et al., 2010; also see Bosak et al. 2010), but there are likely

other salt receptors as well. Sour receptors have not yet been definitively identified. In addition, second messengers that are used for intracellular communication, such as the G-protein  $\alpha$ -gustducin, are involved in the cascade of signal transduction events and have well-defined roles in taste perception (for a review, see Breslin and Huang, 2006). As more becomes known about the taste signaling cascade, the list of proteins involved in taste transduction and signaling will expand. This list will certainly include additional transduction components and regulatory genes such as transcription factors. It may also include additional families of receptors not currently described, which may be found in some species and not in others.

### 43.1.4 Measuring Behavior

Humans have advantages in taste research because they can describe their sensory experience; other animals must demonstrate their perceptions through behavior. One method is to observe what animals eat and how they behave when they encounter foods with particular taste qualities; for example, are they indifferent to it, or do they consume it avidly? Another method is to test taste preferences, typically by offering animals two cups or bowls, one with a fluid or food that contains, for example, sugar or salt, and another with pure water or neutrally flavored food. The amount consumed from each bowl or cup indicates discrimination and preference, but it cannot be used to measure liking unless it is combined with behavioral measures, such as facial expressions (Beauchamp and Mason, 1991; Steiner et al., 2001; for a review of these behavioral methods and their limitations, see Spector, 2003).

Other measurements of taste function involve using electrophysiology to record nerve impulses in response to taste stimuli, or monitoring brain activity patterns by electroencephalography. Metabolic rate within the brain can also be monitored in response to taste stimuli, for example, by using functional magnetic resonance imaging. While these methods are routinely used in humans and laboratory animal models, studies using functional imaging techniques to measure response to taste in birds or reptiles are lacking. However, we expect that this will become possible as the technology becomes adapted for animals other than mammals.

Most of what we know about taste perception and the methods used to study taste behavior come from studies in mammals, particularly humans, mice, and rats. Rodents are models for many human traits due to their commensalism with humans: they eat the same foods and live in the same or similar environments (Crowcroft, 1966; Reed, 2008; Silver, 1995). Mice and rats eat the same types of high-fat,

high-sugar foods that humans do (Sclafani and Springer, 1976) and become obese and diabetic in ways similar to humans, which aids our understanding of these metabolic disorders. Further, mice can be genetically engineered to express human proteins that can generate human-typical taste preferences (Mueller et al., 2005; Zhao et al., 2003). While rodents are a useful model system to study human taste, their use has also contributed to the mistaken belief that *all* vertebrate taste systems are similar. In the following sections, we discuss how dietary niches have likely shaped the taste system of birds and reptiles during evolution and bring to light their sensory experience of food and how this may not be easily translated into human experience.

## 43.2 BIRDS

More than a century ago, Alfred Newton, an English zoologist and ornithologist, wrote in his *Dictionary of Birds*, “The tongue is commonly supposed to be the chief organ of taste; but it is certainly not so in birds, where it is, with a few exceptions, subservient to deglutition [swallowing]” (Newton et al., 1894). Until recently, this point of view has been shared by many researchers working on gustation. Studies showed that birds have fewer taste buds on the tongue than do other vertebrates (Moore and Elliott, 1946) – hardly surprising given how undiscriminating birds appear to be when it comes to dietary choice, prioritizing optimal intake over specific taste qualities. Their apparently indiscriminate foraging behavior and limited expressiveness while feeding suggested that birds care little for the taste of the food they eat. However, more recent research has made clear that, although birds do generally have far fewer taste buds than do other vertebrates (Berkhoudt, 1985), they have many more than we previously thought, and in regions of the mouth that previous researchers had never thought to look (Kudo et al., 2008). Similarly, we have discovered that, far from our previous conception of avian feeding behavior as relying more on an acute sense of vision than on a sense of taste, birds can make fine discriminations between different taste stimuli that rival, and sometimes exceed, the abilities of some other vertebrates (Matson et al., 2000; Medina-Tapia et al., 2012).

Birds are adapted to a diverse range of habitats, including tropical rainforests, deserts, scrublands, lowlands, mountain ranges, and the ocean (Hutson, 1991), and they operate within a broad range of dietary niches, consuming fruits and insects (Chaisuriyanun et al., 2011; Stiebel and Bairlein, 2008; Wilkin et al., 2009); lizards and amphibians (Poulin et al., 2001); mammals and birds

(Geer, 1982; Viitala et al., 1995; Wu, 2011); snails and worms (Goss-Custard et al., 1977); fish, squid, and cuttlefish (Croxall and Prince, 1996; Martins et al., 2011; Polito et al., 2011); cereal grains (Perkins et al., 2007); plants (Picozzi et al., 1996; Soominen et al., 2010; Wilson et al., 2006); beeswax (Cronin and Sherman, 1976); sap (Chapman et al., 1999); and nectar (Gartrell, 2000; Lotz and Schondube, 2006). This diversity of life histories broadens the range of potential nutrients and toxins that birds are likely to encounter and demands an equally varied suite of adaptations for acquiring access to potential foodstuffs.

It has been nearly 30 years since Herman Berkhoudt wrote the last comprehensive review of avian taste cells and taste behavior (Berkhoudt, 1985). Since then the field of genomics has revealed the underlying genetics of taste perception in birds, and behavioral studies have expanded beyond chickens and pigeons to include hummingbirds, parrots, and many species of songbirds (see Figure 43.2 for a phylogeny of birds). This work has revealed that the avian tongue, along with the genetic and neurological systems that govern its function, is more complex than Alfred Newton thought possible. Here we examine these advances in avian taste research, including taste cell distribution and frequency, taste behavior, and taste genomics.

### 43.2.1 Taste System

**43.2.1.1 Structure of Avian Taste Buds.** Taste buds have been extensively studied in a variety of mammalian taxa (Miller and Spangler, 1982; Tichy, 1992a, 1992b, 1994), but studies of the taste organs of birds are scarcer and generally limited to the domestic chicken (Ganchrow and Ganchrow, 1985, 1986; Ganchrow et al., 1994, 1995; Gentle, 1971a, 1975, 1978; Lindenmaier and Kare, 1959). The structure of avian taste buds was described by Bath (1906) and later confirmed by studies on chickens and ducks performed by Berkhoudt (1985; for another early example of taste bud identification, see Botezat 1906). In contrast to human taste buds, which have a single structure that can occur within three different types of papillae, avian taste buds are not associated with papillae and are divided into three types based on shape and other morphology. Type I buds, mainly observed in songbirds, chickens, and pigeons, are ovoid structures that comprise a central core of sensory and sustentacular cells (which provide structural support) surrounded by follicular cells (Berkhoudt, 1985). Type II buds are observed in ducks and waders and are narrower and more elongated than type I buds but with the same supporting and follicular

**Figure 43.2** Representative phylogeny for the major avian lineages. Asterisks represent relative abundances of taste studies (behavior and anatomy) in the surveyed literature. Adapted from Hackett et al. 2008.

cell types. Type III buds are restricted to parrots; these resemble the buds of mammals but lack follicular cells. Kurosawa et al. (1983) identified a taste canal in the taste buds of chickens, a feature not present in mammalian taste buds; it is a lumen, or tube, allowing communication of the sensory cells with the oral cavity. The diversity of taste bud structures across avian orders suggests divergent evolution similar to the way the beaks of Darwin's finches changed over time and may point toward different taste bud systems adapting to different dietary niches.

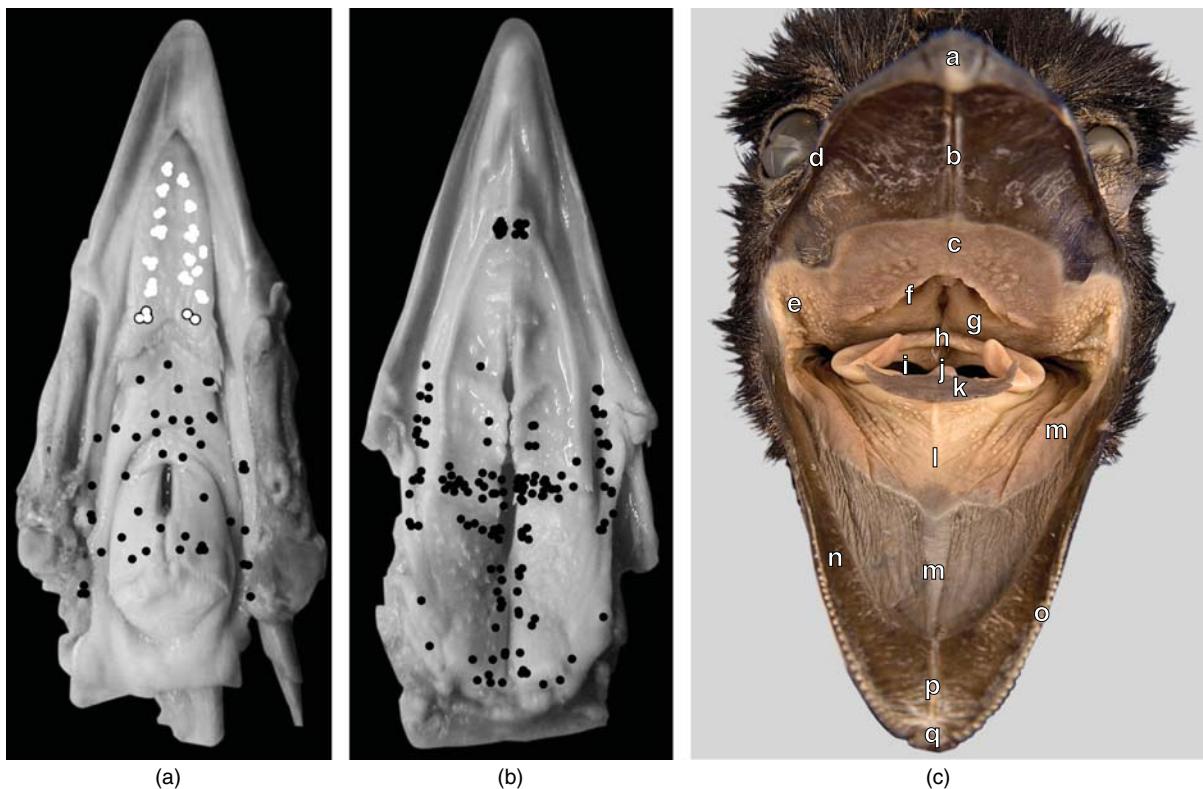

### 43.2.1.2 Distribution and Frequency of Avian Taste Buds.

Avian taste buds are often found in association with salivary ducts (though some also occur freely within the oral mucosa) (Kudo et al., 2008), a feature also observed in reptiles (Ganchrow and Ganchrow, 1985; Gentle, 1971a). Saliva is crucial for the transport of taste stimuli to receptors (Mason and Clark, 1999), as evidenced by the significant reduction in taste ability in chickens with lower salivary flow rate associated with vitamin A and zinc deficiencies (Gentle and Dewar, 1981; Gentle et al., 1981). Birds have higher salivary flow rates than do some mammals (Belman and Kare, 1961), which may compensate for the lower frequency of taste buds. Studies could address this hypothesis by comparing the taste thresholds of species with few versus many taste buds in relation to salivary flow rate.

Unlike mammals, which use their tongues to position food for grinding by the teeth, most birds do not use their tongue during feeding. Instead, they employ a *cranioinertial* feeding action (Berkhoudt, 1985; Gussekloo and Bout, 2005; Zweers et al., 1977): food is initially grasped between the beak tip/anterior mandible and the palatal region of the maxillary glands and then is thrown backward to the posterior surface of the tongue and the esophageal opening. This method of feeding is also seen in many reptiles, such as crocodiles and multiple species of lizards (as well as sea lions; see also Box 43.1).

In mammals, taste buds are predominantly located on the tongue in gustatory papillae, allowing food to come into direct contact with them during feeding. However, in birds we would expect a different distribution of taste buds because of their different feeding action. And, in fact, less than 5% of their taste buds occur on the tongue, generally restricted to the posterior surface (Ganchrow and Ganchrow, 1985; Saito, 1966), where it comes into contact with the food during cranioinertial feeding. This is a low percentage compared with the 73% of lingual taste buds in the hamster (Miller and Smith, 1984) and 79% in the rat (Miller and Spangler, 1982). In contrast, 70% of birds' taste buds occur on the palate, compared with 17% and 15% in the rat and hamster, respectively (Miller and Smith, 1984; Miller and Spangler, 1982), and 25% occur on the lower mandible and the pharyngeal floor (see Figure 43.3a and b). In the emu, structures that resemble taste buds have been reported in the oropharyngeal epithelium, the caudal interramal region, the tongue root, and the laryngo-esophageal junction (see Figure 43.3c). As in mammals, in avians taste buds are innervated by two branches of the facial nerve (VII), the chorda tympani and the palatine (Ganchrow et al., 1986; Gentle, 1983), and the lingual branch of the glossopharyngeal nerve (Halpern, 1962; Mason and Clark, 1999).

The distribution of avian taste buds results in food-stuffs contacting and stimulating each of the taste bud regions sequentially during the feeding action. This is supported by evidence from feeding behavior in ducks and great-crested grebes (*Podiceps cristatus*) (Berkhoudt, 1976, 1985): in ducks, taste buds on the beak tip are used to discriminate between edible and inedible peas (Berkhoudt, 1976), and grebes reject infected fish when held in the mandibular region of the beak, where taste buds are located (Berkhoudt, 1985). Taste buds on the tongue root and esophageal region may act as a final arbiter of food acceptance, after food passes the taste buds in the anterior mouth and those on the palate.

**Figure 43.3** The mouth anatomy of the chicken palate (a) and base of mouth (b) and emu palate and base (c). In the chicken (a and b), each dot corresponds to one taste papilla. In the emu (c), the anatomical features are as follows: a, maxillary nail; b, median palatine ridge; c, nonpigmented roof; d, maxillary rhamphotheca; e, rictus; f, left internal nare of choana; g, tongue frenulum; h, laryngeal mound; i, glottis; j, tongue root; k, tongue body; l, nonpigmented floor; m, pigmented floor; n, mandibular rhamphotheca; o, mandibular serrations; p, mandibular plate; q, mandibular nail. Images (a) and (b) courtesy of Kenichi Kudo; (c) courtesy of Martina Crole.

Some studies describe only the occurrence of avian taste buds, without reporting distribution or frequency (Jain, 1977; Moore and Elliott, 1946; Weymouth et al., 1964). More detailed studies, however, have revealed that the frequency of taste buds in birds is small compared with that in mammals: 24 in the blue tit, *Cyanistes caeruleus*, and 46 in the bullfinch, *Pyrrhula pyrrhula* (Gentle 1975), 250–350 in adult chickens (Ganchrow and Ganchrow, 1985; Kudo et al., 2010; Saito, 1966), and 150–375 in ducks (Berkhoudt, 1976; Stornelli et al., 2000), whereas humans have 9000, and rabbits 17,000 (see Gentle, 1975). Studies on the greater rhea (Feder, 1972) and ostrich (Jackowiak and Ludwig, 2008; Tivane, 2008) have not identified any taste buds. Because previous studies are flawed by incomplete sampling of all of the areas in birds where taste buds occur, future studies should encompass the entire oral cavity and more individuals in order to provide accurate measures.

Age-related changes in the number of taste buds in neonatal vertebrates may reflect a difference in gustatory function with increasing age (Yamaguchi et al., 2001). Mammals show an increase in taste bud number from birth

to weaning and then a decrease in frequency with age (Shin et al., 2012; Yamaguchi et al., 2001). Increases in taste bud frequency occur with age in chickens, but these studies focused only on the tongue (Lindenmaier and Kare, 1959; Saito, 1966). More recently, Kudo et al. (2008) found no age-related changes when assaying taste bud frequency in the whole oral cavity of chickens up to 140 days in age. Whether there are age-related changes in taste behavior in birds is yet to be studied.

### 43.2.2 Avian Taste Behavior and Genetics

Studies on taste behavior in birds vary widely in the methods applied to detect sensitivity thresholds and preferences. Some studies use dried foods (e.g., seeds, crumbs, or rice coated with tastants; Alcock, 1970; Rowe and Skelhorn, 2005; Werner et al., 2008), whereas others use two-bottle choice tests with aqueous solutions (Matson et al., 2000). As mentioned above, in free-choice tests such as these, the greater consumption of one item over another is evidence that the animal can discriminate between the two items but

should not be considered support for an animal liking or disliking the item (Beauchamp and Mason, 1991). Preference is a difficult concept to measure in birds because, in contrast to humans and other mammals (e.g., rats; Grill and Norgren, 1978), birds exhibit a limited repertoire of behaviors in response to oral stimulation. A characteristic response to aversive stimuli includes persistent tongue and beak movement, head shaking, and beak wiping (Ganchrow et al., 1990; Gentle, 1973; Skelhorn and Rowe, 2009), but there is no analogous repertoire in response to neutral or preferred stimuli (Gentle and Harkin, 1979). Many studies also monitor bird behavior over long periods, which make it difficult to tease apart oral perception from learned associations between taste and postigestional state (e.g., the positive energetic state from ingesting carbohydrates or the emetic effects of ingesting bitter toxins). Thus, studying oral perception requires brief-access tests or methods that circumvent ingestion, such as those used in passive avoidance learning (Marples and Roper, 1997) or methods more akin to those that employ lickometers (used in rodent experiments; Breslin et al., 1996). However, the study of taste hedonics in birds will require new methods to overcome their behavioral differences from mammals.

Contrary to the suggestion that the small number of taste buds reported in birds means that their sense of taste is unimportant (Kassarov, 1999), genomic data and quantitative studies on the physiological, molecular, and behavioral responses of birds to different tastants suggest the opposite. In the following sections, we discuss this evidence for three of the taste qualities for which we have genetic and behavioral data – sweet, umami, and bitter taste (see also Berkhouwt [1985] for an excellent review on the early studies of taste perception).

### 43.2.3 Sweet Taste

The diets of many avian species include grains rich in starch, and nectars and fruits containing sucrose, glucose, and fructose (Klasing, 1998). Therefore, the gustatory experience of sweet foods by birds was assumed to be much like our own and other vertebrates, with the expectation of a sweet taste preference and the presence of a functional *TAS1R2* (sweet receptor) gene, which codes for one component of the mammalian sweet receptor. However, surveys of the available avian genome sequences have revealed that chicken, turkey, and zebra finch all lack a gene homologous to *TAS1R2* (Lagerstrom et al., 2006; Shi and Zhang, 2006; Zhao et al., 2010), which was likely independently lost during evolution (Zhao et al., 2010) (see also Box 43.1). This result may not have been unexpected since prior research showed that chickens generally lacked behavioral preferences for sugars (see below), though differences in testing methods have given some contradictory results. While this result led to the suggestion that all birds lack the ability to taste sweet, we know that plant nectar, eaten by hummingbirds (family

Trichilidae) and sunbirds (family Nectariniidae), is rich in the disaccharide sucrose and also contains the hexose monosaccharides glucose and fructose and the pentose sugar xylose (Vanwyk and Nicolson, 1995). Fruits are the second most common food category for some birds after insects and are rich in sucrose, fructose, and glucose. Thus, contrary to the suggestion that all birds lack the ability to taste sweetness, we would expect species of birds that exploit nectar and fruit to exhibit behavioral sensitivity and sugar-type preferences and for these species to have either a functional sweet receptor (i.e., *TAS1R2* gene) or some other molecular mechanisms for detecting sugars (e.g., via glucose transporters). We discuss research on these species after first focusing on those species that lack sweet taste. In 2014 Maude Baldwin, a postgraduate student at Harvard University, cloned the T1R1 and T1R3 taste receptors from the sugar-insensitive chicken, from hummingbirds, and from the hummingbird's closest relative, the insect-eating chimney swift, and tested these in cell culture assay. While the swift and chicken receptors responded only to amino acids, the hummingbird's receptors also fired in response to sweet-tasting sugars, sugar alcohols, and the artificial sweetener sucralose. Baldwin also found that mutations in the birds' T1R1 and T1R3 genes appear to be under positive selection (Baldwin et al., 2014).

**43.2.3.1 Chickens and other Galliforms.** Wagner and Gunther (1971) conducted one of the only studies showing that chickens (*Gallus domesticus*) prefer sucrose and glucose compared with water. However, testing occurred over a 28- to 30-day period, which does not control for postigestive effects. This is an important oversight, because in long-term tests Kare and Maller (1967) showed that diet can influence taste preferences – birds fed a low-calorie diet selected a 10% sucrose solution over water but had no preference under *ad libitum* feeding. Therefore, long-term tests may reflect dietary inadequacies and responses to postigestive factors rather than actual taste preference behavior.

Some researchers have adapted experimental designs to avoid confounds arising from postigestive effects. Gentle's (1972) study used short presentation periods and showed that chickens rejected 5–30% glucose solutions, rejected or were indifferent to 1–30% fructose solutions, and rejected or were indifferent to 1%, 2.5%, 10%, 20%, and 30% sucrose but showed a preference for 5% sucrose. Using electroencephalography, Gentle (1972) found that these same chickens had no responses to glucose concentrations less than 2.5%, rarely responded 10% and 20% fructose, had no response to 1% sucrose, and rarely responded to 10% sucrose. Therefore, many sugar solutions that did not produce behavioral responses did produce nerve responses in the animals (though in other studies electrophysiological responses were low in magnitude [Duncan, 1960; Halpern, 1962]).

In other studies, chickens did not discriminate between water and dextrose or sucrose at concentrations between 2.5% and 25%, and they rejected xylose (Kare and Medway, 1959). Although humans rate saccharin similarly to sucrose at some concentrations (Stromberg and Johnsen, 1990), and many mouse strains show preferences for saccharin (Reed et al., 2004), chickens reject it (Kare and Mason, 1986), perhaps because they cannot perceive its sweet but do perceive its bitter components. Other studies have shown that two other galliforms, bobwhite and Japanese quail, prefer 10% glucose to water (Brindley, 1965; Brindley and Prior, 1968; Hamrum, 1953), and Japanese quail show weak preferences for 1.28% and 2.5% glucose (Urata et al., 1992) and prefer 0.30 M sucrose to distilled water (Harriman and Milner, 1969), although these studies did not rule out postigestive effects. These results for sweet preference are surprising since the amount of sweet food quail encounter in nature is small. We are unaware of any studies on sugar preferences on the other species for which genomic data are available (turkey and zebra finch). However, we expect that their similar diets, which are devoid of sugar, and their lack of *TAS1R2* could also result in behavioral indifference, as is observed in mammalian carnivores (Li et al., 2005). This differs sharply from our expectations regarding nectivorous and frugivorous birds, which have diets high in sugars.

**43.2.3.2 Nectivores.** Baker and Baker (1983) established that nectivorous birds largely fall into two groups, hummingbirds and passerines, and play crucial roles as pollinators for many sugar-producing plants. Most hummingbird-pollinated plants are high in sucrose concentration (0.46–0.81 M) and content (40–46% total sugar) (Baker and Baker, 1983), whereas passerine-pollinated plants are lower in concentration (0.24–0.37 M) and content (0–5% total sugar) (Johnson and Nicolson, 2008). Hummingbirds and other nectar specialists (sunbirds, family Nectariniidae, and honeyeaters, Meliphagidae) are thus thought to prefer high sugar concentrations specific to sucrose, whereas passerine nectivores/generalists should prefer lower concentrations and perhaps nonsucrose sugars.

Initial inspection of the extensive studies on sugar-type preferences in specialist and generalist nectivores (Lotz and Schondube, 2006) seemed to support the hypotheses that specialists exhibit preferences for sucrose over hexose monosaccharide sugars both in the laboratory (Martinez Del Rio, 1990b; Martinez Del Rio et al., 1992; Stiles, 1976) and in the field (Chalcoff et al., 2008), and that generalists have the reverse preference (Brown et al., 2010). However, the story is not so straightforward. Methodology matters when examining sugar preferences, especially in birds, since a species' specific energetic demands can confound interpretation. Different authors control for molarity (Downs, 2000), weight/volume (Blem et al., 2000), or calories (Fleming et al., 2004) in their studies, and as highlighted by Brown et al. (2008), these different methods

can yield conflicting results, which do not support the expected dichotomy in preferences. Much is known about the ecology of food choices in birds, but most studies have failed to control for the role of postigestive effects of the compound tested. Because of these issues, we focus only on those studies that have employed equicaloric solutions.

**SUGAR-TYPE PREFERENCES** Though nectivores are thought to show sucrose preferences, Fleming et al. (2004) found that the broad-tailed hummingbird (*Selasphorus platycercus*) and white-bellied sunbird (*Nectarinia talatala*) show very little discrimination between sucrose and hexose monosaccharide solutions at most concentrations. In another study on nectivores, Fleming et al. (2008) found that the New Holland honeyeater (*Phylidonyris novaehollandiae*) and red wattlebird (*Anthochaera carunculata*) had no preferences for nectar-typical concentrations but did prefer hexose monosaccharides over sucrose solutions less concentrated than natural nectar solutions. They also found that the rainbow lorikeet (*Trichoglossus haematodus*) showed a hexose monosaccharide preference typical of the magnificent hummingbird (*Eugenes fulgens*) and the cinnamon-bellied flowerpiercer (*Diglossa baritula*), a passerine (Schondube and del Rio, 2003). Concentration-dependent preferences for specific sugars may have a physiological root (Lotz and Schondube, 2006). Sucrose must be hydrolyzed to glucose and fructose; thus, a nectivore should prefer hexose monosaccharides at low concentrations to conserve absorption costs (Martinez del Rio, 1990a).

In contrast to specialists, occasional/generalist avian nectivores like the dark-capped bulbul (*Pycnonotus tricolor*) show significant preferences for hexose monosaccharide sugar solutions, irrespective of concentration, when given a choice between hexose monosaccharides and sucrose solutions in equicaloric pairwise choice tests conducted at five different concentrations (5–25%) (Brown et al., 2010). While this suggests different sugar-type preferences in generalist nectivores, this species absorbs hexose monosaccharides more efficiently than sucrose, suggesting absorption efficiency as an explanation, especially since postigestive effects were not controlled here.

**CONCENTRATION PREFERENCES** Hummingbirds typically prefer stronger nectar concentrations (Blem et al., 2000; Gass et al., 1999) and discriminate between 1% changes in nectar-typical (20%) solutions (Blem et al., 2000). Bacon et al. (2011) hypothesized that the taste of a higher concentration of sucrose would be more “rewarding” than that of lower concentrations, suggesting an avian hedonic aspect to taste. They tested this hypothesis with the rufous hummingbird (*Selasphorus rufus*) foraging at artificial flowers containing either 14% or 20% sucrose, stating that if taste alone determined nectar consumption, the birds should drink more 25% sucrose after first feeding on 14% sucrose but not vice versa. But this was not true – experience, it turns out, can shape their preference,

leading the authors to conclude that taste was less important than postigestive feedback in overall preferences. Viscosity of the solutions was not controlled for, nor was its postigestive effect. This highlights the importance of what measures (bout lengths or volumes) should be used to assay taste preferences in studies on birds.

Recently, Medina-Tapia et al. (2012) evaluated the sugar gustatory threshold of the broad-billed hummingbird (*Cynanthus latirostris*) in short taste trials (45 min). They measured bird responses toward sucrose, glucose, fructose, and a 1:1 mixture of glucose-fructose at eight concentrations (0.87–29.2 mM). Chickens and quail exhibit gustatory thresholds for sucrose ranging from 146 to 292 mM (Kare and Medway, 1959), and the cockatiel (*Nymphicus hollandicus*) shows gustatory thresholds of 81.7 and 210.2 mM for glucose and fructose, respectively (Endler and Mappes, 2004). In comparison, the gustatory thresholds of the broad-snouted caiman (*Caiman latirostris*), a nectivorous reptile, was shown to be three to four orders of magnitude lower (1.31–1.54 mM for sucrose, 1.54–1.75 mM for glucose, 0.87–1.31 mM for fructose, and 1.75–3.5 mM for the 1:1 mixture of glucose–fructose), which is comparable with nectivorous mammals like the bare-tailed woolly opossum (*Caluromys philander*) (Medina-Tapia et al., 2012). Interestingly, Medina-Tapia et al. (2012) suggested that at lower sugar concentrations gustatory thresholds may be more important in determining sugar selection, whereas at intermediate and higher concentrations, assimilation rates and osmotic constraints may be more important factors. This may explain why Bacon et al. (2011), who used concentrations of 14% and 25% sucrose, did not find evidence for taste discrimination in all of their measures of hummingbird taste preference, because these may not be close to gustatory thresholds. Future studies should measure gustatory thresholds before testing for taste versus postigestional feeding cues.

**43.2.3.3 Specialist Frugivores.** Fruits differ from nectar in that they are generally considered energetically and nutritionally poor and not adequate to meet a bird's daily metabolic and nutritional demands (Bairlein, 1996). Fruits are generally low in protein and lipid content and high in water and bulk fiber, and they often contain considerable amounts of plant secondary compounds, such as tannins, that bind dietary proteins (making them unavailable for digestion) and negatively affect sugar assimilation (Levey, 1987). Despite this apparent inadequacy, fruits are the second most common food category for birds, after insects (Snow and Snow, 1988).

The hexose monosaccharides fructose and glucose are the most common sugars in fruit pulp (Baker et al., 1998). The sucrose content of passerine-consumed fruit

averages only 8% of the total sugar content (Baker et al., 1998). This leads to the hypothesis that frugivorous birds should show a glucose/fructose preference, as opposed to the sucrose preference hypothesized for nectivorous birds. The preferences of some fruit-eating passerines for hexose monosaccharides over sucrose fit this hypothesis well (Brugger and Nelms, 1991; Martinez Del Rio et al., 1988, 1992; Martinez del Rio and Stevens, 1989). The diet of American robins (*Turdus migratorius*) contains 60% fruit and berries (Sallabanks and James, 1999), and they exhibit lower consumption rates of sucrose compared with hexose monosaccharides due to absorption physiology: robins lack the digestive enzyme sucrase, and the birds experience sickness due to sucrose malabsorption (Brugger and Nelms, 1991). Cedar waxwings (*Bombycilla cedrorum*), in contrast, secrete sucrase and can absorb sucrose, but they still show preferences for simple sugars over sucrose (Martinez Del Rio et al., 1989), which has a lower absorption efficiency (61%) than does glucose (92%) or fructose (88%).

As for concentration preferences, Schaefer et al. (2003) found that tanagers (family Thraupidae) preferred a 12% glucose-sucrose mix over an 8% and 2.5% mix and chose more of the 8% food than the 6% and more of the 6% food than the 5% food. Discrimination of sugar content at the 1% level was noted, depending on absolute sugar content in both foods: the birds exhibiting no preference between 12% and 13% foods but a preference for 6% over 5%. Thus, some frugivores prefer stronger concentrations and are able to make accurate discriminations. This finding is similar to the behavior of hummingbirds discussed in the preceding section (Medina-Tapia et al., 2012), where sugar concentration determines preference for sugar type, because of physiology. In contrast, occasional frugivores may have poorer discrimination and weaker preferences because of low reliance on fruits as foods. We discuss the evidence for this hypothesis next.

**43.2.3.4 Seasonal Frugivores.** Most birds feed largely on insects and other invertebrates throughout the year but consume large quantities of fruit in the autumn and winter. This includes the thrushes and blackbirds (family Turdidae), starlings (Sturnidae), red-winged blackbirds (Icteridae), and warblers (Sylviidae) (Snow and Snow, 1988). We might expect them to have preferences for hexose monosaccharides over sucrose, similar to specialist frugivores. Tests with equicaloric aqueous solutions of hexose monosaccharides (1:1 mixture of fructose and glucose) and sucrose over four days showed that house finches (*Carpodacus mexicanus*) consume increasing volumes of hexose sugars compared with sucrose at concentrations of 4%, 6%, and 10%, but not 2% (Avery et al., 1999). The observed increase in hexose consumption over sucrose

might reflect the same lack of sucrase observed in American robins (Brugger and Nelms, 1991). However, fecal sugar analyses show approximately equal absorption of hexose monosaccharides and sucrose, thus discounting this hypothesis.

Red-winged blackbirds eat more grains, while starlings consume more insects and fruit, leading to the hypothesis that starlings evolved a preference for fructose (Espaillat and Mason, 1990). The responses of both species to aqueous solution of D-fructose (0.1%, 0.5%, 1.0%, and 5.0% w/v) were measured over two-hour test periods and measured consumption at 30-minute intervals. As predicted, red-winged blackbirds drank less fructose per gram of body weight than did starlings. Concentration had no effect on consumption of fructose by blackbirds, whereas consumption by starlings did increase past 0.5% D-fructose. This study demonstrated that the blackbirds' insensitivity to fructose reflects the predominance of grain and insects in their diet and starlings displayed a correlation between fruits and sugar sensitivity. Studies on bird species that rarely consume sugars are uncommon, but for species whose diet is low in sugar, we would hypothesize sugar perception and preference to be weak. However, this is not always the case, as we discuss next.

**43.2.3.5 Insectivores, Omnivores, and Carnivores.** The azure-winged magpie (*Cyanopica cyana*) prefers sucrose over glucose and fructose, suggesting that magpies can efficiently absorb sucrose (see Lotz and Schondube 2006), contrary to the expectation that primarily insectivorous species lack sensory adaptations to frugivory (sweet preferences), the great tit (*Parus major*) shows a preference for 7% and 14% glucose solutions (Warren and Vince, 1963). However, each solution was paired with water for eight consecutive 24-hour periods, which did not control for postigestive effects. Ravens feed predominantly on carrion and do not show a preference for five different sugars over water (Harriman and Fry, 1990). Likewise, Rensch and Neunzig (1925) reported rejection or indifference to sugar by the nonfrugivorous owls (family Strigidae) and ducks (Anatidae). That same study showed that carnivorous kestrels (family Falconidae) and herons (order Gressores) accept sugar, although they were offered only a single-bottle stimulus, which assesses only acceptance and not preference. Further comparative work is needed to tease apart sweet taste function and feeding ecology in different avian taxa.

## 43.2.4 Umami Taste

Birds frequently consume foods containing glutamate and/or amino acids (e.g., meats, insects, grains). Therefore, one might expect that birds should be able to detect

and exhibit preferences for free amino acids, and that these species would express at least the components of the umami receptor (T1R1 and T1R3) if not other umami-related genes.

A comparative genome analysis by Shi and Zhang (2006) showed that chickens possess *Tas1r1* and *Tas1r3* required for the umami receptor (as do mouse, cow, dog, cat, and several fish species), and *Tas1r1* has also been documented in turkey, zebra finch, egret, loon, and tubenose seabirds (Zhao et al., 2012). Roura et al. (2008) did a one-by-one comparison of all farm and companion animals for which *Tas1r* genes are known and found that chicken T1r1 nucleotide homology is lowest, which may equate to qualitative and quantitative differences in taste behavior of chickens compared with other species. A second receptor, a metabotropic G-protein-coupled receptor named mGlu4, which is associated with glutamate taste in rats (Chaudhari et al., 2000), is located on chromosome 26 in the chicken. However, its function, if any, in the chicken taste sensory system is not known.

In humans, the *Tas1r1* and *Tas1r3* genes produce a receptor that is narrowly tuned to L-glutamic acid and L-aspartic acids (Li et al., 2002), whereas in rodents and pigs this receptor has broader tuning, and these species exhibit preferences for many amino acids, among them L-cysteine, L-methionine, and L-alanine (Nelson et al., 2002; Roura et al., 2011). To date, the relationship between umami taste preference and sensitivity and candidate umami receptor genes in birds has not been explored explicitly. However, the available behavioral data on umami/amino acid taste in birds (described below) corroborate the presence of the *Tas1r1* and *Tas1r3* genes in the available genomic data.

**43.2.4.1 Galliforms.** Chickens adjust their food intake to compensate for dietary deficiencies in essential amino acids. In feeding-choice scenarios, hatching broiler chickens show an immediate preference for a diet containing synthetic amino acids rather than one deficient in lysine, methionine, and tryptophan. Cadirci et al. (2009) found that chickens deficient for methionine show a clear preference for methionine-treated water, though color cues on the drinking bottles were necessary and preferences may have been learned following ingestion. Further, Urata et al. (1992) showed that chickens exhibit no preference behavior between 0.01% and 0.64% monosodium glutamate (MSG) in two-bottle choice tests but avoided MSG at concentrations of 1.28–10%. In comparison, Japanese quail showed no preference between water and 0.01% or 5% MSG, but they preferentially consumed water over 10% MSG. *Tas1r* genes in the chicken may be involved in nutrient sensing and metabolism rather than taste behavior. This is supported by cDNA microarray analysis of

gene expression patterns in the hypothalamus, liver, and abdominal fat of chickens, where *Tas1r1* transcripts are differentially expressed between overweight and lean lines of chickens (Byerly et al., 2010). This difference may arise because T1R1 is involved in postigestive nutrient sensing (Ren et al., 2009; Wauson et al., 2012).

**43.2.4.2 Passerines.** Espaillat and Mason (1990) hypothesized that starlings, because they consume more insects than do red-winged blackbirds, would exhibit greater preference for free amino acids. In short one-bottle choice tests that controlled for postigestive effects, both blackbirds and starlings increased consumption of L-alanine in water with increasing concentration per gram of body mass; male starlings consumed more than did male blackbirds. Another study found that blackbirds strongly prefer rice seed soaked in L-alanine compared to seed soaked in tannic acid (Werner et al., 2008). These results could demonstrate either taste-based preference for amino acids and/or aversion to the potentially sour/bitter sensation of tannic acid.

### 43.2.5 Bitter Taste

Many birds consume plants and animals that contain defensive toxins (e.g., cardenolides, iridoid glycosides, and cyanoglycosides Brower, 1969; Nishida, 2002), venoms and stings (Schmidt, 1990), urticating hairs (Bowers, 1990; Wyllie, 1981), phenolics (Johnson et al., 2006), and antinutrient factors such as tannins (Dixon et al., 1997) and saponin (Cheeke, 1971). Humans report these compounds as tasting intensely bitter and strongly avoid them in preference tests (for a review, see Bachmanov and Beauchamp, 2007). Toxic cardiac glycosides and cardenolides trigger the vomiting reflex (Brower, 1969) to avoid absorption. Solutions that are rated as bitter by humans (e.g., quinine sulfate) also result in emesis in birds (Alcock, 1970). Bitter tastes (without ingestion) consistently induce nausea in humans, showing that the body not only detects potential toxins but anticipates their ingestion by inducing a prophylactic aversive state (Peyrot des Gachons et al., 2011). Most studies of bitter taste in birds use taste chemicals that are not necessarily part of insects' chemical defense battery (Marples et al., 1989; Rowland et al., 2007, 2010; Skelhorn and Rowe, 2009, 2010; Tullberg et al., 2000; Yang and Kare, 1968). However, the universal trend in these studies is rejection of bitter tastes. Birds respond to these diverse bitter chemicals with specific rejection responses, which include beak wiping and head shaking (Marples and Roper, 1997), vomiting (Alcock, 1970; Brower, 1969), and taste-rejection behavior, where birds attack and release prey on the basis of defense chemicals (Fink and Brower, 1981; Skelhorn and Rowe, 2006a).

These behavioral responses to bitter chemicals are consistent with bioinformatics surveys and direct sequencing, which have shown that turkeys have one bitter taste (*Tas2r*) gene emus have two (Maehashi et al., submitted), and chickens have three (Hillier et al., 2004). These repertoires are low compared with the functional repertoire of *Tas2r* genes in other sequenced vertebrate genomes, which ranges from 4 in the platypus to 36 in rats (Dong et al., 2009), up to 64 in frogs (Go, 2006; Shi and Zhang, 2006). The range between birds and other species may suggest a reduced ability to detect and discriminate between bitter substances, or fine-tuning of the receptors to the birds' feeding ecology (specialization), or broad tuning of the receptors allowing many taste chemicals to be perceived by fewer receptors. A study by Davis et al. (2010) on the *Tas2r* cluster in the white-throated sparrow (*Zonotrichia albicollis*) shows expansion from one to four genes in the passerine lineage since the most recent common ancestor with the chicken (order Galliformes) around 100 million years ago (van Tuinen and Hedges, 2001), followed by a subsequent expansion to 19 genes in the lineage leading to the white-throated sparrow since its most recent common ancestor with the zebra finch (*Taeniopygia guttata*), which has seven genes. The number of intact *Tas2r* genes in the white-throated sparrow is within the range found in most other vertebrates (i.e., 15–49) (Dong et al., 2009) and may reflect a similar ability to sense and respond to bitter tastants, though this has yet to be confirmed by behavioral assays. What is clear is that avian *Tas2r* genes have undergone dynamic gene expansion and contraction during the course of vertebrate evolution (Dong et al., 2009; Go, 2006), and species likely differ in responses to bitter compounds. We focus first on those species with small *Tas2r* repertoires because those with larger repertoires have not yet been studied.

**43.2.5.1 Chickens.** Chicken bitter taste behavior and neurophysiology have been the most intensively studied because of the chickens' importance as a commercial food source. Though chickens have a small *Tas2r* repertoire, they display discriminative reactions to bitter taste stimuli as measured by stereotypic head and oral movements in prehatchlings (Vince, 1977) and mature animals (Gentle, 1975) and by tests of preference (Balog and Millar, 1989; Kudo et al., 2010) and discrimination (Skelhorn and Rowe, 2006b, 2007). In electrophysiological tests, chickens exhibit lingual nerve responses to 0.01 M (Halpern, 1962; Kadona et al., 1966) and 0.02 M (Kitchell et al., 1959) quinine hydrochloride (QHCl) and 0.0002 M sucrose octaacetate (Halpern, 1962), and they have chorda tympani responses to 0.1 M and 0.05 M QHCl (Gentle, 1983, 1987).

Results from two-bottle choice trials generally support the results from electrophysiology studies but are affected

by the animals' side preferences, testing period length, and dietary deficiencies (Gentle and Dewar, 1981; Gentle et al., 1981). Gentle (1976) found that water deprivation lasting 2–12 hours resulted in increasing acceptance of 0.005 M QHCl and a reduction in the number of aversive responses when the birds were tested for 3 or 20 minutes. In longer-term two-bottle choice tests, chickens show behavioral rejection of QHCl at 0.5 mM and 2.0 mM (Kudo et al., 2010) and at 0.1% (2.77 mM) (Kare et al., 1957). However, while 0.0002 M sucrose octaacetate produces lingual-nerve responses, chickens accept it as well as water (Halpern, 1962). Feed-choice trials suffer from the same confounding factors as two-bottle choice tests, with long test durations indicative of confounding by postigestive effects. Gentle (1971b) found that chickens consume significantly less food coated in 0.5% QHCl within 1 hour; they also consume significantly less food coated in 0.10% quinine hydrobromide compared with a control diet (Balog and Millar, 1989) and reject QHCl concentrations greater than 0.04% over longer periods (Urata et al., 1992).

A useful behavioral assay in chickens is called *passive avoidance training* (reviewed in Rose, 2000). Chicks are allowed to peck at a small, colored bead coated in a distasteful substance (Burne and Rogers, 1997; Marples and Roper, 1997) and are then assayed for avoidance to the colored bead only. This is a pure taste behavior bioassay controlling for postigestive effects. Unfortunately, most passive avoidance tests use methyl anthranilate, which has a strong odor, which complicates disentangling taste from olfaction. However, chicks given bitter taste alone in these assays learn to avoid the visual stimulus, suggesting that denatonium benzoate (Marples and Roper, 1997) and quinine sulfate (Bourne et al., 1991) are aversive to chickens. Similarly, a study on taste-rejection behavior in chicks showed that they more frequently rejected unpalatable food coated with 4% quinine compared with 1% quinine (Skelhorn and Rowe, 2006a).

In summary, despite their smaller Tas2r repertoire, bitter tastants are perceived as aversive to chickens. Whether their gustatory thresholds or discrimination abilities differ from those of other avian orders has not been directly tested, but in the following sections we describe other avian species bitter taste behavior, which is qualitatively similar.

**43.2.5.2 Specialist Insectivores.** Tropical insectivorous birds, such as the rufous-tailed jacamar (*Galbulia ruficauda*) and black-backed oriole (*Icterus abeillei*), specialize on butterflies (Chai, 1996) that possess chemical defenses and advertise this with warning coloration. These birds are expected to be highly selective in their attacks and consumption of insects, based on their evolutionary history with these prey (Speed et al., 2012), and should

exhibit higher thresholds for bitter stimuli than species naive to such prey, such as chickens. To our knowledge, no studies have assessed gustatory thresholds of specialist insectivores for quinine or denatonium benzoate or even chemicals more akin to those found in their prey. However, studies have reported the foraging behavior of these birds in nature (Fink and Brower, 1981) and in the laboratory (Brower, 1969). For example, Chai (1996) assessed the responses of naive jacamars to poisonous butterflies of the Nymphalidae family and observed that birds attacked prey once or several times but rejected them after tasting, suggesting the butterflies were bitter due to their chemical defenses (though texture, odor, etc., cannot be discounted). Likewise, Fink and Brower (1981) observed orioles attacking and releasing most (75%) monarch butterflies (*Danaus plexippus*) encountered. However, after measuring cardenolide content of the rejected butterflies, the birds did not selectively reject the butterflies high in cardenolides, leading the authors to suggest the birds discriminate based on textural or size cues during capture. Interestingly, once the butterflies were killed, the amount eaten per bird was inversely proportional to cardenolide content, which may reflect the emetic effects of the different body parts as opposed to actual taste cues, because the degree of bitterness may not accurately predict prey toxicity (Glendinning, 1994). Monarchs are high in lipids and proteins (Brower et al., 1988). By not relying solely on taste cues, birds may balance the cost of toxin intake with the nutritional benefits of the butterfly.

**43.2.5.3 Generalist Insectivores.** Many generalist avian foragers in the order Passeriformes learn to associate the visual cue and bitter taste/postigestive effect of prey toxins to avoid repeated consumption (reviewed in Mappes et al., 2005; Schuler and Roper, 1992). The most famous example is the blue jay–monarch butterfly paradigm studied by Lincoln Brower. Monarch butterflies are an interesting case study, because they exhibit a spectrum of palatability. When Brower trained blue jays to eat palatable monarch butterflies, they would quickly eat the first highly toxic one offered. The birds shook their heads and puffed their feathers but had no innate cardenolide-based bitter taste rejection. The perceived bitterness of any food is a function of the genotype of the particular animal under consideration because insects or other foods are not inherently bitter; instead, they contain more or less of certain chemicals that, for some species, engage bitter receptors. As such, bitterness may not accurately predict the potential toxicity of food (Glendinning, 1994), so these generalists may exploit food sources that would otherwise be rejected. In line with this prediction, Skelhorn and Rowe (2010) found that European starlings can associate a bitter taste (denatonium benzoate) with

the dose of a second, tasteless toxin (quinine) to optimize their nutrient intake, demonstrating remarkable foraging discrimination.

**43.2.5.4 Granivores and Omnivores.** Seeds and grains can contain bitter secondary compounds such as tannins and are often infected by fungi, which increase the concentration of alkaloids (Wolock Madej and Clay, 1991). For parrots and cockatiels, which primarily eat seeds high in tannins and in various stages of ripeness, we might expect these birds to discriminate among seeds as insectivores do among toxic butterflies. Indeed, cockatiels, like humans, are highly sensitive to quinine and even more sensitive than some mammals, which parallels the birds' mammal-typical taste bud structure (Matson et al., 2004). Similar to humans (who overcome tannins in teas and beers), parrots tolerate bitter chemicals in their foods, though this may be explained by their propensity for consuming clay which binds and neutralizes toxins, rather than by taste habituation (Gilardi et al., 1999).

In contrast to granivores, the diets of omnivorous, meat-eating birds such as crows and ravens are often devoid of secondary compounds, and we would expect them to exhibit low thresholds for bitter tastes because bitterness should reliably indicate poisons. This is supported by evidence from common ravens (*Corvus corax*), which reject QHCl at all concentrations and are nearly as averse to drinking a 0.01% solution as they are to 1.6% (Harriman and Fry, 1990).

### 43.2.6 Summary

Clearly birds can taste, but they do not respond behaviorally the same way to some chemicals that humans do, as illustrated by the dissimilar responses to sweet and bitter compounds. To clarify these issues and enhance our understanding of avian taste perception, shorter test periods are needed to reduce/eliminate postigestive effects. We suggest that future biochemical studies identifying the ligands for the avian Tas2rs would be useful for species conservation and understanding the coevolution of insect defenses and bird responses; functional assays on Tas1r genes in nectivores would elucidate the proximate mechanisms for sugar-type and concentration preferences, and behavioral genetic studies of intra- and interspecies genetic differences could reveal the relationship between dietary niche and taste preferences that could have important implications for our understanding of niche partitioning, habitat choice, dietary changes, and speciation.

## 43.3 REPTILES

A complementary route for understanding the evolution and diversity of taste behavior comes from comparing studies of

birds with those in reptiles, which serve as deep, extant relatives to younger vertebrate classes, such as Aves and Mammalia. Though far less is known about taste in reptiles than in any other vertebrate group, the taste behavior/biology of the squamates (snakes and lizards) is an exception to this, with studies on anatomy, neurophysiology, and behavior that have led to the proposal of squamates as alternative models for taste studies (Young, 1997). Understanding of the reptilian taste system has been hindered by the tendency to focus on other sensory modalities, such as olfaction and vomeronasal systems. We start by discussing the taste system of reptiles, followed by taste genes and behavior.

Class Reptilia comprises four general groups: turtles, crocodilians (crocodiles and alligators), tuatara (a single species, *Sphenodon punctatus*), and squamates (snakes and lizards). Reptiles have a wide geographic range and have radiated into a variety of terrestrial habitats, but they also inhabit marine and freshwater environments. Similar to observations in birds, this diverse range of habitats is mirrored by diets that vary considerably. Turtles are generally considered opportunistic omnivores. For example, the red-eared slider turtle (*Trachemys scripta*) is carnivorous when a juvenile and switches to a more herbivorous diet as it grows (Bjorndal, 1991), whereas the green sea turtle (*Chelonia mydas*) feeds on seagrasses and algae (Garnett et al., 1985). Crocodiles consume aquatic insects, spiders, crustaceans, and fish (Wallace and Leslie, 2008), as well as such terrestrial vertebrates as snakes and mammals (Magnusson et al., 1987). Tuataras feed on a wide range of small animals but predominantly on insects (Wallis, 1981), and squamates feed on mammals, birds, other lizards and snakes, vertebrate eggs, and insects (Vitt et al., 2003; Rodríguez-Robles et al., 1999). The types of foods that birds and reptiles eat overlap somewhat, for instance, insects, nectar, fruit, and spiders, which makes a comparison of evolutionary patterns of taste an interesting avenue to explore.

The avian and reptile literature contains many parallel opinions regarding taste capacity. For instance, it is generally believed that the sense of taste is reduced or completely lost in snakes because taste buds are lacking on the tongue and mucosa of the lower jaw (Auen and Langebartel, 1977; Uchida, 1980; for review, see Young, 1997). However, blind snakes possess taste buds in large numbers (Kroll, 1973). Pit vipers have palatine taste buds that are served by the palatine branch of the facial nerve, and the chorda tympani carries afferents from the oral mucosa of the mandible (Atobe et al., 2004). Similar to birds, snakes have taste buds positioned so that they receive direct stimulation by food particles. Therefore, in the following sections we review the evidence for reptilian taste bud occurrence, taste behavior, and genetics, and similar to the section on birds, we focus on sweet and bitter taste.

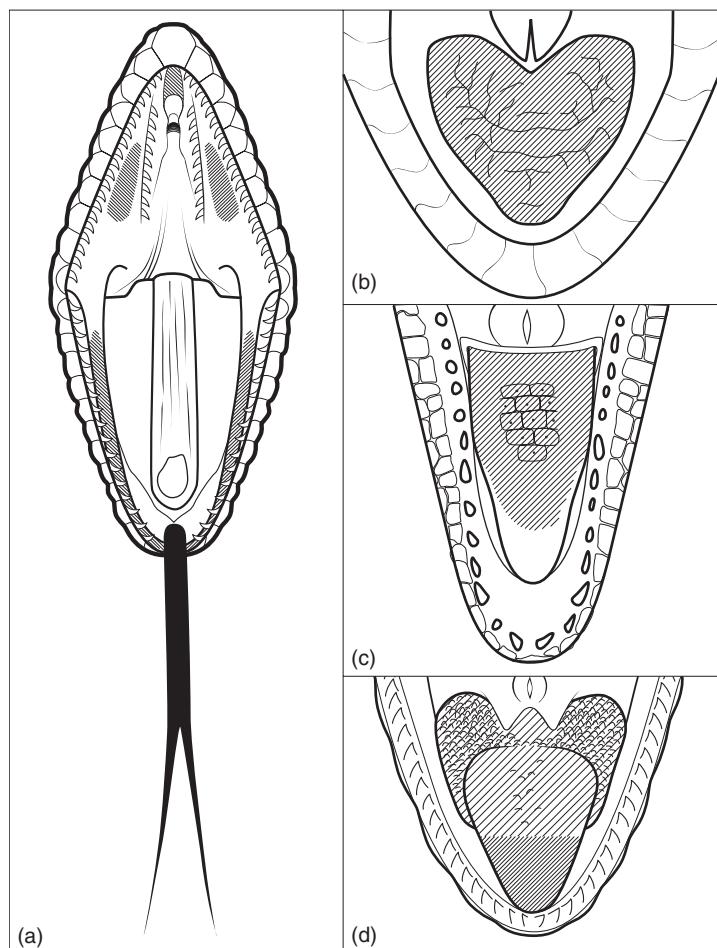

### 43.3.1 Taste System

As is the case for birds, finding the taste cells of reptiles is a matter of knowing where to look. There is a large literature on this topic (reviewed in Schwenk, 2008), summarized in Figure 43.4. Reptilian taste buds are small, flask-shaped organs with the same sensory and support cells as in birds and are considered “intermediate” in form between fish and mammals (Uchida, 1980). Unlike those in birds, however, reptile taste buds generally lack pores, as revealed by ultrastructural examination. Korte (1980) suggested that aquatic reptiles have taste bud structure similar to that in fish and amphibians, which points to convergent evolutionary changes to taste cells in response to a sea versus land environment, and the possibility of underlying differences in the molecular biology of taste cells in aquatic versus terrestrial reptiles.

Taste buds are found in several locations within the oral cavity and pharynx of reptiles and their distribution varies among groups and even among species within groups. The nerves that connect taste cells to the brain are similar to the three cranial nerves in mammals: VII

(chorda tympani and palatine branches of the facial nerve), IX (glossopharyngeal), and X (vagus). The palatine branch of the facial nerve carries afferent tracts from palatine taste buds, whereas the chorda tympani afferents from the oral mucosa of the mandible (Atobe et al., 2004). Most turtles, crocodilians, and lizards have taste buds on the tongue and palate, with some exceptions (e.g., Young, 1997). Taste buds in turtles are usually found on the tongue (Uchida, 1980) and may occur in other parts of the mouth and pharynx, but too few taxa have been examined to generalize. Pacific hawksbill (*Eretmochelys imbricata bissa*) and Pacific ridley (*Lepidochelys olivacea*; Cheloniidae) sea turtles appear to lack taste buds (Iwasaki et al., 1996), though buds are present in the red-eared slider turtle (Korte, 1980). Crocodile taste buds were studied by Bath (1906), in the same study that described avian taste buds (see Section 43.2.1.1), and are typically found on the mucosal surfaces of the tongue, palate, and pharynx.

Snakes have no taste buds on the tongue and few or none on the lower jaw; they are instead found mostly on the palate (Auen and Langebartel, 1977; Uchida, 1980; reviewed in Young, 1997). In xenophidian snakes (cobras,

**Figure 43.4** Oral cavities of each of the major reptile groups. (a) Dorsal (upper) and ventral (bottom) palates of a generalized snake mouth with its forked tongue in black. The teardrop-shaped cavity in the anterior dorsal palate is the opening of the internal choanae/nares. (b-d) The ventral palate of a turtle (b), crocodilian (c), and lizard (d). Hatched lines in each drawing represent areas where putative taste papillae have been identified histologically. The tongue tip of most lizards, as with most mammals, is highly concentrated with taste papillae, as indicated by denser hatching (d). Images were redrawn from pictures generously provided by K. Schwenk and E. Taylor. Drawing credit: Mary Leonard from the University of Pennsylvania, Philadelphia.

vipers, and sea snakes), taste buds are elevated on small papilla-like projections that also contain mechanoreceptors, which may allow the identification and manipulation of prey in the mouth (Nishida et al., 2000; Schwenk, 2008). This organization is reminiscent of that in ducks and grebes. Although little studied, the rare tuatara, the only extant nonsquamate lepidosaur, possesses numerous filamentous papillae, some of which are purported to be gustatory based on their structure and staining (Schwenk, 1986). The most interesting aspect of the tuatara's taste bud pattern is that the adult structure of the taste papillae is most similar to the papillae of embryonic mammals, squamates, and crocodilians. This finding highlights the research gains that could be made in our understanding of taste developmental and molecular biology by examining the taste physiology and cellular biology of specific groups and/or species of reptiles.

The taste cells, buds, and papillae in reptiles are thus similar in some ways to those of birds and mammals. And as has occurred in some genera of mammals and birds, the function of the reptilian tongue has evolved roles outside of gustation and food manipulation. For example, the tongue can be used to capture and lure prey, to warn predators, to feign death, and to excrete salt. The most pertinent example of an extragustatory role of the reptile tongue is seen in squamate reptiles, where the tongue is essential to their chemosensory system because it captures and transports nonvolatile chemicals to the vomeronasal organ (VNO). An interesting aside is that these same chemicals on the tongue may also make contact with putative taste receptor cells located near the opening of the VNO, emphasizing a possible anatomical convergence that would maximize food chemical detection (Atobe et al., 2004; Kroll, 1973; Schmidt et al., 2010).

When gathering nonvolatile chemicals, lizards lick the food or other item, called a *substrate lick*; when they are gathering volatile chemicals, they lick air, called a *tongue flick* (Greenberg, 1993; Schwenk, 1985). The study of taste behavior in reptiles has therefore been problematic, especially in squamate reptiles, due to a focus on the vomeronasal and olfactory systems for chemosensation. The VNO of most reptiles is exquisitely developed and responds to a remarkable diversity of chemical cues. However, the delivery of chemicals to the VNO requires the involvement of the tongue, especially in squamates (see below). During a tongue flick, a reptile physically transfers chemicals from the external environment to the ducts leading to the chemosensory epithelium of the VNO. It is tempting to postulate that the reliance on the tongue as a chemical cue delivery device in some lizards and snakes may partially explain the complete loss of taste buds on the tongue and oral mucosa in these reptiles. Such a concomitant loss of chemosensory anatomy alongside a suite

of major morphological shifts (mass reduction, lengthening, and forking of the tongue) is not unprecedented in vertebrates. Indeed, porpoises apparently lack an olfactory sense, including loss of their olfactory bulb, which may have arisen alongside the cranial restructuring that was favored in a completely aquatic environment (see Box). Further, the taste gene *Tas11* in the bottlenose dolphin is considered to be nonfunctional based on a recent study of pseudogenization in carnivore taste genes (Jiang et al., 2012). It would be interesting to know if the carnivore pattern of major taste loss is true in a subset of reptiles that are strict carnivores, such as snakes and crocodilians.

### 43.3.2 Taste Behavior

Very few studies of reptiles examine taste behavior, due in part to the belief that reptiles have little or no ability to taste, and researchers have a tendency to instead focus on the vomeronasal system. There are also inherent difficulties in testing these species in a controlled laboratory environment or observing their natural behavior, especially because classic gustation research methods like the two-bottle preference test are impractical. Current methods for examining taste in reptiles are to observe whether they reject food adulterated with a bitter chemical or avidly consume those with an added sweet chemical or, in the case of snakes and lizards, whether the tongue behavior changes when it encounters a chemical or food. Anecdotal evidence points to taste behavior in American alligators when food extracts are introduced to water (Schwenk, 2008). They show increased rates of lateral head movements and mouth opening and snapping, and because crocodilians likely do not use olfaction underwater, this suggests a role for taste. What is known, as reviewed below, suggests that reptiles can perceive at least some compounds that humans perceive as sweet or bitter.

### 43.3.3 Sweet Taste

The study of sweet taste in birds is logical because some birds eat foods that are sweet, such as fruit or nectar, but the motivation to study sweet taste in reptiles is less obvious because the habitual diet for the bulk of reptiles is meat, eggs, and/or insects. That said, some lizards do eat sweet food, the best-known example being fruits and flower nectar (e.g., Liner, 1996; summarized in Olesen and Valido, 2003, 2004). The reaction to sweet taste has been studied directly in the lacertid Boettger's lizard (*Gallopia caesaris*), which exhibits both substrate-licking and tongue-flicking behavior when offered sucrose (Cooper and Pérez-Mellado, 2001). The behavior of the lizard changes with the concentration of the sucrose: as the solution becomes more concentrated, the number of tongue flicks decreases and substrate licks increase. These

data suggest that vomeronasal sensing (tongue flicks) is used with lower concentrations of sucrose, whereas taste (substrate licks) is used to assess chemicals at higher sucrose concentration (Cooper and Pérez-Mellado, 2001). Though it is unknown if the VNO can respond to sucrose, the behavioral data suggest that chemical detection strategies shift along the sucrose concentration gradient. It could also be that taste buds in the roof of the mouth, near the opening of the VNO, are sufficient to detect low concentrations of taste chemicals as mentioned above. Although these data suggest that lizards perceive sweet as a taste quality, another study drew the opposite conclusion: Stanger-Hall et al. (2001) found that a sweet mixture (aspartame, with a small amount of dextrose) did not affect food choices in a learning paradigm. However, aspartame is not sweet to many animals (e.g., Li et al., 2011), so it is not the ideal sweet stimulus for these experiments. Overall, these studies suggest that some lizards do respond appetitively to sugars that humans describe as sweet, but given the extreme paucity of data, further study is warranted.

#### 43.3.4 Bitter Taste

As discussed in the section on birds, the ability to sense bitterness may evolve over time and help an animal adapt to the food sources in its environment. As the environment has changed over time, the types of food and toxins that reptiles have found have also changed, sometimes creating an evolutionary mismatch between the presence of a poison (usually a bitter substance) and an animal's ability to taste it (e.g., poisonous cane toads in Australia, highlighted below). Several methods have been used to study the reptilian bitter taste system, typically involving observations of their response to poisonous prey or food that has been tainted with noxious animal secretions (e.g., Barach, 1951; Scott and Weldon, 1989; Weldon and McNease, 1991). When we mention "noxious" or "bitter" compounds, these are, of course, based on human taste perceptions of the same chemicals. Many of the studies below are difficult to interpret because taste is not separated from the other chemosensory systems of reptiles, though investigators do try to make this distinction.

**43.3.4.1 Snakes.** Burghardt et al. (1973) watched snakes' behavior in response to earthworms that the snakes had been trained to find noxious through pairing with an emetic (lithium chloride, LiCl). Snakes would tongue flick and then accept earthworms following the aversion training; rejection occurred only after the earthworm had been seized in the snake's jaws (and presumably encountered taste cells), suggesting a taste-mediated behavioral response. Stanger-Hall et al. (2001) took an even more direct approach: they reported that lizards avoided contact

with crickets treated with QHCl even after the VNO ducts were sealed, suggesting that taste alone was sufficient to elicit the rejection. Many other studies have drawn the conclusion that reptiles can perceive bitter tastes (e.g., Benes, 1969; Price-Rees et al., 2011, 2012; Shanbhag et al., 2010; Sword, 2001) but typically have not accounted for the contribution of the other chemosensory systems, either through behavioral observation or by occluding the olfactory and vomeronasal systems.

The red-spotted garter snake (*Thamnophis sirtalis concinnus*) feeds on rough-skinned newts (*Taricha granulosa*) (e.g., Brodie et al., 2002) that synthesize and secrete the poison tetrodotoxin from their skin. The garter snakes eat these newts, even the ones with the strongest concentration of the toxin, and sometimes go into cardiac arrest and die. Incredibly, though, some populations of these snakes have adapted to detect the toxin, but newts are rejected only after consumption and not during oral contact, which raises the question of whether it is a simple toxicity reaction during digestion or, less likely, taste receptors in the gut that initiate this response. These two possibilities are not mutually exclusive, but the emphasis here is that we simply do not understand the taste biology of this or any other predator-prey system in reptiles. Garter snakes will reject other types of toxic prey after making oral contact with them (e.g., poison frogs, family Dendrobatidae), which suggests they can perceive the bitterness of toxic prey generally (Brodie and Tumbarello, 1978; Dumbacher et al., 2009) but cannot taste tetrodotoxin. Tetrodotoxin (newts) and alkaloids (poison frogs) elicit different gustatory sensations in humans, with the former having no taste and the latter having bitter taste (J. Daly and R. Saporito, pers. comm.; Daly and Myers, 1967; Saporito et al., 2007). Thus, garter snakes may not be able to taste tetrodotoxin either.

In a different example of reptile bitter taste ecology, invasive cane toads (*Bufo marinus*) in Australia produce bitter bufadienolides that apparently cannot be sensed by many resident species, such as varanid lizards and crocodiles, which routinely eat the cane toads and die as a consequence (e.g., Griffiths and McKay, 2008; Letnic et al., 2008). As with the red-spotted garter snake, it may be that these crocodiles and lizards cannot taste the cane toad poison, though other Australian species do exhibit taste-based recognition of bufadienolides (see below). Such relationships may be examples of an evolutionary lag between the introduction of a new poison in the environment and the ability of a predatory species to perceive and avoid it.

**43.3.4.2 Lizards.** The most convincing experimental work on bitter taste behavior in lizards was by Stanger-Hall et al. (2001) on green anoles (*Anolis carolinensis*), which

learn to avoid contact with crickets treated with QHCl (powder or solution, 1 mM). The crickets were colored with tempera paint, and the anoles exhibited strongest learned avoidance behavior to colored crickets treated with quinine (powder but not QHCl solution) when trained. They found that the avoidance behavior could still be learned by anoles with sealed VNO ducts. This finding strongly suggests that gustation is the mechanism for assessing bitter stimuli in green anoles and that it leads to gustation-based learning.

An interesting study using the agamid eastern garden, or changeable lizard (*Calotes versicolor*) also discovered taste aversion learning. Using prey coated with chloroquine phosphate (a compound that tastes bitter to humans) or sucrose (pastes made with pure powders), Shanbhag et al. (2010) found that the lizards exhibited a strong aversion to chloroquine-coated prey. Further, they demonstrated that the lizards learned to visually associate the bitter prey with the color of the presentation dish. Bitter responses to toxic prey and bitter-compound-coated prey have been shown in other lizard species but not in a learning context (e.g., Benes, 1969). This observation corroborates what is known for the eastern blue-tongued lizard (*Tiliqua scincoides*), which will consume poisonous plants that contain bufadienolides. Populations without experience with the toxic flowers will eat them, but some of these lizards will spit them out before swallowing, suggesting gustation enables toxicity assessment (Price-Rees et al., 2012). There are locally adapted populations of the lizards that, because they can metabolize the bufadienolides, can also survive consuming cane toads that produce the same class of toxic compounds (Price-Rees et al., 2012). This same species exhibits rapid taste learning as well, suggesting it can associate toad-based stimuli with the effects of toxin consumption and thus learn to avoid eating the cane toads, though it is not clear if this is taste or vomeronasally mediated (Price-Rees et al., 2011). Other lizards, such as anoles, will reject grasshoppers raised on toxic diets, suggesting an ecological role for bitter perception that may be widespread across lizard groups (Sword, 2001).

Food aversion learning has also been demonstrated in other lizards (*Basiliscus basiliscus*, *B. vittatus*, *Eumeces schneideri*, and *Mabuya multifasciata*) using LiCl injections, which typically make the animal feel sick (Paradis and Cabanac, 2004). In that same study, the researchers have shown that amphibians (*Bufo paracnemis* and *Pachytriton breviceps*) do not exhibit LiCl-induced food aversion learning, though LiCl may not have the same aversive effects in amphibians as it does in reptiles. The evolution of gustatory-based learning may have been a necessary adaptation as a fully terrestrial vertebrate since the lizards tested span a wide range of terrestrial vertebrates that is quite ancient (Bergmann and Irschick, 2011).

**43.3.4.3 Crocodilians.** Studies on taste behavior in this group of reptiles are lacking. There are suggestions that some crocodilians will reject poisonous prey or food that has been tainted with noxious animal secretions (e.g., Barach, 1951; Scott and Weldon, 1989; Weldon and McNease, 1991). A fascinating aside to the putative role of gustation in crocodilians is that female crocodilians carry their offspring in their open mouths. It has been hypothesized that gustatory cues (or at least a signal from the oral cavity) must suppress the mother's biting and swallowing reflexes, though there has been no test of this idea (Ferguson, 1981).

**43.3.4.4 Turtles.** Turtles cannot be trained in operant conditioning using taste alone, but olfactory cues enable conditioning (Manton et al., 1972). Burghardt and Hess (1966) used gustatory cues in food imprinting with neonatal turtles, suggesting that taste plays a role at least in the development of these preferences. However, the turtles in that study had access to olfactory cues from the food items, and it is likely that food choice following conditioning was affected by these cues. Turtles have an exquisitely developed olfactory epithelium and bulb, and much work has demonstrated a central role of olfaction in specific behaviors, such as foraging and open-water homing behavior.

### 43.3.5 Summary

All indications are that at least some reptiles can taste, but little effort has been focused on this neglected sensory system, in part because of the better-known role that the other specialized chemosensory systems play in their ecology. There is a clear need for behavioral methods to study taste as a sense separate from olfaction and to define the qualities that reptiles can detect and at what concentration. Anatomical studies should be expanded to include molecular methods to characterize taste cells; genomic analysis is just beginning, but the presence of apparently functional taste receptors and other taste signaling molecules (Dong et al., 2009) may encourage further work in this area. The green anole (*Anolis carolinensis*) was the first reptile genome to be sequenced (Alföldi et al., 2011), and it has multiple taste genes (Dong et al., 2009), so this new information may guide new research. Anoles have multiple TAS2R genes that form independent clusters when analyzed alongside other tetrapods and fish (Hillier et al., 2004). Anoles also possess the putative sour receptor PKD1L3 (Chen et al., 2011), as well as multiple G<sub>α</sub> subunits (G<sub>q</sub>, G<sub>s</sub>, G<sub>i</sub>, and three forms of G<sub>t</sub>; Ohmoto et al., 2011). It would be most informative to conduct sequence alignments for all of the known lizard sequences with their homologues in mammals. We know that the green

anole possess several bitter receptors (37), a putative sour receptor (1), and the sweet/umami receptor (3 subunits) (summarized in Dong et al., 2012). Thus, the taste world of at least the green anole may actually be quite similar to that of humans and rodents. Though some research has been conducted on sweet and bitter responses in some lizards, there is a glaring lack of behavioral work concerning any of the other taste modalities. In particular, it would be of fundamental use to know which reptiles can sense umami, salty, and sour compounds and, further, what the detection ranges are for these compounds. Terrestrial species would likely offer the most tractable information to complement human and rodent work on the evolution of taste receptors, especially if taste compound preference experiments were expanded to include nerve recordings.

## 43.4 DISCUSSION

### 43.4.1 Challenges and Opportunities in Comparative Taste Biology

When we attempt to study taste from a comparative perspective, the answers even to simple questions, such as whether a given chemical results in taste perception, are not obvious. Most or all chemicals could be tastants for some species. This is a crucial point because often the chemical stimuli chosen for taste research in animals are compounds that have clear tastes to humans and come from the five basic taste qualities. But some species may perceive chemicals and qualities that we cannot, and thus many important tastants are likely unknown and therefore unstudied. Consider the example of artificial sweeteners. Humans detect many compounds as sweet (e.g., aspartame) that apparently do not taste sweet or may even have no taste for other species. This may lead to the conclusion that humans have a “more advanced” sweet taste because it could appear that humans can detect a wider variety of sweeteners. But isn’t it also likely that these other species detect other compounds as sweet that to humans are tasteless or at least do not taste sweet? And how would we identify these compounds? Recent research indicates that the giant panda (*Ailuropoda melanoleuca*) has a strong preference for many of the sugars humans describe as sweet. But to humans, bamboo, the major food of the panda, certainly does not taste sweet. Are there compounds in bamboo that are sweet to the panda? This specific example provides a fascinating area for further research, but more important, it illustrates how humans may often be in the dark when examining the taste worlds of other species.

Taste is tied to diet, but beyond this simple idea there is much we do not understand. What we do know

suggests that every species lives in its own taste world and that understanding an animal’s diet is a first step toward understanding the taste system. Taste ecology has been hampered by the difficulty of comparing the taste systems of diverse species. Rarely are more than one or two species studied at one time with the same methods, and thus attempts must be made to compare results across studies, as we have done here. What is apparent is that seemingly minor differences in testing methodology may lead to different conclusions; for instance, the choice of tastant concentration is paramount when testing sweet preferences in birds. Largely because of these difficulties, direct cross-species comparisons of taste ecology are an underexplored pathway to discovery.

Studies in animals must move beyond a human-centered view of the taste world. The study of sucrose as the exemplar sweet stimuli may favor some areas of research, such as the wealth of data on sweet perception in birds. This serves other species less well, a point made clearly from the study of carnivores, with their “broken” sweet receptor gene, which do not perceive sweetness at all. As a further example, quinine is unlikely to be an exemplar bitter compound for the snake, which rarely encounters this chemical found in tree bark. Therefore, researchers should be vigilant in finding ways to identify chemicals that are ecologically important to animals, especially those that humans cannot taste.

Likewise, researchers need to reconsider traditional boundaries between taste and other types of chemosensory systems. For instance, the differences between taste and the common chemical sense or chemesthesia (cool, burn, sting, etc.) are clear and straightforward for oral chemosensation because they are mediated by different cranial nerves and have different initial connections in the central nervous system. However, things become more confusing for extraoral taste receptors. In this case these “taste” receptors may communicate directly with trigeminal (chemesthetic) nerves (Finger et al., 2003), thereby confusing these two sensory systems at the anatomical as well as the functional level. We may need to revise what we mean by “taste.”

### 43.4.2 Applied Aspects of Animal Taste

Understanding the taste perceptions of animals has practical implications. An obvious benefit is that understanding what an animal perceives as good or bad taste can help us provide them with more palatable, perhaps more nutritious food, or help us generate repellents for nuisance species. A less obvious but not less important benefit may be the contribution of taste ecology to conservation efforts, especially understanding which chemicals might be most toxic to which species. Each species has its own repertoire of bitter receptors (Conte et al., 2002, 2003; Dong et al., 2009;

Fredriksson and Schioth, 2005; Gloriam et al., 2007; Go, 2006; Lagerstrom et al., 2006; Shi and Zhang, 2006). New bitter receptors emerge or are silenced over time within an animal's genome (Go, 2006; Parry et al., 2004), and some receptors evolve to recognize toxins in the environment (Kim et al., 2005; Wang et al., 2004). Thus, understanding the bitter receptor repertoire in each animal group might point to the chemicals most damaging to them.

### 43.4.3 Conclusion

Comparative taste biology is an old field with new and exciting opportunities. More studies, especially those that integrate anatomy, behavior, and genotype, are needed to deepen our understanding of the relationship between the sense of taste and feeding ecologies of different species. These studies may also help us understand how our own evolutionary history shaped human taste and diet choice. Such an understanding is necessary if we are to successfully confront a changed food and taste environment that now results in such high rates of obesity, diabetes, and hypertension, all diseases directly relevant to our taste biology.

## Functional Organization of the Gustatory System in Macaques

THOMAS C. PRITCHARD and THOMAS R. SCOTT

### 44.1 INTRODUCTION

The Primate Order spans a range of animals comprising prosimians, New World (platyrhini) and Old World (catarrhini) monkeys, greater and lesser apes, and humans (homonids). Simians have been genetically distinct from prosimians for nearly 60 million years, Old from New World monkeys for 36 million years, and apes from Old World monkeys for 25 million years. Given these periods of prolonged genetic isolation, the consistency in gustatory structure and function across the Order is perhaps more surprising than the variations.

Primates offer a faithful neural model for human gustation, so it is a matter of concern that the laboratories on three continents that provided this evidence have now closed. This has been due largely to retirements, and to the demands and expense of maintaining primates, but, on a more positive note, to the increasing prominence of non-invasive imaging techniques in humans, particularly functional magnetic resonance imaging (fMRI) and positron emission tomography (PET). Although non-invasive imaging techniques have brought important insights into complex sensory, cognitive, clinical, and behavioral issues in humans, coding by individual neurons remains well beyond its scope, and due to its invasive nature, these studies must be performed on laboratory animals. Non-invasive imaging techniques also lack the spatial and temporal resolution necessary to address important issues in sensory perception and integration that typically occur on a millisecond time scale. Even with these limitations, data collected with fMRI and PET are relevant to our discussion of the gustatory system in nonhuman primates, and for this reason, imaging data, collected mostly from

human subjects, will be included, as necessary, to expand the picture of taste processing in monkeys.

In this chapter, we will summarize what is known about the anatomy, physiology, and function of five levels of the gustatory system in the primate: (1) peripheral nerves, (2) medulla, (3) thalamus, (4) cortex, and (5) ventral forebrain. The extant taste literature is not uniformly distributed across these areas, so this review, likewise, will emphasize research on the peripheral gustatory system and the cerebral cortex. The content of this review also reflects the broad focus of research in the periphery on both New and Old World monkeys, and the great apes, versus the almost singular use of Old World monkeys and humans for central nervous system research.

### 44.2 PERIPHERAL ORGANIZATION OF TASTE

#### 44.2.1 Taste Buds

Gustatory transduction occurs when sapid stimuli in the oral cavity bathe the exposed pores of taste buds embedded in the epithelial surface of the tongue, soft palate, epiglottis, pharynx, and larynx (Bradley, 1971). Taste buds are small (50  $\mu\text{m}$  diameter), goblet-shaped ensembles of 40–60 receptor, sustentacular, and basal (stem) cells (Miller, 1995). Each receptor cell has an apical tuft of microvilli that communicates with the intraoral cavity via a small opening or taste pore. Taste transduction takes place via receptor proteins and ion channels that line the microvillar membrane. Taste buds on the tongue are encased within larger structures called papillae. Three types of papillae

have been identified: fungiform, foliate, and circumvallate; they vary in size and shape, and each has a unique regional distribution on the tongue.

Fungiform papillae, which are located along the perimeter of the anterior two-thirds of the tongue, are the easiest to access, and for that reason, they have received the most attention from sensory physiologists. Sergovia et al. (2002), after counting the number of taste pores on the superficial surface of fungiform papillae in humans, reported that each papilla contains an average of six taste buds (range = 0–28). The foliate papillae are a series of four or five epithelial folds along the lateral edge of the tongue, adjacent to the palatoglossal arch. Because taste buds line the walls of the foliate papillae, sapid stimulation is most effective when the mechanical action of chewing opens the papillary folds. Although taste buds of the foliate papillae are described as vestigial in some textbooks, sapid stimulation of the foliates in monkeys evokes a robust response in neurons within the thalamic taste relay (Pritchard, unpublished observations, 2000) and presumably the rest of the gustatory neuraxis.

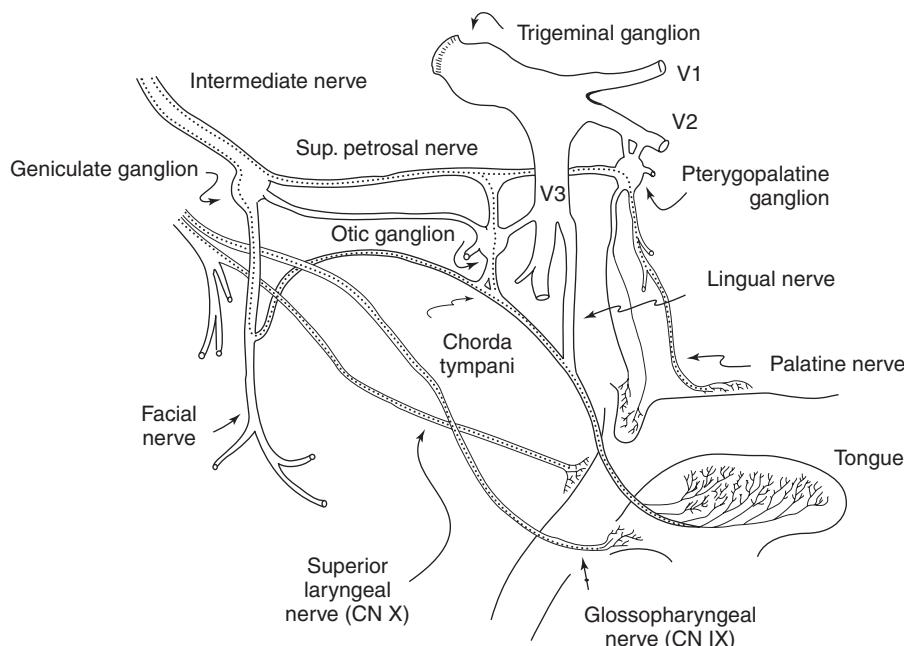

In monkeys, the circumvallate papillae are 3–6 bunker-like structures that straddle the midline on the posterior tongue (Bradley et al., 1985; Emura et al., 2002). Each papilla is surrounded by a deep trench or vallum that is filled with the mucous secreted by nearby von Ebner's glands (Sbarbati et al., 1999). Mucous within the vallum helps dissolve tastants and transport them through the narrow cleft and toward the taste receptors (Beidler, 1995). Optimal stimulation of the circumvallate taste buds occurs

during mechanical stimulation of the posterior tongue by the hard palate during mastication. In monkeys, taste buds line the papillary surface; in humans, they are also found on the epithelial surface. Even though the circumvallate papillae contain almost half of all taste buds, their relative inaccessibility has limited investigation of their response properties.

All mammals examined to date have taste buds on the soft palate, pharynx, epiglottis, and larynx. Unlike taste buds located on the tongue, those on the extralingual surfaces are not embedded in distinct papillae. In both primate and non-primate species, the extralingual taste buds are found in small clusters within islands of keratinizing, stratified, squamous epithelium (Cleaton-Jones, 1971; Klein and Schroeder, 1979; Klein et al., 1979). Taste buds located on the extralingual epithelium are more likely involved with airway protection than taste perception (Harding et al., 1978; Miyaoka et al., 1998; Sweazey et al., 1994; Jowett and Shrestha, 1998).

#### 44.2.2 Taste Bud Innervation

In primates, the taste buds within the fungiform papillae and the anterior half of the foliate papillae are innervated by the chorda tympani (CT) nerve, a branch of the facial nerve (McManus et al., 2011; see Figure 44.1). The lingual nerve provides non-gustatory innervation to the fungiform and foliate papillae on the anterior two-thirds of the tongue. Taste buds within the circumvallate papillae and the posterior foliate papillae, as well as non-gustatory structures

**Figure 44.1** Neural innervation of the oral cavity. (Diagram adapted with permission from Oxford University Press).

on the posterior third of the tongue surface, are innervated by the lingual branch of the glossopharyngeal (GP) nerve (Taillibert et al., 1998).

The neural supply of the extralingual taste buds remains uncertain, but research conducted in a variety of primate and nonprimate species implicates branches of the GP and vagus nerves, and just as importantly, excludes other nerves from consideration. Because the GP and vagus nerves carry information from multiple sensory modalities, it is not uncommon for individual gustatory axons to respond to thermal and even tactile stimulation, typically of the same receptive field. For this reason, tracing studies have not been able to isolate gustatory, tactile, and thermal axons from one another, but this design limitation bears more on the central projections of these modalities than the nerves that innervate the peripheral structures.

Based on comparative data, the anterior part of the soft palate is innervated by the greater superficial petrosal nerve (rat, Miller and Spangler, 1982), while the posterior region is supplied by the GP nerve (rat, Hamilton and Norgren, 1984; cat, Yoshida et al., 2000), and possibly the vagus nerve (rat, Hamilton and Norgren, 1984). In monkey and human, the GP nerve innervates the nasopharynx (Kanagasuntheram et al., 1969; Leela et al., 1971) and probably the epiglottis and pharynx (Mu and Sanders, 2000; Toure and Vacher, 2005), but based on data in sub-primate species, a role for the superior laryngeal branch of the vagus nerve cannot be ruled out (Hanamori and Smith, 1986; Yoshida et al., 2000). The superior laryngeal nerve, which innervates the larynx in the rat and cat (Norgren, 1984; Stedman et al., 1980; Yoshida et al., 2000), is presumed to supply the larynx in the monkey as well.

### 44.2.3 Response Properties of Peripheral Taste Nerves

**44.2.3.1 Fiber Types and Labeled Lines.** The first electrophysiological recordings from taste nerve fibers of primates were conducted in Sweden using rhesus macaques more than a half century ago (Gordon et al., 1959). As has become the custom, the authors separated the fibers into types, in this case, those rather specifically responsive to sodium, to acids, or to quinine, and those more broadly tuned to sugars and non-sweet stimuli.

Breadth of sugar sensitivity proved meaningful in the interpretation of gustatory coding strategies. In the late 1960s, whole nerve recordings from the CT nerve of the squirrel monkey established the order of effectiveness of saccharides: fructose > sucrose > glucose (T. Snell, unpublished thesis, 1968). The order of neural effectiveness, however, differed from the order of behavioral preference: sucrose > fructose > glucose (Ganchrow and Fisher, 1968). Pfaffmann (1974) resolved this discrepancy

to his satisfaction upon recording from single fibers in the chorda tympani nerve of the squirrel monkey and discovering that sweet-best fibers reliably showed the sequence that paralleled behavior (sucrose > fructose > glucose) which had been obscured in the whole nerve recordings by sideband sensitivity to fructose in salt-sensitive fibers. Pfaffmann concluded that the perception of sweetness that was driving the monkey's behavioral preferences was carried exclusively by sweet-best fibers and that activity induced in other fibers by sugars was irrelevant to the afferent code, i.e., that sweetness was carried in a labeled line devoted to its detection. Since Pfaffmann had been the author of the competing "across-fiber pattern" theory, in which activity of all fibers was integral to each afferent signal (Pfaffmann, 1941), his conversion, based on monkey data, was a signal moment in the history of gustatory neural coding.

Further recordings from the CT nerve of macaques reaffirmed the existence of four fiber types, although those responding to sweet, salty, and bitter stimuli were more narrowly tuned than those sensitive to acids, which usually had sideband sensitivity to salts (Sato et al., 1975).

This theme of specificity is repeated through the succeeding decades of recordings from primate peripheral taste nerves. Danilova and colleagues recorded single fiber activity from both the CT and GP nerves of the marmoset (a New World monkey), and reported three prevalent fiber types: sweet-best, bitter-best, and sour-best, with a lesser representation of salt (Danilova et al., 2002; Danilova and Hellekant, 2004). Stimuli that activated narrowly tuned fibers elicited the expected preference or avoidance behavior in two-bottle preferences tests, implying that each fiber type serves as a labeled line for its associated taste quality.

Hellekant et al. (1997) established a clearer distinction between the contributions of the CT and GP nerves when they compared the sensitivities of their respective single fibers in macaques. Salt responsiveness characterized 40% of the CT fibers, but only 15% of those in the GP nerve; sucrose activated 34% of CT fibers versus 24% of those in the GP; acids stimulated 17% of CT fibers, but none in the GP. Thus, three of the presumed basic taste qualities were favored in the CT nerve. By comparison, activity in the GP nerve was heavily skewed toward the fourth basic taste quality: quinine activated 61% of GP axons, but only 9% of those in the CT nerve. Upon application of the sweet inhibitor lactisole, responses to sugars were suppressed in sweet-best fibers but not in other fiber types that had side-band sensitivity to sugars. This finding, once again, implied that the perception of sweetness was carried exclusively by sweet-best fibers (Wang et al., 2009). The themes of specificity and separation of function among peripheral nerve fibers of the macaque were reinforced and then extended to chimpanzees, one of the great apes. Recordings

from single fibers of the CT nerve in chimpanzees revealed an exceptionally low breadth-of-tuning coefficient of 0.30,<sup>1</sup> indicating that each axon had a high degree of response specificity (Hellekant et al., 1997). Here, in distinction to reports from macaques, fibers were divisible into three classes: sucrose (50%), NaCl (31%), and quinine (19%); none responded to acid. Sodium-responsive fibers were further divisible into subclasses that were (1) specifically responsive to sodium (i.e., salt-best fibers) and suppressed by the sodium-channel blocker amiloride, (2) broadly sensitive to sodium and potassium, but not affected by amiloride, and (3) responsive to sodium and monosodium glutamate, a stimulus that presumably carries the umami quality.

Hellekant et al. (1998) then examined whether labeled lines were responsible for coding specific taste qualities, as had been implied by the reports above. They reasoned that if a defined set of fibers were responsible for coding a basic taste quality, then suppression of activity in that group of fibers would block the associated perception; conversely, activation limited to those fibers would create the signature percept. To this end, Hellekant et al. (1998) used gymnemic acid and miraculin to manipulate the sweetness of sapid stimuli. Gymnemic acid suppresses sweet taste in humans (Frank et al., 1992) and chimpanzees (Hellekant et al., 1996); miraculin, contains a glycoprotein whose sugar component is unable to stimulate sweet receptors until its conformation is altered in the presence of acids (Miller and Bartoshuk, 1991). Hellekant et al. (1998) reported that gymnemic acid suppresses the responses of sucrose-best fibers in the CT nerve, while preserving sucrose side-band sensitivity in sodium-best and quinine-best fibers. Conversely, application of miraculin to the tongue caused sucrose-best fibers in the CT nerve to respond to acids, an effect that was subsequently abolished by the application of gymnemic acid. The authors concluded that sucrose-best fibers satisfied the criteria for a labeled line because (1) they are activated either by sucrose or by miraculin's effect on acids; (2) their activity is positively correlated with sweet perception, as judged by behavioral acceptance; and (3) gymnemic acid, which suppresses CT neural responses to sweet stimuli, also blocks sweet perception.

<sup>1</sup>The breadth-of-tuning coefficient is a measure of the degree to which a single cell responds to each of the four prototypical stimuli: sucrose, NaCl, HCl, and quinine (Smith and Travers, 1979).

The equation is:  $H = -k \sum p_i \log p_i$

where  $H$  = breadth of tuning;  $k$  = a scaling constant (here,  $k = 1.661$ ) such that  $H = 1.0$  when the neuron responds equally to all four stimuli;  $p_i$  = proportional response to each of the four stimuli;  $i = 1-4$  stimuli.

#### 44.2.3.2 Variability of Taste Perception Across the Primate Order.

##### PERCEPTION OF SALTY AND SOUR STIMULI

Salty and sour perception is similar across Primate species because transduction for both qualities is mediated by the widely distributed classes of ionotropic receptors.

##### PERCEPTION OF SWEET STIMULI

Differences among primate species with respect to sweetness are the rule rather than the exception. The most accurate diagnostics to evaluate interspecies differences in sweet perception is relative sensitivity to sugars, amino acids, dipeptides, proteins, etc., and the differential effectiveness of sweet-inducing or sweet-suppressing chemicals such as miraculin and gymnemic acid.

Glaser et al. (1995) provided important insight into the evolution of sweet receptors by testing preference for the sweeteners aspartame and thaumatin in 50 species of Primates including prosimians, New and Old World monkeys, lesser and greater apes, and humans. The two-bottle preference data from this massive survey were consistent: all species of prosimians and New World monkeys were indifferent to aspartame and thaumatin; all species of Old World monkeys, and apes, as well as humans preferred them to water. As a demonstration of how idiosyncratic these binding interactions can be, the sweetener alitame, a dipeptide derived from aspartame, was preferred by all primate species. Thus, the binding site for alitame is older than the 60 million year division between prosimians and simians, while the binding site for aspartame and thaumatin is more recent than the 36 million year split between New and Old World monkeys (Kappelman, 1992). On a finer time scale, miraculin induces sweet taste in the presence of acids in simians (New and Old World monkeys), apes, and humans, but not in the more primitive prosimians (Hellekant et al., 1981).

The basis for species differences in sweet perception have been traced to a specific region of the sweet receptor. The genes Tas1R2 and Tas1R3 produce the associated G-protein-coupled receptors T1R2 and T1R3, which together form the heterodimer that detects sweet stimuli. While the docking site on the T1R2 receptor that is stimulated by monosaccharides (e.g., glucose, fructose) and the disaccharide sucrose is universal across the Order, the effectiveness of other molecules appears to vary across primate species.

With the discovery of the T1R family of receptors for sweet stimuli, Nelson et al. (2001) and Li et al. (2011) sequenced the genes between aspartame tasters and non-tasters in three New World monkeys (tamarin, marmoset, squirrel monkey), three Old World monkeys (macaque, patas monkey, baboon), three apes (chimpanzee, gorilla, orangutan), and humans. These studies revealed nine variant sites along the Tas1R2 gene, and 32 variants

along the Tas1R3 gene in New and Old World monkeys. Li et al. (2011) concluded that the most likely binding location for aspartame was an allosteric site on the T1R2 receptor that could cause a conformational change in the protein. Based upon the work of Glaser et al. (1995), it appears that prosimians and New World monkeys lack this allosteric site.

The similarity of Old World monkeys, apes, and humans in the taste preference experiments conducted by Glaser et al. (1995) suggest that these species represent an homogenous group. However, use of a different diagnostic test – suppression of sweet taste by gymnemic acid – shows that sweet perception is not identical in these primates. Gymnemic acid suppresses sweet taste in humans, chimpanzees, and gibbons (Hellekant et al., 1990), but not in macaques (Hellekant et al., 1996). Studies of the kinetics of gymnemic acid action on taste imply that it does not compete with the sweet molecule, but rather binds to a site on the receptor that renders the normal sweet receptor sites inoperable (Kennedy, 1989). These results, considered in light of the Glaser et al. (1995) data, suggest that the sweet receptors of Old World monkeys are similar to, but not identical to those of humans and apes. Whether humans and apes (chimpanzees, gibbons) perceive sweet in an identical fashion is an empirical question.

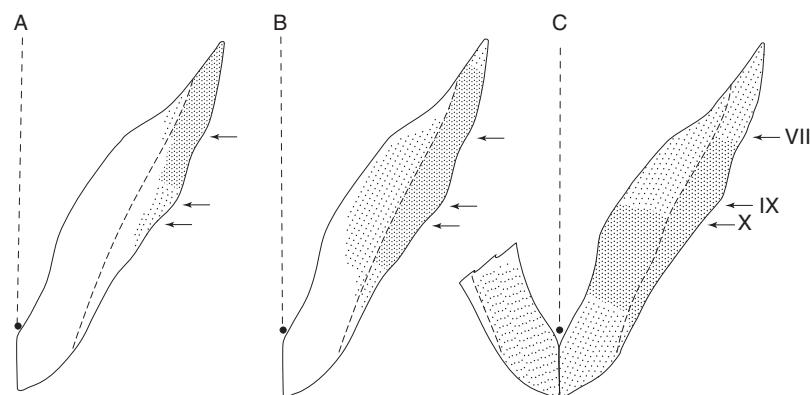

**PERCEPTION OF BITTER STIMULI** Primates deploy a large family of genes which produce the proteins that, collectively, detect most harmful chemicals (Chandrashekhar et al., 2000). Despite the prevalence of harmful, bitter substances in the environment, few studies have investigated bitter perception in primates. The demonstration by

Behrens and Meyerhof (2008) that the Tas2R bitter gene family is identical in humans and chimpanzees indicates that the genes and pseudogenes of bitterness have been conserved over the six million years of separation between these two species.

## 44.3 CENTRAL TASTE PATHWAYS

### 44.3.1 Nucleus of the Solitary Tract

**44.3.1.1 Anatomy.** Gustatory axons of the facial, GP, and vagus nerves enter the rostral medulla and coalesce into the solitary tract, which divides its namesake, the nucleus of the solitary tract (NST), into lateral and medial segments (Beckstead and Norgren, 1979). The facial and GP fibers terminate in the lateral division, while axons of the vagus nerve terminate within the medial division; the GP nerve terminates in both (Beckstead and Norgren, 1979; Satoda et al., 1996; Rhoton, 1968; Figure 44.2). These anatomical data are complemented by numerous electrophysiological studies in the rat (Norgren, 1978; Chen and DiLorenzo, 2008), rabbit (Schwartzbaum and DiLorenzo, 1982), hamster (Travers, 1988; Cho and Li, 2008), and monkey (Beckstead et al., 1980; Scott et al., 1986a) which confirm that second-order gustatory neurons are located within the rostral NST while viscerosensory neurons are located further caudally. Based upon data collected in the rat, neurons that respond to taste stimulation of the anterior tongue are located rostrally to those with receptive fields on the posterior tongue (Travers and Norgren, 1995).

**Figure 44.2** Central distributions of cranial nerves VII, IX, and X (Panels A, B, and C, respectively) within the NST of the macaque. The three panels show outlines of the NST in the horizontal plane, with rostral to the top of the page and lateral to the right, viewed from above. In each panel, the vertical dotted line indicates midline, the obex is marked by a filled circle, and the entry level of cranial nerves VII, IX, and X into the NST are marked by arrows. The dotted line coursing through the NST separates the medial and lateral subdivisions of the nucleus. Autoradiographic label density within the NST following injections of cranial nerve VII, IX, and X ganglia is indicated by two stippling densities. Only the vagus projects to the contralateral side of the NST. (Diagram constructed with data originally summarized in Beckstead and Norgren, 1979. Used with permission from Lippincott, Williams, and Wilkins).

**44.3.1.2 Physiology.** In Old World monkeys, there is substantial overlap of facial, GP, and vagal terminals within the gustatory region of the NST (Pritchard et al., 2000), yet this rostral-to-caudal (gustatory-to-viscerosensory) organization is preserved (Beckstead et al., 1980). In humans, Topolevec et al. (2004) and Komisaruk et al. (2002) used fMRI to demonstrate that sapid stimulation of the tongue activates the rostral NST whereas tasks designed to modulate blood pressure and heart rate (forced maximal inspiration, sustained isometric muscle contraction, and the Valsalva maneuver) activate the medulla more caudally. Thus, based upon a variety of complementary anatomical, electrophysiological, and imaging studies, the organization of the NST into a rostral-lateral, gustatory region and a caudomedial, visceral region is highly conserved across species. The proximity of these two systems in the medulla may contribute to brainstem control of feeding and digestion; further rostrally, however, the organization of the gustatory and visceral afferent systems differ significantly from each other, both within and across species.

Whereas gustatory data from the peripheral nerves of Primates have accumulated over a half century from laboratories around the world, information on the NST began and ended in Oxford in 1984. Two reports emerged from that effort.

In the first, Scott et al. (1986a) reported that NST taste neurons respond at threshold concentrations and have concentration-response functions matching those from human psychophysical studies (Collings, 1974). In distinction to data from peripheral nerves, NST cells are broadly tuned across the prototypical taste stimuli, with a mean breadth-of-tuning coefficient of 0.87. The majority of NST cells respond maximally to sweet (40%) and salty (35%) stimuli more often than to bitter (17%) or sour (8%) fluids.

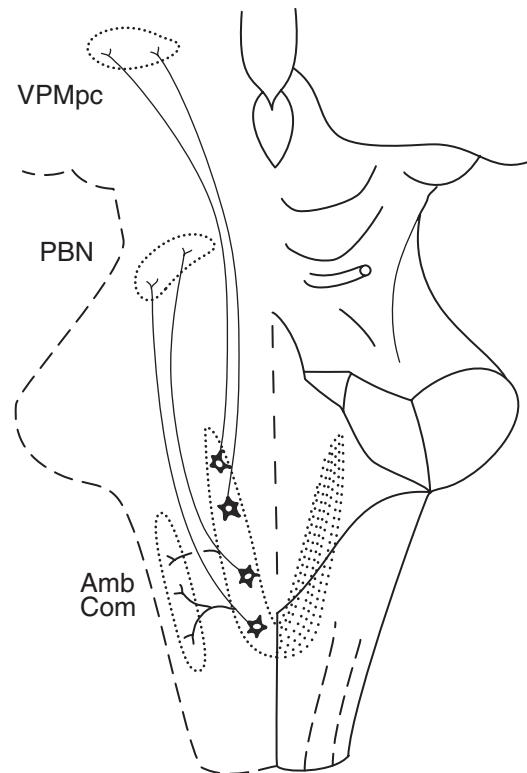

The second report had its roots in previous rodent research, specifically studies by Scott and colleagues that suggested that the taste system was malleable according to the physiological state of the animal, altering its sensitivity to direct the animal's food choices (Chang and Scott, 1984; Giza and Scott, 1983; Jacobs et al., 1988). Rolls and colleagues countered that human gustatory perception remained unchanged during the progression from hungry to satiated during a meal, a finding that would not permit such malleability at the hindbrain level (Rolls et al., 1981, 1982). In a series of studies, beginning in the NST, Scott and Rolls addressed this issue by cutting through the three levels of ambiguity inherent in the literature (rodent vs primate, anesthetized vs awake, NST vs a presumed cortical perception).

Yaxley et al. (1985), by recording from individual NST neurons of awake macaques over the course of a meal, determined that feeding to satiety has no effect on taste responses to the prototypical stimuli. These data countered

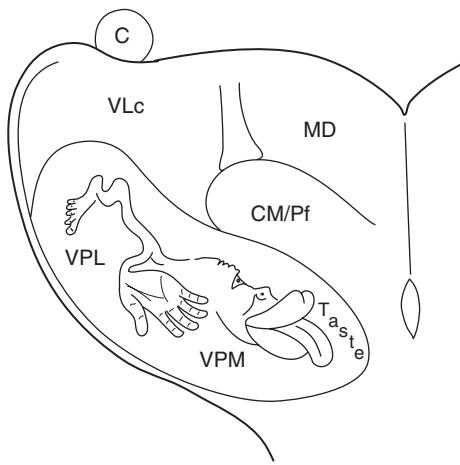

the predictions based on previous rodent experiments, but more importantly, they were consistent with data from human psychophysical studies (Rolls et al. 1981). Subsequent studies at the cortical level on this issue are described below.

Isolating taste cells from the NST of awake macaques is a daunting task. Because the NST is a narrow, elongated nucleus consisting of small, tightly-packed neurons, deep in the posterior cranial fossa where brain movements are common, it is unlikely that the literature on the macaque NST will expand in the near term.

**44.3.1.3 Projections.** Axons originating in the rostral, gustatory region of the NST ascend through the brainstem within the central tegmental tract and terminate in the parvicellular division of the ventroposteromedial nucleus of the thalamus (VPMpc; Beckstead et al., 1980; see Figure 44.3). The location of the taste relay within the most medial aspect of the ventrobasal complex completes the image of the sensory homunculus that stretches across the ventral nucleus of the thalamus. As Figure 44.4

**Figure 44.3** Projections of the NST to the caudal brainstem and diencephalon of the Old World monkey. Projections to the PBN originate in the caudal NST, which receives significant afferent input from the vagus nerve. Axons originating in the rostral, primarily gustatory part of the NST, bypass the PBN and terminate in the caudal aspect VPMpc. (Used with permission from John Wiley & Sons, Inc.).

**Figure 44.4** Diagram showing the topographic organization of the somatosensory and gustatory systems within the ventrobasal thalamus. The head and face representations are located within the ventroposteromedial nucleus (VPM), which is located medially to the body representation within the ventroposterolateral nucleus (VPL). The thalamic taste area, the most medial tenant of the ventrobasal thalamus, is located with the parvicellular division of the ventroposteromedial nucleus (VPMpc). Abbreviations: CM/Pf=centromedian/parafascicular nucleus; CN=caudate nucleus; IC=internal capsule; LD=lateral dorsal nucleus; VLc=ventral lateral nucleus, pars caudalis; VPI=ventroposteroinferior nucleus.

shows, somesthetic sensation from the torso/limbs, and head/mouth is represented within the ventroposterolateral nucleus (VPL) and VPM nuclei, respectively, while taste and visceral sensation are located most medially within the adjacent VPMpc.

This direct NST-VPMpc projection in nonhuman primates represents a significant departure from the ascending taste pathway rats, hamsters, mice, and cats. In these subprimate species, gustatory neurons in the NST project to the pontine parabrachial nucleus (PBN), which in turn, sends axons to VPMpc (Loewy and Burton, 1978; Norgren, 1978; Norgren and Leonard, 1973; Tokita et al., 2009; Halsell, 1992; Nomura et al., 1979). There is ample electrophysiological evidence showing that the PBN in these species contains gustatory neurons (Halsell and Travers, 1997; Halsell and Frank, 1991, 1992; Cho and Li, 2008; DiLorenzo and Schwartzbaum, 1982), but there is no evidence in any primate species that the PBN neurons respond to taste (Pritchard et al., 2000). Rather than gustation, the PBN in the monkey is an important relay for general visceral and nociceptive information bound for the forebrain, and accordingly, it receives direct projections from the caudal viscerosensory NST (Beckstead et al., 1980) and lamina I of the spinal cord (Westlund and Craig, 1996). A minor, but direct, projection from the PBN to VPMpc exists in monkeys, but based upon the afferent

connectivity of the PBN, this presumably relates to visceral sensation. It is also significant that the visceral projections from the PBN terminate in the rostral half of VPMpc rather than the thalamic taste area which is located further caudally (Pritchard et al., 2000). Thus, VPMpc and NST both have gustatory and visceral subdivisions, but unlike the NST, in the thalamus, the taste area is located within the caudal half of the nucleus (Pritchard et al., 2000).

### 44.3.2 Thalamus

**44.3.2.1 Anatomy.** In every species studied to date, electrophysiological studies have confirmed that the thalamic gustatory relay is located in VPMpc (primate: Benjamin, 1963; Pritchard et al., 1986, 1989; Reilly and Pritchard, 1995; subprimate: Scott and Erickson, 1971; Verhagen et al., 2003). As discussed above, gustatory neurons are located only within the caudal half of VPMpc, and further sequestered within the medial half of the nucleus; the lateral half of VPMpc is populated by neurons that respond to oral somatosensory or visceral stimulation (Burton and Benjamin, 1971; Pritchard et al., 1986).

**44.3.2.2 Physiology.** Like neurons in the NST, the coding properties of cells in the thalamic taste relay have received little attention from the taste community. One reason may be that the sensory thalamus, in general, has been an enigma and often dismissed as a passive relay to the cerebral cortex where conscious perceptions are probably generated. Although clearly not true, when the techniques of chronic recording in awake, behaving monkeys finally reached the gustatory system, little was accomplished in the NST or the thalamus before the attention shifted to the cerebral cortex.

A significant finding reported by Pritchard et al. (1989) was the presence of ipsilateral gustatory receptive fields in VPMpc. Although this result was expected based upon previous anatomical studies in monkeys, the confused clinical literature on this issue has called into question whether taste ascends from tongue to cortex ipsilaterally (Pritchard et al., 1989; Pritchard, 2012). Other electrophysiological evidence that the taste system in primates is organized ipsilaterally was provided by Lenz et al. (1997). In these studies, the posterior thalamus in the vicinity of the ventroposterolateral nucleus, pars oralis and caudalis (VPLo, VPLc, respectively) and VPMpc was electrically stimulated in three awake thalamotomy patients. Lenz's patients reported a variety of intra- and perioral sensations, including a sour taste that localized to the side of the tongue ipsilateral to the locus of stimulation.

Pritchard et al. (1989) reported that gustatory-evoked responses are less sluggish in the thalamus than reported for the NST by Scott et al. (1986a); sugar and salt remain

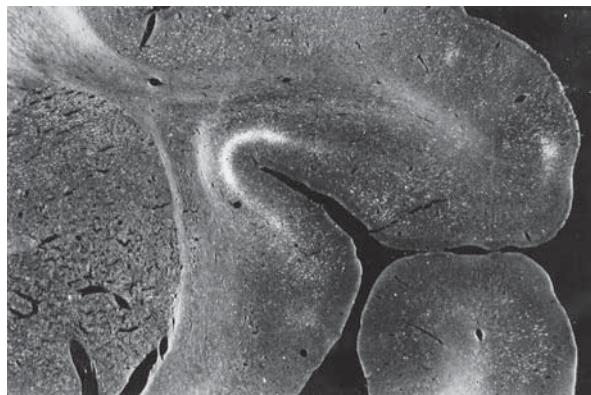

the most effective stimuli. Although the minor decrease in breadth of tuning from 0.87 in the NST to 0.73 in the VPMpc suggests that neurons in the thalamus are almost as broadly tuned as those in the medulla, this appearance primarily reflects the nonlinearity of the entropy statistic (see Pritchard et al., 1989 for a discussion of this issue). In fact, NST neurons are considerably more broadly tuned than taste neurons in the thalamus. As in all other levels of the gustatory neuraxis, VPMpc is an admixture of sensory modalities (Benjamin, 1963; Pritchard et al., 1989). Taste-responsive neurons constitute 36% of those in the nucleus, but tactile (11%) and thermal-responses (<1%) neurons are present, as are non-responsive cells (18%) and neurons that respond prior to stimulus delivery (35%).

### 44.3.3 Insular-Opercular Cortex

**44.3.3.1 Anatomy.** Third-order gustatory neurons in VPMpc project to a small crescent of granular neocortex at the junction of the rostral insula and the inner operculum (Benjamin and Burton, 1968; Benjamin et al., 1968; Pritchard et al., 1986; see Figure 44.5). This terminal area is densest within the fundus of the superior limiting sulcus and tapers gradually into the dysgranular cortices of the body of the insula and the inner operculum. Because these thalamocortical projections originate in the medial, gustatory portion of VPMpc, this terminal area is, by anatomical definition, primary taste cortex.

Taste responses have been recorded from three areas that either receive direct projections from VPMpc or from primary taste cortex (1) insular-orbital cortex; (2) the inner and outer frontal opercula; and (3) the posterior insula. The latter two contain predominantly, if not exclusively, higher-order cortical taste neurons.

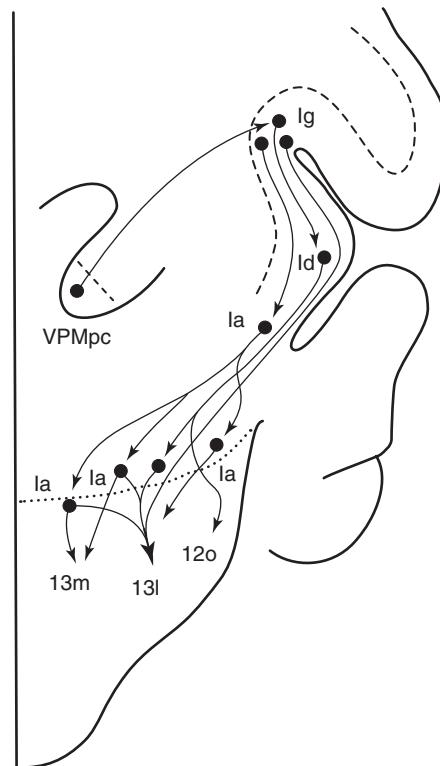

1. The most significant projections from primary taste cortex terminate in the dysgranular and agranular cortices that stretch from the body of the insula ventrally

**Figure 44.5** Darkfield photomicrograph of terminal label in insulo-opercular cortex after a tritiated amino acid injection into the taste-responsive area of VPMpc.

and rostrally across the posterior orbital cortex, and finally into the posterior orbitofrontal cortex (OFC; Carmichael and Price, 1995). The agranular insula also receives direct projections from the dysgranular insula (see Figure 44.6; Mesulam and Mufson, 1982; Mufson and Mesulam, 1982; Morecraft et al., 1992; Barbas, 1993; Carmichael and Price, 1995). Based upon its connectivity to primary taste cortex, the dysgranular and agranular insulae represent higher-order taste cortices. Given the complexity and redundancy of this multi-neuron network, it is not possible to specify or even separate the admixture of secondary from tertiary (from quaternary and beyond) taste cortices in these areas. For this reason, the body of the insula as well as the orbital and orbitofrontal cortices should be designated only as higher-order taste cortices.

2. A minor projection from primary taste cortex to the inner operculum (Brodmann areas (BAs) 1 and 2) and the precentral extension of BA 3b on the lateral convexity (Pritchard, unpublished observations, 1991) probably accounts for the few taste-responsive neurons found in these areas (Sudakov et al., 1971; Ogawa et al., 1989). These are the same areas of

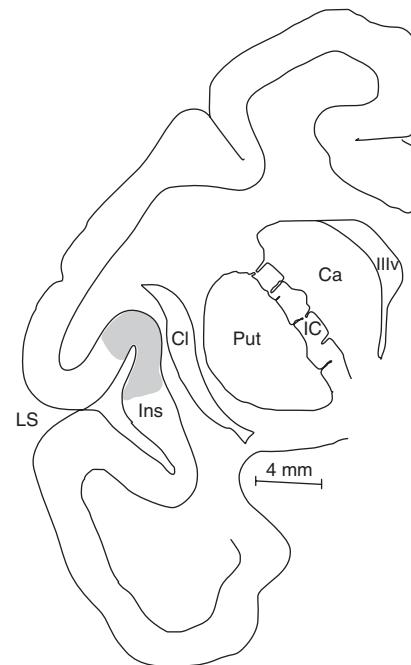

**Figure 44.6** Thalamocortical and cortico-cortical gustatory projections of the Old World monkey. This diagram shows the thalamic and insular gustatory relays in the coronal plane appended to the ventral surface of the OFC. Abbreviations: BA12o, BA13l, BA13m; Ia=agranular insula; Id=dysgranular insula; Ig=granular insula.

cortex where evoked potentials have been recorded following electrical stimulation of the chorda tympani and lingual-tonsillar branch of the glossopharyngeal nerve (Benjamin and Burton, 1968; Benjamin et al., 1968). The precentral extension of BA 3b also receives a direct projection from the oral somatosensory area located at the VPMpc/VPM border (Pritchard et al., 1986).

- There are no direct projections from the gustatory thalamus to the middle or posterior insula, where taste responses have been observed in humans using magnetoencephalography (MEG; Wakita et al. (2009)), fMRI (Del Parigi et al., 2005), and PET (Kobayashi et al., 2002), and reported during psychophysical testing of stroke patients (Pritchard et al., 1999). The most plausible route for taste information to reach the middle and posterior insula is a minor projection that originates in the body of the rostral insula (Mesulam and Mufson, 1982).

**44.3.3.2 Physiology.** Sudakov et al. (1971) provided the first description of taste-responsive neurons in the insula, inner operculum, and the lateral convexity of alert monkeys. Perhaps the most salient feature of this and subsequent studies is that taste cortex contains so few taste neurons. This study, the only one conducted in New World monkeys to date, showed that only 3.2% (14 of 437) of the neurons located in primary taste cortex respond to sapid stimulation of the tongue. Although these taste neurons are interspersed with oral, tactile neurons, convergent taste/tactile responses were not encountered. Within the adjacent frontal operculum, gustatory neurons account for only 3.7% of the population. Ogawa et al. (1989) examined these areas in anesthetized monkeys and reported that about half of the taste-responsive neurons in their sample are located within the granular cortex adjacent to the crest of the superior circular sulcus. Only 3.1% of the neurons within the inner and outer opercula respond to sapid stimulation of the tongue, and in the dysgranular cortex of the insula, neurons responsive to mechanical stimulation of the oral cavity outnumber taste neurons 8 to 1. Ito and Ogawa (1994), using alert monkeys and working with a larger sample of neurons, reported that most of the taste neurons they sampled were located within the inner operculum. Together, these reports show that somatosensory neurons and other neurons for which the adequate stimulus cannot be identified greatly outnumber gustatory neurons within the insula and frontal operculum.

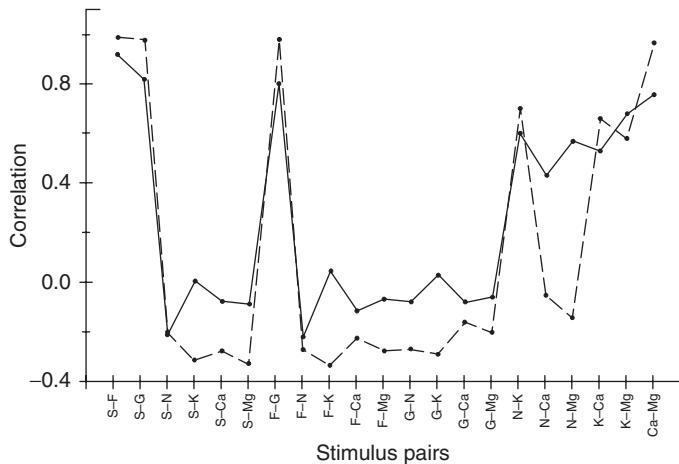

Detailed electrophysiological experiments have built upon the early anatomical and physiological studies of the insula and operculum (Scott et al., 1986b; Ogawa et al., 1989; Yaxley et al., 1988; Scott et al., 1991; Ito and Ogawa, 1994; Rolls and Baylis, 1994). These latter reports estimate that the taste-responsive area within the rostroradial insula

**Figure 44.7** The shaded area within the insula shows the taste-responsive region where many of the taste neurons described by Scott and Plata-Salamán (1999) were recorded. Ca=caudate; Cl=claustrum; IC=internal capsule; Ins=insula; LS=lateral sulcus; Put=putamen; TL=temporal lobe; IIIv=lateral ventricle.

occupies  $50 \text{ mm}^3$  (Scott and Plata-Salamán, 1999), which is slightly larger than the area defined by less sensitive, anatomical methods. These studies examined both insular and opercular regions but many of the taste-responsive neurons they recorded were located within the dysgranular cortex that lies outside the boundaries of primary taste cortex (Figure 44.7). The minor projection from the thalamus to the dysgranular insula is overshadowed by input from the granular cortex at the insular-opercular junction, which means many if not most of the neurons within the body of the insula are second, or even third-order cortical taste neurons. Consistent with previous studies, Scott and Plata-Salamán (1999) and Lara et al. (2009) report that only 6.5% of insular neurons respond to gustatory stimulation.

One of the main goals of these electrophysiological investigations was to determine whether the Old World monkey could serve as a neural surrogate for human taste perception. To that end, a series of experiments compared electrophysiological activity from the monkey with human psychophysical data with regard to: (1) thresholds and intensity-response functions (Scott et al., 1991), (2) coding of quality for each of four basic tastes (Smith-Swintosky et al., 1991): sweetness (Plata-Salamán et al., 1993), saltiness (Scott et al., 1994), sourness (Plata-Salamán et al., 1995), and bitterness (Scott et al., 1999), (3) coding of

**Figure 44.8** Taste quality correlations between human psychophysical data (dotted lines; Kuznicki and Ashbaugh, 1979) and monkey electrophysiological data (solid lines; Smith-Swintosky et al., 1991).

amino acids (Plata-Salamán et al., 1992), and (4) taste mixtures (Plata-Salamán et al., 1996). In each case, the analysis of the macaque neural responses, carried out with sophisticated, quantitative tools associated with patterning theory (Erickson, 1967), implied that neural coding of taste quality in nonhuman primates matches the psychophysical reports of humans. In one analysis, however, patterning theory was wanting. The patterning theory assumes that the gustatory code is carried by all neurons, so whether a neuron is highly responsive or unresponsive to a stimulus, each data point contributes to the response pattern representing that taste. The competing labeled-line theory assumes that the quality code is restricted to the most responsive channel, and that lesser activity from other cells is irrelevant. If perceived taste intensity and stimulus concentration rise in tandem, then the most responsive channel – the putative labeled line – should provide a match between macaque and human. The data from monkeys support the labeled-line theory, and thus, reinforce the conclusions drawn from experiments in the gustatory periphery showing that the taste system encompasses discrete channels, each devoted to coding a basic quality (Scott and Giza, 2000). This discrepancy notwithstanding, patterns of neural activity elicited from the macaque insula (Smith-Swintosky et al., 1991) correlate +0.91 with psychophysical measures of taste similarity in humans (Kuznicki and Ashbaugh, 1979; see Figure 44.8). This high correlation between the macaque neural responses and human psychophysical reports implies that coding of taste quality is complete either before the signal reaches the insula or within the insula itself.

Just as in the NST (Yaxley et al., 1985), the responses of taste neurons in the insular-opercular cortex remained stable over the course of a meal, even as the hedonic value of the sugar with which the animals were satiated shifted from positive to negative (Rolls et al., 1988; Yaxley et al., 1988). This conclusion was confirmed by two more recent reports that used NaCl and sucrose as cues and rewards

(Ifuku et al., 2003; Ogawa, et al., 2005). In these experiments, regardless of the hedonic tone conferred on the tastants during a GO/NOGO behavioral task, the evoked responses remained unchanged. Similarly, de Araujo et al. (2003), in an fMRI study of humans, observed that water is an effective stimulus for insular neurons, and that the magnitude of activation elicited does not change as subjects drink to satiety and hedonic value wanes. Contradictory evidence, however, was reported by Small et al. (2001a) who used PET to demonstrate in humans that chocolate activates the insula when the stimulus is appealing, but not after satiety develops. Similarly, Tataranni et al. (1999), Gautier (2001), and Del Parigi et al. (2002), also using PET, reported that activation of the insula is greater in hungry than in sated humans. Thus, a firm conclusion on whether neurons in the insula signal hedonic appeal is obfuscated by species differences and varied experimental approaches.

Taste perception is but one aspect of ingestive behavior that has been localized to the insula. Scott and Plata-Salaman (1999) reported that non-gustatory insular neurons also respond during mouth movements (23.8%), tactile stimulation of the oral cavity (3.7%), approach of the stimulus delivery syringe (1.2%), tongue extension (0.3%) and olfactory stimulation. Insular neurons also respond to the viscosity (53%), temperature (35%), fat content (8%), grittiness (8%), and astringency (8%) of savor stimuli, as well as to capsaicin, the active ingredient in chili peppers (Critchley and Rolls, 1996; Rolls, 2005). Verhagen et al. (2004) reported that half of all insular neurons respond to only one of these components;<sup>2</sup> half are bi- or multimodal. Collectively, these data speak to the insula's involvement in the perception of flavor, the amalgam of gustatory, olfactory, and somesthetic (touch, temperature, nociception), information.

<sup>2</sup>Verhagen et al. (2004) tested all of the stimulus modalities above except astringency.

**44.3.3.3 Imaging.** It is a curious twist of the discipline and its techniques that the monkey model was developed as a surrogate for human gustation; that after having established itself as such, electrophysiology went into decline, partly to be replaced by neural imaging techniques suitable for use in human subjects; and that the data from imaging is now being used to help complete the picture of taste processing in the monkey. Functional MRI studies using humans have confirmed the original observations in nonhuman primates that the insula is activated by water (de Araujo et al., 2003), stimulus viscosity (de Araujo and Rolls, 2004), temperature (Guest et al., 2007), and texture (de Araujo and Simon, 2009).

Perhaps unexpectedly, photographs of food activate the anterior insula while those of non-food objects do not (Simmons et al., 2005), reminiscent of the observation in the macaque by Scott and Plata-Salamán (1999) that insular neurons respond selectively to the sight of the feeding syringe. Many studies have shown that activation of the insula is not limited to sensory stimulation originating in the external environment. For example, activation of the insula accompanies stimulation of the esophagus (Aziz et al., 1995; Weusten et al., 1994) and the throat (Roper et al., 1993), as well as general visceral arousal induced by phobic anxiety (Rauch et al., 1995). PET scans reveal insular activation while subjects are instructed to move their mouths and tongues, as well as during speech (Raichle, 1991), implying a role for the insula in oromotor functions. Insular-based seizures (Fiol et al., 1988) and electrical stimulation of the insula induce vomiting (Oppenheimer et al., 1992). Thus, insular cortex is involved in multiple aspects of feeding, including the appearance (vision) and perhaps detection (smell) of food, as well as contact and engagement of the tongue with food, and perhaps even the digestive process.

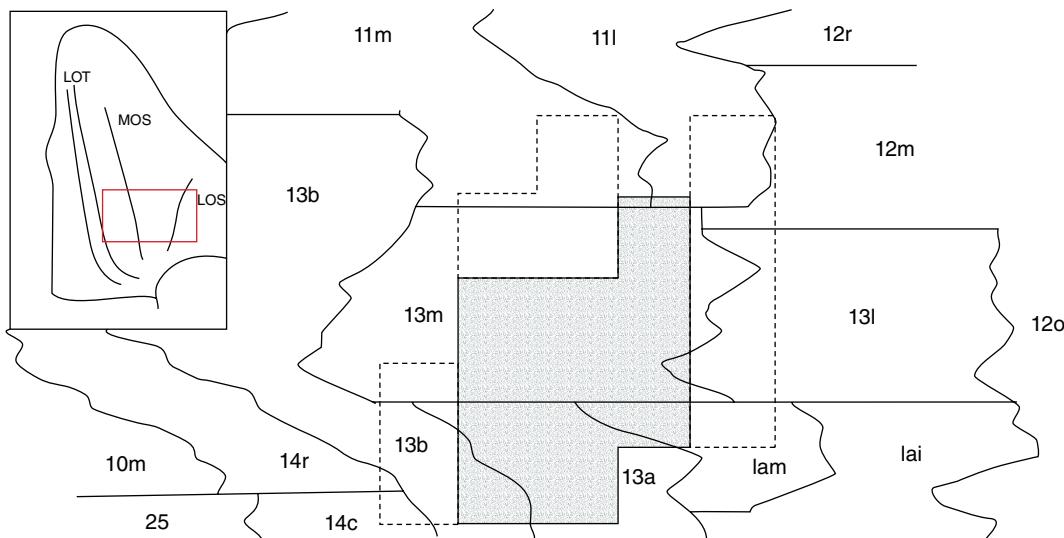

Beyond the sensory and motor realms, the insula also has been implicated in various forms of cognitive behavior. For example, the insula is active when subjects imagine sweetness or saltiness (Levy et al., 1999). Subjects who are misled and told that the subsequent taste would not be bitter show less activation than normal when they are given quinine (Nitschke et al., 2006). When subjects are instructed to detect a taste that is, in fact, absent, their taste-related attention elicits an insular response (Veldhuizen et al., 2007). Viewing facial expressions of disgust also activates the insula (Phillips et al., 1997; Wicker et al., 2003; Jabbi et al., 2008). Finally, both when anticipating and consuming food, obese subjects show larger activation in the insula than lean subjects (Stice et al. (2008)). Thus, imagination, expectation, attention, emotion, and anticipation all contribute to the set of features that can affect activity in the insula.

Because most of these electrophysiological and imaging studies focused on the dysgranular and agranular insulae that constitute higher-order cortical taste areas, it is not surprising that many of their findings expand the role of the insula beyond sensory analysis of sapid stimuli. If the insula marks the transition from sensory analysis to utilization (i.e., cognition and behavior), how should the mission of the insula be defined? Craig (2009) has suggested that the insula's primary function, broadly defined, is homeostatic control, interoception, and self-awareness (see also Evrard et al., 2012). If one accepts this grand view of the insula, its mission may encompass expansive issues such as nourishment, risk-taking (Ishii et al., 2012), and ultimately protection of the organism. The sense of taste, with its charge to identify and accept nourishing foods while rejecting toxins, fits well into this broad view of insular function.

#### 44.3.4 Orbital Cortex

**44.3.4.1 Anatomy.** Taste neurons have been recorded across a broad swath of the OFC stretching from the medial orbital sulcus as far laterally as the precentral operculum (area PrCO). Except for the medial orbitofrontal cortex (mOFC) and the caudolateral orbitofrontal cortex (cLOFC), the taste-responsive neurons in the OFC are too widely scattered to constitute an “area.” Gustatory projections to the mOFC and cLOFC follow multiple, multisynaptic pathways through the ventral insula and the posterior orbital cortex (Carmichael and Price, 1995), but divergence, convergence, and overlap of these pathways obscures the circuitry and, ultimately, leaves us with an incomplete understanding of how taste information reaches the OFC. That said, we know that the last leg of the afferent pathway to the OFC originates in the higher-order taste areas within the dysgranular and agranular insulae, and the posterior orbital cortex rather than primary taste cortex (Carmichael and Price, 1995, 1996; Mufson and Mesulam, 1982; Barbas, 1993; Mesulam and Mufson, 1985; Baylis et al., 1995; Pritchard, unpublished observations, 2005). Thus, like other sensory systems that project to the prefrontal cortex, the gustatory afferent neurons that terminate in the OFC are located in sensory association cortices rather than in primary taste cortex (Carmichael and Price, 1995; Barbas, 1993, 2007). Through these detailed descriptions of the local circuitry within the OFC, we also know that the cLOFC is synaptically more remote from the insular taste areas than the mOFC.

The highest concentration of taste neurons in the OFC lies in the mOFC, the narrow isthmus of cortex between the medial and lateral orbital sulci (Pritchard et al., 2005). In this region, which consists primarily of BAs 13m and 13a, almost 20% of the neurons respond to gustatory stimulation; only 8% of the neurons in the 1mm perimeter area

**Figure 44.9** The core and perimeter taste areas within the mOFC projected onto an unfolded BA map of the OFC of the macaque. Inset shows the location of this partial OFC map relative to the ventral surface of the frontal lobe. (Adapted from Pritchard et al., 2005).

(BAs 13b, 13l, 12m, 11l, and 11m, and the medial agranular insula) respond to taste (see Figure 44.9<sup>3</sup>). A subsequent study by Lara et al. (2009) reported that 11% of the neurons in the mOFC respond to taste stimulation. The relatively high proportion of taste cells in the mOFC stands in marked contrast to the rest of the OFC where, on average, only 3.8% (range=1.6 to 7.3%) of the population respond to sapid stimuli (Thorpe et al., 1983; Rolls et al., 1990; Rolls and Baylis, 1994). The cLOFC, although not well defined, is located along the lateral edge of the OFC, adjacent to the border with the posterior orbital cortex. The cLOFC is within, but is not synonymous with BA47/12o. About 2% of the neurons in the cLOFC respond to sapid stimulation of the tongue (Rolls et al., 1990).

**44.3.4.2 Physiology.** Although some sensory analysis of taste certainly takes place within the gustatory association cortices in the dysgranular and agranular insulae, as described above, these areas are noteworthy for their role in taste-mediated guidance of feeding behavior and nourishment. Based upon several detailed electrophysiological experiments and a more extensive imaging literature, it appears that the progression from sensory analysis to sensory support for behavior that was the hallmark of the insula, continues in the OFC.

Taste-responsive neurons are sparsely distributed across much of the posterior OFC, but detailed descriptions are only available for two regions: the mOFC (Pritchard

et al., 2005; Lara et al., 2009) and the cLOFC (Rolls et al., 1990). Tract tracing experiments have demonstrated that the mOFC is one of several entry points to the OFC for projections that originate in the dysgranular and agranular insulae (Carmichael and Price, 1995).

The response properties of mOFC gustatory neurons resemble those of taste neurons in the insula in some ways and the cLOFC in others. Like the insula, mOFC neurons are broadly tuned to the four basic taste qualities (mOFC  $H = 0.79$ ; insula  $H = 0.70$ ), with sensitivity to each in the 50–60% range. This contrasts sharply with the cLOFC where 82% of the neurons respond to glucose, with salty, sour, and bitter sensitivity accounting for less than 12% each. Such narrow tuning is reflected in the extremely low entropy coefficient of cLOFC neurons ( $H=0.39$ ). Surprisingly, the narrow response breadth of cLOFC taste neurons is accompanied by significantly more convergent visual, olfactory, auditory, and somatosensory information than observed in the mOFC, which has only a modest number of multimodal neurons; few taste neurons in the insula respond to other sensory modalities (Rolls and Baylis, 1994; Critchley and Rolls, 1996; Rolls, 2004; Thorpe et al., 1983; Scott and Plata-Salaman, 1999; Pritchard et al., 2005). It remains to be seen whether the multimodal character of cLOFC neurons provides a platform for the type of sensory integration that defines flavor perception.

The OFC, long recognized for playing a role in emotion, is now considered a vital area of the brain for evaluating reward and risk in the often complicated process of decision-making (Tremblay and Schultz, 1999; O'Neill and Schultz, 2010; Rempel-Clower, 2007; Summerfield and Tsetsos, 2012). Rudebeck and Murray (2011), who have used the term “balkanized” to describe the anatomical

<sup>3</sup>Because BA 13l receives direct projections from primary taste cortex, it is possible the percentage of taste neurons reported for this area has been underestimated due to limited sampling.

and multifunctional specialization of the OFC, find support for their view in both the animal and human literatures.

Electrophysiological experiments in the OFC of monkeys that emphasize cue-guided behavior and reward contingencies instead of passive taste properties (e.g., Pritchard et al., 2005) engage a much higher percentage of the cells in the OFC. For example, Hosokawa et al. (2007), using a delayed color matching test that included both positive and negative reinforcement, showed that the responses of 31% of cOFC neurons code the relative preference of the reward. Schultz et al. (1998), using a GO-NOGO paradigm, reported that neurons in BAs 11, 13, and 14 respond to cues that predict reward in proportion to the value of the reward. When the reward contingencies are changed, the responses of some neurons increase, others decrease, and some neurons change from non-responders to responders (Tremblay and Schultz, 2000a, 2000b). The ability of OFC neurons to track the monkey's behavioral adjustments to the fluctuating relationship between cue relevance and reward availability has also been reported by Baeg et al. (2009). The responses of other OFC neurons follow reward magnitude or the taste of the reward (Padoa-Schioppa and Assad, 2006; Padoa-Schioppa, 2007).

The response magnitude of OFC neurons is also modulated by postigestive factors that decrease the rewarding value of food, the subject's incentive to eat or drink, and internal need states. For example, when a specific food is consumed to the point of satiety (sensory specific satiety), the rewarding value of that food declines, sometimes to the point that it loses its ability to serve as a reinforcer. Using this paradigm, Scott et al. (1986a) and Yaxley et al. (1985) concluded that satiety does not affect the magnitude of taste responses in the NST and insula, respectively. By comparison, Rolls et al., (1989) demonstrated that the taste-evoked responses of cOFC neurons decrease as a linear function of satiety. In other words, response magnitude decreased in parallel with reward devaluation. In the mOFC, the relationship between satiety-induced reward devaluation and response magnitude is more complex and not as decisive. For most neurons, response magnitude decreased as satiety developed, although in a more graded fashion than reported for the cOFC. For a small cohort of neurons, response magnitude increased with satiety. Perhaps most interesting, some mOFC neurons that initially did not respond to sapid stimulation, began responding to taste after the monkeys reached satiety (Pritchard et al., 2008). Collectively, this research drives home the message that the OFC is not a higher-order taste area in the traditional sense, but rather an area where taste information is used to support reward-evaluation, risk assessment, and decision-making. Damage to the OFC would be expected to undermine these processes, and predictably, monkeys with OFC lesions show normal satiety, but no evidence of

satiety-induced reward devaluation (Izquierdo et al., 2004; Murray and Izquierdo, 2007).

**44.3.4.3 Imaging.** Functional imaging techniques are now in their adolescence and like their human counterparts, they have a voracious appetite for exploration and adventure. The field of cognitive neuroscience, which historically has struggled against the brain's almost infinite complexity, seemed like a worthy target for these nascent technologies. Attention quickly focused on the OFC, which is probably the crown jewel of cognitive neuroscience, and was directed toward the well-established role of the OFC in emotion, reward, and their derivative behaviors. Multiple studies have shown that the OFC is involved with behaviors driven by both primary (taste) and secondary (money) reinforcers (Bechara et al., 1994; Knutson et al., 2000; O'Doherty et al., 2001).

The imagining literature confirms the general findings of the electrophysiological literature that the OFC is more likely to use sensory information, including taste, to fuel decisions related to reward comparison and decision-making rather than the more mundane business of quality or intensity identification. For example, Fitzgerald et al. (2009) used fMRI to demonstrate that the mOFC encodes the relative subjective value of rewards, both positive and negative, rather than the absolute reward value of the choices available to the subjects. These findings, like the neurophysiological data of Hosokawa et al. (2007), show that the OFC encodes relative rather than absolute preference and aversion for cue-associated consequences. The ability to focus on the relative value of rewards creates a common currency for the daily decisions that people make about real life issues such as the diet versus hot fudge sundae dilemma. Just as importantly, the ability to normalize rewards is a labile process that supports adaptation to an ever-changing environment. Damage to the OFC impairs reversal learning in both monkeys and humans (Iverson and Mishkin, 1970; Fellows and Farah, 2003; Rolls (1994); patients with OFC damage have impaired decision-making (Fellows, 2011).

Imaging studies have confirmed electrophysiological demonstrations that taste-evoked activity in the OFC reflects internal states such as hunger and satiety (Pritchard et al., 2008; Rolls et al., 1989). For example, Kringlebach et al. (2003) have shown that sensory specific satiety decreases fMRI activity in the OFC during consumption of the satiating liquid, but not when the subject drinks a novel liquid. Goldstone et al. (2009), using fMRI, showed that fasting increases activation in the mOFC and cOFC when the subjects view photographs of high caloric foods. Fasting also enhances subjective ratings of these foods, which is consistent with earlier psychophysical reports (Cabanac, 1971; Cameron et al., 2008). Other studies

have shown that gustatory-evoked responses in the OFC are modulated by body composition (lean vs obese) and memory (Del Parigi et al., 2002, 2005). The differential emphasis of the OFC and the insula on reward-driven decision-making and sensory processing, respectively, is illustrated by a study conducted by Grabenhorst and Rolls (2008). In this fMRI experiment, activation shifted from the insula to the OFC when the subject was instructed to attend to the pleasantness of the stimulus instead of its intensity.

Taken together, the insula and the OFC clearly run the gamut from advanced and perhaps final processing of the sensory signal to taste-guided cognitive behavior. If a precise transition point for this functional shift exists, it is not currently known. At present, this functional shift in taste processing appears to lie in the immediate vicinity of the dysgranular and agranular insula. Identifying this transition point awaits a better understanding of what each area contributes to regulation of the internal milieu, risk vs reward decisions, and sensory-guided executive function.

## 44.4 DESCENDING GUSTATORY PROJECTIONS

Two subcortical areas have been implicated in feeding and gustation: the hypothalamus and the amygdala. Gustatory information in the insula and OFC probably reaches the hypothalamus, both directly and indirectly, through the amygdala (Aggleton et al., 1980; Fudge et al., 2005; Mufson et al., 1981; Price and Amaral, 1981).

### 44.4.1 Amygdala

In the amygdala, overlap of the representations of the internal and external worlds permits needs to be assessed relative to the external resources available to fulfill them (Turner et al., 1980). Because the amygdala is able to guide need-driven behavior, it is well-positioned to influence emotion, motivation, and hedonic tone (Aggleton et al., 1980; LeDoux, 1987). The ability of the amygdala to integrate visceral and exteroceptive information enables it to play an active role in initiation and guidance of feeding (Lénárd and Hahn, 1982; Nakano et al., 1986). Accordingly, normal feeding and taste perception are disrupted by amygdala lesions in monkeys (Jones and Mishkin, 1972; Klüver and Bucy, 1939) and humans (Kim and Umback, 1973; Narabayashi, 1977; Small et al., 2001b, 2001c).

Taste neurons have been recorded in the amygdala of rats (Sadacca et al., 2012), rabbits (Schwartzbaum and Morse, 1978), and macaques (Scott et al., 1993; Yan and Scott, 1996; Kadohisa et al., 2005). Although each study had a different thrust, collectively they showed that the response properties of neurons in the amygdala are similar

in some respects to those in the anterior insula from which they presumably receive their input. For example, Scott et al. (1993) showed that taste neurons in the amygdala are distributed over a volume of about  $76 \text{ mm}^3$  (vs  $50 \text{ mm}^3$  in the insula) and they compose approximately 7% (vs 6.5%) of the cell sample. Amygdalar and insular neurons are similarly tuned across the four prototypical taste stimuli, with a mean breadth-of-tuning coefficient of 0.82 and 0.70, respectively.

The key difference between the amygdala and the insula was in their respective response characteristics. Taste neurons in the amygdala have a higher spontaneous rate than cells in the insula (8 vs 3 spikes/s.), which makes response inhibition a more credible option. In the insula, only 2% of taste responses met the criteria for inhibition (Scott and Plata-Salamán, 1999), while in amygdala, fully 17% did so (Scott et al., 1993). Of greater import, unlike the insula, taste-evoked activity in the amygdala lack the resolution to match the degree of taste quality and intensity discrimination that both monkeys and humans demonstrate. Instead of taste quality or intensity, the taste-evoked responses of amygdalar neurons reflect the hedonic value of the stimuli. For example, response magnitude in the amygdala decreased 58% as the hedonic value of the sweet satiating stimulus shifted from positive to negative (Yan and Scott, 1996). This hedonic-related decrement in taste responsiveness stands in marked contrast to the NST and the insula where neurons are unaffected by satiety-induced decrements in hedonic value. The impact of satiety on taste responses in the amygdala appears to complement the finding by Sanghera et al. (1979) that the responses of visual neurons in the amygdala decrease to the sight of food that monkeys are fed to satiety.

A mechanism for such a reduction may be the sensitivity that some amygdala neurons show for vascular and interstitial glucose levels. About 17% of neurons in the amygdala respond to the iontophoretic application of glucose, and the impact is nearly always inhibitory (Karádi et al., 1998). As blood glucose levels rise with feeding, circulating glucose may suppress the responses that would previously have been evoked by taste stimuli. This effect is seen yet more clearly in the hypothalamus, as described below.

In summary, the amygdala focuses on the emotive aspects of taste and feeding rather than the precise coding of taste quality or concentration, which are likely fully processed within the insula. The amygdala, in conjunction with the OFC, the hypothalamus, and perhaps the ventral striatum and anterior cingulate gyrus, may add context to the sensory aspects of taste perception by integrating input from other senses for the appreciation of flavor, and by coordinating the animal's needs with the hedonic aspects of taste.

#### 44.4.2 Hypothalamus

Early lesion-behavioral studies demonstrated that the hypothalamus plays a critical role in feeding (Anand and Brobeck, 1951; Hetherington and Ranson, 1940). The subsequent discovery of presumed gustatory (Mesulam and Mufson, 1982) and olfactory (Takagi, 1986) projections to the hypothalamus in the macaque have made it a prime target to investigate the relationship between the chemical senses and feeding. A role for the hypothalamus in feeding was further bolstered when Oomura et al. (1964) demonstrated that a subset of hypothalamic neurons in the rat respond to fluctuating blood glucose levels. Oomura et al. (1974) then used microiontophoretic injections of glucose into the hypothalamus to reveal two sets of neurons: those whose activity is suppressed by the presence of glucose (“glucose-sensitive” (GS) cells), and those that are unaffected (“glucose-insensitive” (GIS) cells; Aou et al., 1984; Nishino et al., 1988; Oomura et al., 1974; 1991).

Karádi et al. (1991, 1992) showed that GS and GIS cells comprise 27% and 73% of the neurons in the macaque hypothalamus, respectively. GS neurons respond primarily to chemosensory stimuli with olfactory-responsive neurons (86%) more common than taste-responsive neurons (66%); 67% of all GS cells respond to both modalities (Karádi et al., 1989, 1992). GIS cells, by comparison, were significantly less likely to respond to gustatory and olfactory stimuli. Rather, GIS neurons respond to external cues related to the acquisition of food such as a cue light that signals the availability of an operant task to obtain food, or a cue tone that indicates the task has been successfully completed. Thus, Oomura’s multifaceted approach revealed two types of hypothalamic cells: GIS cells that respond to food-related, environmental, non-chemical cues, and GS cells that respond to the more intimate chemosensory signals associated with ingestion and digestion.

Burton et al. (1976), recording from individual neurons in the lateral hypothalamic area and substantia innominata, reported that 2.5% of the cells respond to taste, and 9.3% respond to the sight of food. As in other gustatory areas, taste-related neurons constitute only a small fraction of the population, and as in the amygdala, a robust spontaneous rate of approximately 10 spikes/s made response inhibition a relatively common observation. As in the OFC and the amygdala, both excitatory and inhibitory responses to the taste and sight of food are attenuated as the monkeys are fed to satiety with a particular food; responses elicited by other foods are largely unaffected. Unlike the amygdala where satiety decreases taste responses by 58% (Yan and Scott, 1996), Burton et al. (1976) reported response suppression is complete in the hypothalamus. Thus, in the macaque, the amygdala appears to be functionally intermediate between the insula, where satiety is reported to have no effect on taste-evoked activity (Yaxley et al., 1988),

and the hypothalamus, where it causes total suppression. As the authors point out, these hypothalamic data may reflect the neural mechanism underlying psychophysical reports of sensory-specific satiety in humans (Rolls et al., 1981; 1982). Whether these satiety-related neurons are GS cells is not clear.

### 44.5 CONCLUSION

Gustation, which emerged in coelenterates some 500 million years ago, is among the most ancient of our senses, yet it has been well conserved across phyla. Within the Mammalian Class, taste is consistent in its receptor distribution, peripheral innervation, and, with the notable exception of the parabrachial nucleus, its central pathways.

In the Primate Order, the accumulated data imply that identification of broad taste categories (i.e., qualities) is addressed at the peripheral level as separate lines of communication (labeled lines) transmit information to the central nervous system with a high degree of specificity. Second-order neurons in the nucleus of the solitary tract show greater breadth and this is preserved more centrally. Qualitative specificity is restored in the caudolateral orbitofrontal cortex, where multisensory interactions, learning, and hedonics dominate.

Electrophysiological research in nonhuman primates since the mid-1980s has addressed each level of the gustatory neuraxis. Unfortunately, coverage has been uneven, and despite the precision of the data, the picture that has emerged is so grainy that trying to understand central taste processing has been like assembling a photograph from its randomly acquired pixels. More recently, non-invasive imaging technology has provided optical images of neural activity, typically across large areas of cortex. The imaging data have brought ensemble coding to the fore, fostered a more integrated view of brain activity, and provided at least partial support for the following conclusions.

Functionally, the nucleus of the solitary tract is most likely involved in orchestrating gustatory reflexes associated with ingestion or rejection of gustatory stimuli. The parabrachial nucleus does not appear to play a role in Primate gustation, unlike its involvement in assessing taste quality and hedonic value in rodents (Yamamoto et al., 1994). The contribution of the thalamic relay in Primate taste processing has not yet been determined, but based upon studies in the rat, it is unlikely to be simply a passive relay for gustatory information bound for the cerebral cortex (e.g., Schroy et al., 2005). Primary taste cortex in the granular insula is the likely locus where quality and intensity identification is completed. Neurons here offer the closest match between macaque electrophysiological and human psychophysical reports. Beyond primary taste cortex, gustatory information participates in complex

processes that involve multiple cortical and subcortical areas, other sensory modalities, and feedback from internal receptors. Accordingly, taste information contributes to multisensory evaluation of flavor, and reward comparison, as well as food selection and hedonic assessment guided by internal variables such as blood glucose levels. As a central character in this varied and complex mixture, taste helps ensure that diet selection serves the manifold and changing nutritional requirements of Primates.

# Central Integration of Olfaction, Taste, and the Other Senses

# Chapter 45

---

## Chemosensory Integration and the Perception of Flavor

JOHN PRESCOTT and RICHARD STEVENSON

### 45.1 INTRODUCTION

The use of the word flavour/flavor in English is thought to date from the late 14th or early 15th century. Originally it had a predominantly olfactory meaning, in that it referred to a fragrance or aroma (The New Shorter Oxford English Dictionary, 1993). In contrast, a meaning that is more consistent with our current view but which (in modern terms) undervalues the role of olfaction – “a quality perceived by taste (aided by smell)” – emerged somewhat later, in the late 17th century. Rozin (1982) notes that not all languages carry this latter, multisensory meaning, in that they do not distinguish well between primary tastes qualities and the overall flavor (taste plus smell) of a food in the mouth. In other words, not all languages (not even all European languages) acknowledge the role of olfaction in flavor. This may reflect widespread ignorance until relatively recently of the importance of both taste and smell to flavor. It is also consistent with the everyday, non-technical use of the terms “taste” and “flavor” as interchangeable.

The then existing general confusion between taste qualities and overall flavor was remarked on by a well-known English physician of the early 19th century, William Prout (Brock, 1967). In an essay dating from 1810, Prout explicitly recognized the olfactory component of flavor, noting that “substances in general have the strongest flavor that are volatizable or partly soluble in air as well as water,” and further that “it is probable that the major part of our sense of flavor comes from the stimulation of the olfactory nerve by odorous air which is ejected when, during the act of swallowing food, the epiglottis

closes the trachea.” Prout’s definition of flavor as “that sensation which is produced when substances under certain circumstances are introduced into the mouth, the nostrils being at the same time open” was in fact influential (despite its lack of detail), in that it was adopted in physiology texts of the day.

Writing around the same time from a less scientific perspective, the French gastronomic pioneer, Brillat-Savarin was “tempted to believe that smell and taste are in fact but a single sense, whose laboratory is the mouth and whose chimney is the nose” (Brillat-Savarin, 1825). He thus not only explicitly valued the contribution of both smell and taste in flavor perception, but also anticipated J. J. Gibson’s ecological approach to perception (Gibson, 1966). Gibson argued that the primary purpose of perception is to seek out objects in our environment, particularly those that are biologically important. As such, the physiological origin of sensory information is less important than that the information can be used in object identification. The key to effective perception is that sensory information is interpreted as qualities that belong to the object itself. Within this context, flavor can be seen as a functionally distinct sense that is cognitively “constructed” from the integration of distinct physiologically defined sensory systems (primarily olfaction and gustation) in order to identify and respond to objects that are important to our survival, namely foods.

The recognition that our experiences of food flavors reflect combinations of taste, olfactory, and other sensory (e.g., somatosensory) information is therefore not recent. Nonetheless, how these inputs are combined, and the

resultant interactions between the senses involved in flavor perception, have recently enjoyed increased interest. This has been born, to some extent, out of a realization that in our everyday food experiences we respond, perceptually and hedonically, not to discrete tastes, odors, and tactile sensations, but to flavors constructed from a synthesis of these sensory signals (Prescott, 2004b). In addition, recent neuroimaging studies (see Chapter 35) have provided evidence that flavor is not merely a shorthand description for an aggregation of different senses involved in food perception but rather involves brain structures working as a distinct, functional neural network.

Understanding flavor perception has also benefitted from the emergence of multimodal sensory perception as a distinct field of study (see for example Driver and Spence, 2000). In contrast to earlier emphases on perceptual discrimination – essentially how we resolve William James's “blooming, buzzing confusion” (James, 1890) – multimodal perceptual studies address how information from physiologically distinct sensory systems is combined to provide more accurate and perceptually salient information. This has led to questions regarding binding, which initially referred to the combination of features especially in visual perception (Treisman, 1998), but is now posed to help understand how information is combined to facilitate a single percept from multiple senses (sometimes referred to as the *unity assumption*) (see Section 45.4 below).

## 45.2 SENSORY INTERACTIONS WITHIN FLAVORS

Cross-modal sensory integration is frequently inferred from the influence of one modality on responses to another. Commonly, this is an enhanced (sometimes supra-additive) response to information from one sensory system due to concurrent input from another modality. For example, in a noisy environment, speech comprehension is improved if we see the speaker's lip movements (Sumby and Polack, 1954). There has similarly been considerable interest in determining the cause of sensory interactions with flavor, as some have significant practical implications. For example, certain interactions can allow a reduction in the quantity of sugar, fat or salt needed to make a product acceptable (e.g., Nasri et al., 2011) (see Section 45.5.2 below). Two basic causes of interactions have been established. One involves events at the periphery, including, for example, chemical reactions between food ingredients, bulk effects of food that alter volatile or tastant release, and receptor competition between the chemicals in food. The other involves events in the brain, and it is this type of interaction that forms the main focus of this section. As the interaction literature is extensive, the interested reader is directed to

Delwiche (2004), Keast et al., (2004), or Stevenson (2009), for detailed treatments.

### 45.2.1 Interactions with a Peripheral Cause

Interactions between oral irritation and taste, taste and temperature, taste and touch, irritation and temperature, odor and temperature, odor and oral irritation, and oral irritation and touch, all seem to have peripheral causes – with the caveat that the evidence is often suggestive rather than definitive. In this section, these interactions and their probable cause are summarized.

**45.2.1.1 Irritation and Taste.** Capsaicin, the pungent principal of the chili pepper, can suppress sweetness and bitterness, but not saltiness and sourness (Simons et al., 2002; Prescott et al., 1993). This may occur because capsaicin affects the protein-based taste receptors that detect sweetness and bitterness, but not the ion based channels that detect saltiness and sourness. Sweetness has been shown to be reduced by the mechanical oral irritation produced by the calcium oxalate crystals present in some fruits (Walker and Prescott, 2003). The effect is probably secondary to increased viscosity associated with increased concentration of these crystals in solution. Certain sweet tastants (e.g., sucrose) can also suppress the irritation induced by capsaicin (Prescott et al., 1993) and by carbonic acid (the agent that generates the pungency associated with carbonation; (Yau and McDaniel, 1991). In this case the effect may arise via sucrose's capacity to promote salivation, which then acts as a diluent. Conversely, irritation can be shown to be increased in the presence of acids (Walker and Prescott, 2003) and salt (Prescott et al., 1993), consistent with the irritant properties of both of these tastants (Gilmore and Green, 1993).

**45.2.1.2 Irritation and Touch.** Viscous foods appear to reduce capsaicin's burn intensity (e.g., Nasrawi and Pangborn, 1989). However, this may owe more to the capacity of fats to capture capsaicin, preventing receptor binding, than any specific viscosity related effect (Lawless et al., 2000). Irritation may also be reduced by concurrent oral mechanical stimulation although the locus of this effect has yet to be established (Green, 1990).

**45.2.1.3 Irritation and Temperature.** The common terminology applied to sensations driven by chemical irritants – burning and cooling – and that from thermal stimuli suggests some commonality in processing. Higher temperature (37°C vs 21°C) capsaicin solutions have been shown to produce more burn, although this may have been

through burn suppression in the lower temperature solutions (Prescott et al., 1993). Albin et al. (2008) examined irritant/temperature commonality by applying an irritant to one side of the tongue tip and then placing the tongue tip on a hot or cold thermode. Participants were then asked to judge which side of the tongue was hotter. Whenever one side of the tongue was treated with capsaicin, mustard oil or cinnamaldehyde, and placed on the hot thermode, the treated side was always selected as “hotter.” In contrast, when one side of the tongue was treated with menthol and placed against a cold thermode, the treated side was judged as cooler. These effects are probably peripheral in origin, as identical outcomes were obtained after pretreating the tongue with the irritant, waiting until all irritant sensation had dissipated, and then conducting the thermode test.

**45.2.1.4 Irritation and Olfaction.** When an irritant with no olfactory component is sniffed at the same time as a relatively pure olfactory stimulus, the irritant exerts a far more potent suppressive effect on odor perception than odor perception exerts on irritant perception (Murphy and Cain, 1980). This effect is almost identical in magnitude to that obtained when the odor and the irritant are applied to different nostrils, indicating that for orthonasal stimuli there is a significant central component to irritant suppression of orthonasal olfactory perception (Cain and Murphy, 1980). However, when an irritant is placed in the mouth, alongside an odor (i.e. odor-irritant mixture), there does not seem to be any centrally mediated effect paralleling that seen for orthonasal olfaction (Prescott and Stevenson, 1995).

**45.2.1.5 Temperature and Taste.** Higher temperatures have been consistently found to enhance the sweetness of sucrose – but not other tastants – with cooling having the reverse effect (Bartoshuk et al., 1982). This seems to occur as a consequence of the vehicle either warming or cooling the tongue (Green and Frankmann, 1987). Indeed, simply warming the tongue can generate illusory sensations of sweetness, with cooling generating sensations of sourness and saltiness (Cruz and Green, 2000). These illusory taste effects driven by tongue warming or cooling may account for the changes in sweetness perception observed with higher or lower temperature. They also suggest that thermal stimuli can directly activate certain classes of taste receptor.

More recently Green and Nachtigal (2012) observed a difficulty in perceiving sweet tastes – for example, while licking a lollipop – when the tongue remained outside of the mouth. Once the tongue was retracted into the mouth, however, the sweetness was obvious, raising the possibility that the higher internal mouth temperature was responsible for this effect. By comparing the rate of adaption to sweetness at different temperatures, these investigators were

able to show that warming the tongue outside of the mouth by dipping it into a solution with the same temperature as inside the mouth ( $37^{\circ}\text{C}$ ) produced the same effect on sweetness as withdrawing the tongue into the mouth. An intriguing question is why the same effects did not occur when the study was carried out using the bitter taste of quinine. Why there are particular interactions between sweetness and temperature and not other tastes and temperature is unknown. Such findings are consistent with those of earlier studies that have been unable to consistently show that tastes at different temperatures vary in intensity.

**45.2.1.6 Temperature and Olfaction.** Food temperature exerts a relatively straightforward effect on retronasal olfaction. Greater temperature initially increases volatile chemical release, while cooler temperatures initially reduce it, leading to greater intensity of the same odor when presented in a warmer vehicle than in a cooler vehicle (Pangborn et al., 1978).

**45.2.1.7 Taste and Touch.** The principal focus in studying tactile/taste interactions has been on the impact of viscosity on taste. Initial studies found that increasing viscosity reduced the intensity of all tastants (Moscowitz and Arabie, 1970). Later studies revealed a more complex picture, showing that the particular type of agent used to generate viscosity, its concentration, and the type of tastant used all effect whether taste intensity suppression occurs (e.g., Christensen, 1980; Cook et al., 2002; Walker and Prescott, 2000). This suggests that the effects of viscosity on taste perception are mediated by the individual chemical properties of the viscous agent, with each varying in the capacity to impede the movement of different tastants to the taste receptor. The impact of taste on viscosity perception has not yielded consistent results (see Theunissen and Kroese, 1995).

Green and Nachtigal (2012), in a study of how tastes and touch sensations interact, compared the effects of passive to active tasting of sweet, salty, sour, and umami (mono-sodium glutamate, or MSG taste) tastes. In the former condition, tastants were applied with a swab to different parts of tongue, but the tongue remained immobile. In the active condition, the participants were asked to touch the tongue to the roof of the mouth and also swallow. Hence, this condition more closely resembled normal eating. Active tasting had a strong impact on taste intensity, but only for the taste of MSG. Of all the tastes, *umami* tastes seem to have a “mouthfilling” quality. Moreover, as these researchers point out, active food manipulation including chewing is needed to break down the food’s physical structure, releasing the glutamate and other amino acids responsible for *umami* tastes. This process may also be behind the fact that, in this study, MSG intensity in

either condition was highest at the rear of the tongue. No such “tongue geography” effects were seen for the other tastes.

### 45.2.2 Interactions with a Central Cause

Three types of centrally based interaction are described in this section. Two of these, somatosensory-olfactory interactions involving texture and interactions between taste and smell, occur within the mouth, while others such as the impact of external visual and auditory cues on flavor perception do not.

**45.2.2.1 Olfaction and Touch.** It is well established that textural variables such as viscosity and hardness can affect the intensity of odorants (e.g., Lundgren et al., 1986). A centrally-based cause for such interactions has recently been established. Weel et al., (2002) measured volatile release *in vivo* for a set of odorized gels that varied in hardness. While increasing hardness progressively reduced odor intensity, the volatile release profile was the same irrespective of hardness. A similarly compelling finding in regard to viscosity was made by Bult et al., (2007). In this study participants were nasally catheterized. One catheter then delivered odorants to the anterior nares and the other to the posterior nares. Odorants were delivered during the time period in which participants sampled by mouth either plain or thickened milk. Odor intensity was significantly reduced in the presence of thickened milk irrespective of whether the odor was presented to the anterior or posterior nares. Stevenson and Mahmut (2011a) observed the same effect when participants were asked to sniff an odor while holding a viscous fluid in their mouth. The viscous fluid was associated with reduced odor intensity judgments relative to holding plain water in the mouth. While these interactions are robust and centrally mediated, their function and causes remain obscure.

A smaller body of work has suggested that odors consistently associated with creamy or viscous textures can act to enhance participants’ judgments of these textural properties (e.g., Weenen et al., 2005). These effects are also centrally mediated, as the addition of the target odorant to the viscous mixture does not alter the physical properties of the stimulus.

**45.2.2.2 Effects of Vision and Audition on Flavor Perception.** A food’s appearance gives many clues to its flavor, including its texture, freshness, and fattiness, but only food color has been explored in any depth. Color does not seem to exert any consistent effect on taste or odor perception in the mouth (e.g., Frank et al., 1989), in contrast to its well-established effect on odor intensity

judgments in orthonasal perception (e.g., Zampini et al., 2007). Color does, however, exert a significant influence on qualitative aspects of flavor perception, biasing the perceived identity of a flavor in a manner consistent with the color (e.g., DuBose et al., 1980). This effect has been most dramatically demonstrated by Morot et al. (2001), who found that changing the color of white wine to red using an odorless and tasteless colorant, acted to shift the flavor profile from that of a white wine to that of a red. Finally, one interesting study examined the effect of visual texture on actual texture perception (De Wijk et al., 2004). Here, participants could see a custard, which they *believed* they were sampling via a straw, when in fact the straw entered a separate lower compartment containing the target custard. Visual texture in the upper compartment significantly affected participants’ judgments of the texture of the target custard in the lower compartment, even though this remained unchanged throughout the experiment. All of these effects would seem to be driven by learning, with visual cues presumably generating expectancies, which in turn act to bias participants perception and/or judgment of the target flavor.

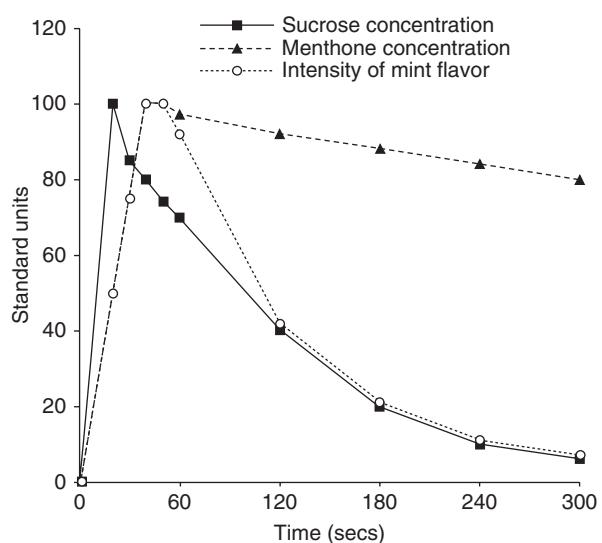

Auditory cues can also influence flavor perception. Vickers and Bourne (1976) originally suggested that a significant part of crispness perception might be driven by auditory cues. Zampini and Spence (2004) directly manipulated this by having participants receive false auditory feedback via headphones, while sampling the same potato chips (crisps). High frequency amplification enhanced judgments of crispness, while attenuation of overall loudness, and the high frequency component in particular, reduced crispness judgments. While finding no parallel effect for judgments of carbonation (Zampini and Spence, 2005), their data indicate that auditory cues can affect textural perception in certain situations.

**45.2.2.3 Olfaction and Taste.** Of all forms of flavor interaction, that between taste and smell is the most extensively studied. Pioneering experiments by Murphy, Cain, and Bartoshuk (1977) and Murphy and Cain (1980), in addition to several follow-up studies by other authors, indicated no interaction between these two modalities. However, as Lawless and Schlegel (1984) illustrated, this depends upon what is measured. Lawless and Schlegel (1984) had participants sample a series of odor-taste mixtures, judging on some trials the intensity of the taste, on others the intensity of the olfactory component, and on others still the overall intensity of the mixtures. This rating approach produced results entirely consistent with the preceding studies, demonstrating independence between taste and smell (Murphy et al., 1977; Murphy and Cain, 1980). However, when participants were asked to discriminate between all possible odor-taste mixtures

used in the experiment (e.g., weak sucrose and strong citral vs weak sucrose and weak citral), there was substantial evidence of taste–smell interactions, with some mixtures being much harder to discriminate between than others. Lawless and Schlegel (1984) concluded that the attentional strategy which participants adopted for each of these tasks – an analytical focus on one aspect of the stimulus for intensity judgments, and global comparison for discrimination – were responsible for these apparently discrepant outcomes. This work was instrumental in creating a particular way of thinking about how the task adopted by the experimenter influences the way in which participants evaluate, and perhaps experience, odor-taste mixtures (e.g., Frank et al., 1993) (see also Section 45.4.2 below).

Two types of taste–smell interaction have been documented. The first can be termed taste-induced odor enhancement. The early literature observed several examples (e.g., von Sydow et al., 1974) where the presence of a particular taste would increase intensity judgments of an olfactory attribute. For example, in a sucrose-strawberry mixture, the presence of sucrose would increase the judged intensity of the strawberry odor. The most interesting demonstration of this effect was made by Davidson, Linforth, Hollowood, and Taylor (1999), using chewing gum flavored with sucrose and menthone. First, they established the release rate of the sucrose and menthone by physically measuring these properties *in vivo*. Sucrose was lost rapidly upon chewing, while release of the menthone remained fairly constant over the 5 minutes of recording. Second, they had an experienced sensory evaluation panel chew the same type of gum in the same manner, while making judgments of its mint flavor. The fascinating finding was that variation in mint flavor judgment was *wholly* explained by variation in sucrose concentration. So even though the menthone concentration remained largely constant, reductions in mint flavor tracked reductions in sucrose (see Figure 45.1). More recent findings have confirmed this same general effect, with vanilla flavor judged far stronger in the presence of a stronger sweet taste than a weaker one (Green et al., 2012). These findings suggest that tastes, under appropriate circumstances, can act to enhance or reduce the magnitude of purely olfactory qualities.

The second type of effect, which has received more attention, concerns the effect of odorants on taste perception. Contemporary interest in this form of interaction was triggered by Frank and Byram's (1988) observation that strawberry odor, but not peanut butter odor, could increase judgments of sweetness when added to a sweet base. Subsequently, odor-induced taste enhancement has been obtained in many different settings using diverse odorants and tastants (e.g., Stevenson et al., 1999; Nasri et al., 2011; Prescott, 1999).

**Figure 45.1** Changes in physical release of sucrose and menthone in the mouth during gum chewing, alongside ratings of the intensity of the mint flavor across time (adapted from Davidson, Linforth, Hollowood & Taylor, *J. Agric. Food Chem.*, 47, 4336–4340, 1999).

Sufficient information about odor-induced taste enhancement effects, and taste-induced odor enhancement effects, is available to provide a fairly comprehensive account of their cause. One explanation, which can now be dismissed, is that they emerge from some form of physiochemical interaction (e.g., the tastant “salts out” volatiles in the mixture, thereby increasing its intensity). While salting can occur, it typically does not at tastant concentrations used in most psychophysical experiments (e.g., von Sydow et al., 1974). Another possibility, pertinent to odor-induced taste enhancement, is the ability of certain odorants to stimulate taste receptors. Again, although some odorants have this property, careful testing that has evaluated taste with the odorant in water and the nose pinched (to eliminate retronasal olfaction) finds this not to be the case (Stevenson et al., 2000).

Both taste-induced odor enhancement and odor-induced taste enhancement seem to depend upon some form of psychological congruency between the taste and smell (e.g., Frank and Byram, 1988). Although, at least theoretically, such congruency could result from the odor and taste being hedonically similar (Schifferstein and Verlegh, 1996), this does not seem to be the case as some pleasant odors (e.g., peanut butter) will not enhance pleasant tastes (e.g., sucrose). A more promising possibility concerns prior experience with a particular taste–smell combination. Stevenson, Prescott and Boakes (1999) observed that sniffed odor sweetness, that is, the sweetness that becomes attributed to an odor as a result of its prior history of co-occurrence with sweet tastes, was the single best predictor of the degree to which that odor would

enhance the sweetness of sucrose in the mouth. They also reported examples of sweetness suppression by odors that were very low in smelled sweetness, as well as the suppression of sourness by a sweet-smelling odor. Clearly, taste–smell interactions depend to a large degree upon learning (Stevenson et al., 1995).

Enhancement can also be observed under experimental conditions that do not rely on judgments of intensity. Dalton et al., (2000) measured detection thresholds for the sweet almond smelling odorant benzaldehyde against a background of saccharin, and in later experiments against monosodium glutamate (MSG). Participants were able to detect the saccharin-benzaldehyde compound at a significantly lower concentration than either benzaldehyde or saccharin alone. This was not the case for the saccharin-MSG compound, presumably because it was incongruent. One concern with these types of findings is probability summation. Detecting the presence of one stimulus when only one is present is harder than detecting the presence of one stimulus when two are present (Treisman, 1998). When estimates of probability summation are made, subthreshold integration effects between taste and smell disappear (Delwiche and Heffelfinger, 2005). However, a more recent study using reaction times to detect weak tastes, odors and taste-odor combinations indicates that reaction times are quicker even taking into account probability summation (Veldhuizen et al., 2010). This suggests that odor-taste interactions can occur even under conditions that do not favour more cognitive response based strategies.

## 45.3 FLAVOR LEARNING

The mouth affords plenty of opportunity for peripheral interactions to arise within and between food ingredients and receptors, and several different types of such interactions have been identified. Centrally mediated interactions have also been observed, most notably between taste and smell, and smell, viscosity and hardness, as well as between vision, audition, and flavor. While some of these centrally mediated effects may have pre-attentive (that is, automatic) causes, most seem to rely upon learning.

The ability to identify nutritious food is an essential prerequisite for survival. This requires learning the many and varied signals for safe and nutritious food, as well as those for energetically impoverished and poisonous food. Gibson (1966) suggested that the sensory components with flavors are “functionally united when anatomically separated” (p.137) in order to increase the chances of successful dietary selection. There is considerable evidence that learning underlies this process in humans.

Human flavor learning can be divided into two basic categories, depending upon whether its outcome involves

a perceptual or an affective change (note this is principally an organizational scheme and it does not imply any commonality of mechanism). Three types of flavor learning result in perceptual change: (1) a form of learning in which an odor associated with a previously encountered flavour comes to recover the original flavor (termed redintegration flavor learning); (2) flavor perceptual learning, in which experience with a particular class of flavor leads to an improved ability to describe, categorise, identify and discriminate between members of that class; and (3) flavor recognition learning, in which implicit perceptual/semantic templates of previously consumed foods form the point of comparison for new foods of the same general type (e.g., comparing a shop bought apple pie to that of your Grandma’s apple pie). A change of affect towards a flavor, or one of its components, occurs in several forms of flavor learning, including: flavor-flavor, flavor-calorie, flavor-drug and flavor-aversion learning, observational learning, and learned satiety. Each of these different forms of human flavor learning is reviewed below.

### 45.3.1 Learning that Results in Perceptual Change

**45.3.1.1 Redintegrative Flavor Learning.** The observation that certain odors are reported as smelling sweet, and that such odors are typically those that occur in sweet tasting foods, prompted speculation that this might be caused by learning (Frank and Byram, 1988). Stevenson et al., (1995) explored this possibility by having participants swirl and spit samples composed of one unfamiliar odor in sucrose solution, and another in citric acid solution. On a later sniffing test, it was found that odor-sucrose pairings led to that odor being judged as sweeter smelling, while odor-citric acid pairings led to the odor being judged as sourer smelling. This effect has now been obtained under several different conditions, which varied number of pairings, presentation format, and selection of odors and tastes (e.g., Prescott et al., 2004; Stevenson et al., 1998; Yeomans and Mobini, 2006). The effect has also been observed in rats (Gautam and Verhagen, 2010).

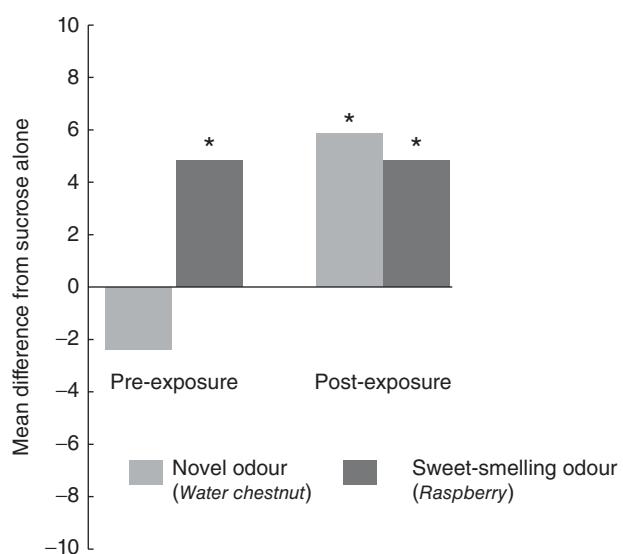

Redintegrative flavor learning has unusual properties relative to other forms of human associative learning (c.f. Shanks, 2010). It occurs rapidly (Prescott et al., 2004), it is resistant to interference (Stevenson et al., 2000), and acquisition seems to require only minimal conscious awareness of the odor-taste contingencies (Stevenson et al., 1998). Redintegrative flavor learning can also occur independently of the affective change that typically accompanies pairing an odor with a pleasant or unpleasant taste (see Flavor-flavor learning below). While odor-sucrose pairings, for example, generate *both* affective and sensory learning, only affective learning is sensitive to participants’ internal state (i.e., hungry/full) and to the extent to which

the taste is hedonically valenced (i.e., like/dislike; Yeomans et al., 2006; Yeomans and Mobini, 2006; Yeomans et al., 2009).

The perceptual consequences of this type of learning – the acquisition of a taste-like quality – seems to share many properties in common with taste sensations generated by gustatory stimuli. Perceptual similarity has been suggested by priming effects, in which sweet smelling odors facilitate identification of sweet tastes, and sour smells facilitate the identification of sour tastes (White and Prescott, 2007). The same conclusion emerges from other studies where participants smell several sweet odors and taste several sweet tastes, followed by a surprise frequency test, revealing that participants conflate the number of “real” sweet tastes with odor induced “sweet” tastes (Stevenson and Oaten, 2011a). Tastes and odor-induced tastes also seem to share some neurophysiological correlates. Damage to brain areas involved in taste perception is associated with impaired odor induced taste perception, suggesting some commonality of neural processing (Stevenson et al., 2008). This is also suggested by a study that demonstrated increased pain tolerance after sniffing sweet smells, but not pleasant non-sweet smells, an effect akin to that observed with sweet tastes (Prescott and Wilkie, 2007).

Whether somatosensory properties present within a flavor compound can be acquired by odors in a manner akin to taste has also been examined. Sundqvist et al. (2006) paired odors with milks of varying fat and sugar content. Odors paired with high fat milks were later found to enhance the perceived fat content of the same test milk relative to odors paired with low fat milks. Unfortunately, this experiment could not determine whether this effect was driven by somatosensory, gustatory or olfactory cues to fat content. A more recent study (Stevenson and Mahmut, 2010) confirmed that odors can acquire purely tactile properties. Odors were either paired with water, with the thickener carboxymethyl cellulose (CMC) or with CMC and sucrose. The odor paired with the sweetened CMC increased viscosity judgments of a partially thickened solution of CMC to a greater extent than odors that had been paired with water or CMC alone. This suggests that tastes may need to be present to support odor-viscosity learning.

One explanatory model for these effects proposes that each experience of an odor always invokes a search of memory for prior encounters with that odor. If, in the initial experience of the odor, it was paired with a taste, a cross-modal configural stimulus – that is, a flavor – is encoded in memory. Subsequently sniffing the odor alone will evoke the most similar odor memory – the flavor – that will include both the odor and the taste component. Thus, for example, sniffing caramel odor activates memorial representations of caramel flavors, which includes a sweet taste component.

**Figure 45.2** Mean ratings of the tasted sweetness of the odor/sucrose mixture relative to sucrose alone, prior to and following repeated pairing of the odor and sucrose, for an already sweet-smelling odor (*raspberry*) and a novel odor (*waterchestnut*). \*indicates significantly different (5%) from sucrose alone. Reprinted with modification from *Food Quality and Preference*, 10, J. Prescott, Flavour as a psychological construct: implications for perceiving and measuring the sensory qualities of foods, pp. 349–356, Copyright (1999), with permission from Elsevier.

This results either in perceptions of smelled taste properties such as sweetness or, in the case of a mixture, a perceptual combination of the memorial odor representation with the physically present taste in solution (Stevenson and Boakes, 2004; Stevenson et al., 1998; see Figure 45.2).

**45.3.1.2 Flavor Perceptual Learning.** Flavor perceptual learning has mainly been studied by exploring the difference between experts – for wine, beer and food – and novices. Two general points are worth making before looking in more detail at the findings from this literature. First, *perceptual expertise* in the flavor domain seems to be passively acquired (Melcher and Schooler, 1996; Valentin et al., 2007) and it is unclear if training programs can improve upon this. Second, because much of the research focus has been on comparing experts to novices, any observed performance difference could be attributable to selection bias rather than expertise. For example, anosmic people are unlikely to gravitate to wine tasting, so it may be that flavor expertise reflects a bias towards those with naturally better sensory ability or sensitivity. Although this point cannot be definitively settled, it would seem unlikely. One study of chefs (Hirsch, 1990), for example, revealed little difference in chemosensory ability relative to controls. Others have found at best

only small differences in general chemosensory ability favouring the expert (Tempere et al., 2011).

Flavor expertise seems to involve two discrete components, which then interact extensively during deployment of the special skill (Frost and Noble, 2002). The first component is perceptual expertise, which as noted above seems to be acquired passively via experience (e.g., Melcher and Schooler, 1996; Valentin et al., 2007). Melcher and Schooler (1996) found that regular wine drinkers and wine tasters were similar in discriminative ability when the test involved only discrimination, as did Valentin et al. (2007) in a comparison of expert and regular beer drinkers. Such findings point to the importance of choosing an appropriate control group when examining perceptual expertise. For example, Solomon (1990) found that expert wine tasters were significantly better at discriminating a set of white wines than participants who had rarely drunk wine before. Such differences tend to disappear when untrained but regular consumers are used instead of naïve controls, suggesting the likely importance of passive exposure. Unfortunately, we do not currently know what exposure parameters are optimal – a significant issue when considering training a sensory panel.

The second component of expertise is the extensive semantic knowledge that is accrued about the product (e.g., Solomon, 1990). Accruing such knowledge has several important benefits. One of these is the ability to verbally communicate about the product in a reliable manner. This has been demonstrated in several wine tasting studies, whereby expert wine tasters have been asked to match descriptions of wine they made on an earlier occasion, to the same wines on a later occasion. They are better at this than novices, but not dramatically so (Lawless, 1995). A more precise matching between language and sensory experience can also improve the reliability of product profiling, such that ratings made at one point in time are more closely aligned to those made at a later time, relative to those from untrained participants (Roberts and Vickers, 1994; Moskowitz, 1996).

A further benefit of semantic knowledge is the ability to organize information into meaningful categories. This is most evident in wine expertise, where knowledge of varietal features aids categorization of wines and hence their identification (Hughson and Boakes, 2002). The benefits of this type of knowledge can be seen in a study reported by Ballester et al. (2008). Here wine tasters and regular wine drinkers were initially asked to judge the similarity of several wines drawn from two varieties. Both groups produced nearly identical sets of similarity judgments, arguably reflecting common underlying perceptual differentiation. However, the participants were then asked to judge the typicality of each wine, that is the degree to which each wine reflects the features typical of its respective variety. Not surprisingly there was little agreement

amongst the novices, but substantial agreement among the experts, a consequence of their well-developed knowledge of varietal features.

**45.3.1.3 Flavor Recognition Learning.** One of the least explored aspects of flavor learning and memory is our ability to retain generalized “flavor templates” for a particular food or beverage that we have previously experienced (Barker, 1982; Mojet and Koster, 2005; Koster et al., 2004). These templates seem to be important in identifying deviations from expectation and do not appear to be directly experienced. They serve an important function in assisting the detection of spoiled, poisonous or otherwise atypical food. Studies suggest that the degree of deviation between a food and its template may need to be moderately large before participants actually notice the difference (e.g., Zellner et al., 2004). However, obvious deviations such as when a sample *looks* like strawberry ice cream but turns out to be savoury salmon mousse are readily detected – and rejected (Yeomans et al., 2008a). At least some of this ability must rely upon quite abstract flavor representations, as patients with semantic dementia demonstrate an impaired ability to identify both congruent and incongruent flavors, while showing a spared ability to discriminate one flavor from another (Piwnica-Worms et al., 2010).

### 45.3.2 Learning that Results in Affective Change

Likes and dislikes naturally arise from the integrated perception of flavor, since we are responding to substances that we have learned to recognize as foods and that are therefore biologically, culturally, and socially valued. Initial (“gut”) responses to foods are almost always hedonic and this naturally precedes accepting or rejecting the food. As with perceptual changes in odors, hedonic properties of flavors arise from associative learning.

**45.3.2.1 Flavor-Flavor Learning.** Pairing an odor with a taste can also manifest as a change in liking for that odor, one that mirrors the participants liking or disliking for the taste. In the first demonstration of this effect, Zellner et al. (1983) had participants sample one tea flavor with sucrose and another flavor in water. Across several experiments they obtained evidence that the sweet-paired tea came to be liked more than the tea experienced in water. Similar changes in odor liking based upon pairing with pleasant or unpleasant tastes have now been obtained in several different paradigms (e.g., Baeyens et al., 1990; Dickinson and Brown, 2007; Wardle et al., 2007). As noted above, these affective changes are independent of alterations in an odor’s perceptual taste-like properties (Yeomans and Mobini, 2006). As with changes in an odor’s

perceptual properties, it was originally suggested that odor affective changes occurred independently of awareness (Baeyens et al., 1990). Recent work has cast doubt on this assertion and suggests that as with many other forms of human learning, awareness of the contingencies is necessary for conditioning to occur (Wardle et al., 2007).

**45.3.2.2 Flavor-Calorie Learning.** Through repeated pairing, flavors become associated with post-ingestional consequences, including those related to the intake of nutrients (e.g., glutamate) or energy in the form of fats or carbohydrates (Mobini et al., 2007; Kern et al., 1993; Prescott, 2004a; Yeomans et al., 2008b). Flavor-calorie learning can occur independently of flavor-flavor learning. Capaldi and Privitera (2007) had participants consume either a high-fat bitter tasting food with a distinct odor or a low-fat bitter tasting food with a different distinct odor. The odor used in training was then tested in a non-bitter test food. The group which had experienced the odor paired with the high-fat food liked the test food flavor more than the group that had experienced their odor in the low-fat food. Clearly, the only difference between these groups was the energy associated with the odor, indicating the capacity of the foods energy content to change liking. Although flavor-calorie learning is likely to be a significant contributor to food preferences, and perhaps to the amount of each food that we eat, it has not been well explored in humans, so many basic questions remain unanswered (e.g., does the type of nutrient matter? How is the effect exerted? Is awareness necessary?).

**45.3.2.3 Flavor-Drug Learning.** Although most orally consumed psychoactive drugs could in theory become associated with their vehicle's flavor (but see Pliner et al., 1985), this has only been examined in any depth for caffeine. With caffeine, participants can form associations between the presumed pleasure obtained from relieving a deprivation state and the odorous component of the flavor in which it was embedded. As this would suggest, participants need to be deprived of caffeine both to learn such associations and to demonstrate them (e.g., Yeomans et al., 2007).

**45.3.2.4 Flavor-Aversion Learning.** Experiencing a flavor contingent with nausea commonly results in a long-lasting aversion to that flavor. Survey research suggests that many North Americans have one or more aversions, many of these being formed on the basis of a single flavor-nausea pairing (Logue et al., 1981). Flavor aversion learning can also be demonstrated in the laboratory using nausea induced either by chemicals or motion. Either can produce reliable aversions to flavors consumed

prior to nausea onset (e.g., Cannon et al., 1983). Apart from the rapidity of this form of learning it is especially interesting because it can occur even when a person knows that the nausea results from a cause (e.g., chemotherapy, radiotherapy, flu) other than food (e.g., Bernstein, 1978). Most recently, a form of flavor aversion arising from pairing a flavor with exercise, but without nausea, has also been reported in humans (Havermans et al., 2009).

**45.3.2.5 Observational Learning.** Much learning about food and flavor occurs during childhood. One component of this is likely to involve observing parental facial and vocal reactions to food, and the formation of attitudes on that basis. There is certainly evidence consistent with this, particularly in younger children (e.g., Marinho, 1942; Harper and Sanders, 1975). Whether observational learning exerts an effect in older children, adolescents, and adults is more contentious, and has not received consistent support (e.g., contrast Baeyens et al., 1996, with Baeyens et al., 2001).

**45.3.2.6 Learned Satiety.** A final form of flavor learning concerns the ability of prior experience with a food to regulate future intake of that food. An energy dense food will produce more rapid satiety, and it is argued that this information is learned and then used to modulate intake when the food is encountered again (e.g., Booth et al., 1982). This effect has not been consistently demonstrated and its importance in governing energy intake is not currently known (e.g., Brunstrom and Mitchell, 2007).

## 45.4 FACTORS INFLUENCING BINDING OF SENSORY SIGNALS IN FLAVORS

### 45.4.1 Spatial and Temporal Contiguity

Studies of interactions between visual, auditory, and somatosensory systems have demonstrated the importance of spatial and/or temporal contiguity in facilitating cross-modal sensory integration (Driver and Spence, 2000). In flavors, the different stimulus elements are associated temporally. However, while both gustatory and somatosensory receptors are spatially located in the mouth, olfactory receptors are not. The question then arises of how odors become bound to taste and touch. Central to this process is the *olfactory location illusion*, in which the odor components of a food appear to originate in the mouth (Rozin, 1982). Thus, we *never* have a sense that the *oranginess* of tasted orange juice is being perceived

within the nose, even if we are aware that it is an odor. This illusion is both strong and pervasive, despite the fact that we are frequently presented with evidence of the importance of the olfactory component in flavors, e.g., through a blocked nose during a head cold. One probable manifestation of this phenomenon is the interchangeability of chemosensory terms such as *flavor* and *taste* in common usage – that is, we routinely fail to make a distinction between olfactory and taste qualities within flavors.

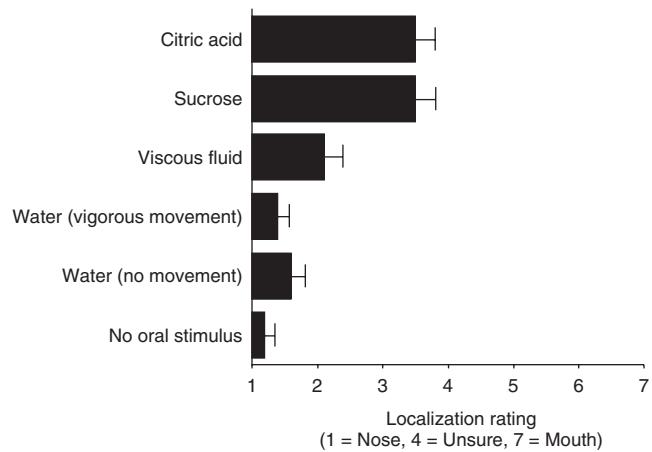

How crucial are spatial and temporal contiguity of the discrete sensory inputs to the olfactory location illusion and to odor-taste binding? Von Bekesy (1964) pointed to the likely importance of temporal factors as potential determinants of odor/taste integration by showing that the perceived location of an odor (mouth vs nose) and the extent to which an odor and taste were perceived as one sensation or two could be manipulated by varying the time delay between the presentation of the odor and taste. With a time delay of zero (simultaneous presentation), the apparent locus of the odor was the back of the mouth and the odor/taste mixture was perceived as a single entity. When the odor preceded the taste, the sensation was perceived as originating in the nose. While this report is consistent with models of binding across other sensory modalities, insufficient details were provided to judge the reliability of the conclusions.

Few subsequent studies have addressed this issue. A key role for temporal synchrony in facilitating integration is suggested by a demonstration that odor-induced taste enhancement can occur regardless of whether the odor is presented orthonasally or retronasally, providing that the odor and taste are presented simultaneously (Sakai et al., 2001). Pfieffer et al. (2005) manipulated both spatial and temporal contiguity for the odor and taste while assessing the threshold for benzaldehyde odor (almond/cherry) in the presence of a subthreshold sweet taste, but failed to find convincing evidence of their manipulations. However, a recent study, albeit preliminary, suggests that synchronicity judgments of odor and taste may be less sensitive to onset discrepancies than other multimodal stimulus pairs, including audio-visual stimuli and odors and tastes that are individually paired with visual stimuli (Kobayakawa et al., 2009). One interpretation of such a finding, if confirmed, would be that odor-taste binding operates under less stringent requirements for spatio-temporal synchrony than the multisensory integration of other sensory systems. Binding under conditions in which there is a tolerance for asynchrony might reflect the high adaptive significance of chemosensory binding or the fact that in normal eating much of the retronalusal olfactory stimulus occurs subsequent to swallowing, following initial tastes by seconds. Alternatively, at least in the case of temporal asynchrony, congruency between the odor and taste may be crucial. Thus, judgments of audio-visual asynchrony are more

difficult when the different modalities are bound by a common origin (Spence and Parise, 2010).

It has been a matter of conjecture as to whether concurrent tastes or oral tactile sensations, or both, are chiefly responsible for the capture and referral of olfactory information to the oral cavity and to binding the sensory inputs to one another and to a physical stimulus such as a food (Murphy and Cain, 1980). Prima facie, somatosensory input is strongly implicated since it provides more detailed spatial information than does taste (Lim and Green, 2008). Thus, tactile stimulation is able to capture taste, presumably by providing superior spatial information and enhancing localization (Lim and Green, 2008; Todrank and Bartoshuk, 1991). Moreover, in neuroimaging studies, retronalusal odors have been shown to activate the mouth area of primary somatosensory cortex, whereas the same odors presented via the nose do not (Small et al., 2005). This distinction, which occurs even when subjects are unaware of route of stimulation, suggests a likely neural correlate of the binding process, and supports a role for somatosensory input in the process.

However, several recent studies suggest that the key role in odor localization is played by concurrent tastes. Stevenson et al. (2011) confirmed that the presence of a taste in the mouth while an odor was sniffed was sufficient to localize that odor sensation to the mouth. Further, in a series of studies that compared the presence of tastes with tasteless somatosensory stimuli in the mouth (including the addition of mouth movements), localization was found to be primarily a function of the presence of tastes (see Figure 45.3). Much the same finding was reported by Lim

**Figure 45.3** The relative importance of tastes in localization of odors to the mouth. Mean (+SEM) judgments of where participants perceive an odor to be arising, when either no stimulus, water under various conditions, a viscous fluid (carboxy methylcellulose) or tastants are present in the mouth (adapted from Stevenson, Oaten and Mahmut (2011b), *Q.J. Exp. Psychol.*, 64, 224–240, 2011).

and Johnson (2011) who showed that odors experienced retrorosally, while poorly localized to the mouth in the absence of another stimulus, increased in the presence of tastants but not tasteless water. Moreover, they showed the effect was strongly a function of odor/taste congruency. Thus, referral was only evident when sweetness was paired with vanilla odor, and saltiness with soy sauce odor, in contrast to these odors with non-congruent tastes. This finding was subsequently replicated using sets of different congruent and incongruent odor/taste combinations presented within a solid, food-like object made from gelatin (Lim and Johnson, 2012). In contrast, however, Stevenson et al. (2011b) using a different measure of odor localization, found little evidence that odor/taste congruency was important, showing that even non-congruent tastes clearly improved odor localization over water alone. Overall, these recent studies strongly support the role of tastes in odor referral over somatosensory input and they also suggest that the effect may at least partly depend on prior learning.

The binding of odors to tastes and tactile stimuli may also rely on processing information about the origins of odor stimulation. Orthonasally presented odors are more readily identified and have lower thresholds than the same odors presented retrorosally via the mouth (Pierce and Halpern, 1996; Voirol and Daget, 1986), and there is a strong suggestion that the two routes of stimulation are processed with some independence. Thus, neuroimaging studies show different activation patterns in cortical olfactory areas as a result of route of administration (Small et al., 2005). From an adaptive point of view, this makes sense. Olfaction has been described (Rozin, 1982) as the only dual sense because it functions both to detect volatile chemicals in the air (orthonasal sniffing) and to classify objects in the mouth as foods or not, and each of these roles has unique adaptive significance. Since the mouth acts as the gateway to the gut, our chemical senses can be seen as part of a defense system to protect our internal environment – once something is placed in the mouth, there is high survival value in deciding whether or not consumption is appropriate. Sensory qualities (tastes, retrorosinal odors, tactile qualities) occurring together in the mouth are therefore bound into a single perception, which identifies a substance as a food.

#### 45.4.2 Cognitive Processes in Flavor Binding

Even though an odor's snuffed "taste" qualities and its ability to enhance that taste in solution are highly correlated (Stevenson et al., 1999), the enhancement of tastes in solution by congruent odors appears to operate under some constraints. This became evident from findings that whether or not an odor enhances taste was dependent

on task requirements. Thus, while strawberry odor was found to enhance the sweetness of sucrose in solution when the subjects were asked to judge only sweetness, the enhancement was not evident when other sensory qualities of these mixtures, such as sourness and fruitiness, were rated as well (Frank et al., 1993). Similarly, significantly less sweetness enhancement was found when subjects rated the odor as well as taste intensity of flavors (sweetness plus strawberry or vanilla) than when they rated sweetness alone (Clark and Lawless, 1994).

In attempting to explain such effects, Frank and colleagues (Frank, 2003; Frank et al., 1993; van der Klaauw and Frank, 1996) suggested that, given perceptual similarity between an odor and taste, the conceptual "boundaries" that the subject sets for a given complex stimulus will reflect the task requirements. In the case of an odor/taste mixture in which the elements share a similar quality, combining those elements is essentially optional. If so, then the apparent influence of the number of rating scales on odor/taste interactions may result from the impact of these scales on how attention is directed towards the odor and taste. In keeping with this view, van der Klaauw and Frank (1996) were able to eliminate taste enhancement by directing subjects' attention to the appropriate attributes in a taste/odor mixture, even when they were only required to *rate* sweetness.

These attentional effects appear to correspond to the differing modes of interaction that occur *within* sensory modalities. The blending of odors to form entirely new odors is a commonplace occurrence in flavor chemistry and perfumery (at least for complex odor mixtures), and hence is referred to as *synthetic* interaction (analogous to the blending of light wavelengths). By contrast, the mixing of tastes is typically seen as an *analytic* process, because individual taste qualities do not fuse to form new qualities and, like simultaneous auditory tones, can be distinguished from one another in mixtures. A further category of interaction, namely *fusion* – the notion of sensations combined to form a single percept, rather than combining synthetically to form a new sensation – was proposed and applied to flavor perception by McBurney (1986).

The notion of fusion in flavor perception implies that the percept remains analyzable into its constituent elements even when otherwise perceived as a whole. While our initial response to *apple flavor* is an effortless combining of all of its sensory qualities into a single percept, we can, if required, switch between a synthetic approach to flavor and an analysis of the flavor elements. Hence, apple flavor can be both a synthetic percept and, with minimal effort, a collection of tastes (sweet; sour), textures (crisp; juicy) and odor notes (*lemony*; *acetone-like*; *honey*). A more precise way of conceptualizing flavor therefore is that cross-modal sensory signals are combined to produce a percept, rather than combining – in the way that odors themselves do – to form a new sensation. During normal food consumption,

we typically respond to flavors synthetically – an approach reinforced by the olfactory illusion and by the extent to which flavor components are congruent. As noted earlier, this implies a sharing of perceptual qualities, e.g., sweetness of a taste and of an odor, derived from prior experience of these qualities together.

Conversely, analytic approaches to complex food or other flavor stimuli (e.g., wines) are often used by trained assessors to provide a descriptive profile of discrete sensory qualities, as distinct from an assessment of the overall flavor. Asking assessors to become analytical appears to produce inhibitory effects on odor-taste interactions. In one study using both trained descriptive panellists and untrained consumers (Bingham et al., 1990), solutions of the sweet-smelling odorant *maltol* plus sucrose were rated as sweeter than a solution of sucrose alone by the untrained consumers. In contrast, no such enhancement was found in the ratings of those trained to adopt an analytical approach to the sensory properties of this mixture.

A configural account of odor/taste perceptual learning (Stevenson and Boakes, 2004; see Section 45.3.1.1) implies that when attention is directed towards a flavor, it is attended to as a single compound or configuration, rather than a collection of elements. A configural explanation for the ability of an odor to later summate with the taste to produce enhanced sweetness implies an attentional approach that combines the odor and taste, rather than identifying them as separate elements in the flavor. In other words, for a complete binding of flavor features via configural learning, synthesis of the elements via attending to the whole flavor is critical. The limited evidence that exists suggests that the binding and joint encoding of odors, tastes and tactile sensations is automatic. This is indicated both by the finding that perceptual changes in odors following pairing with tastes appears not to require conscious awareness on the part of the subject of the particular odor-taste contingencies (Stevenson et al., 1998) and data suggesting that a single co-exposure of an odor and taste can result in transfer of the taste properties to the odor (Prescott et al., 2004).

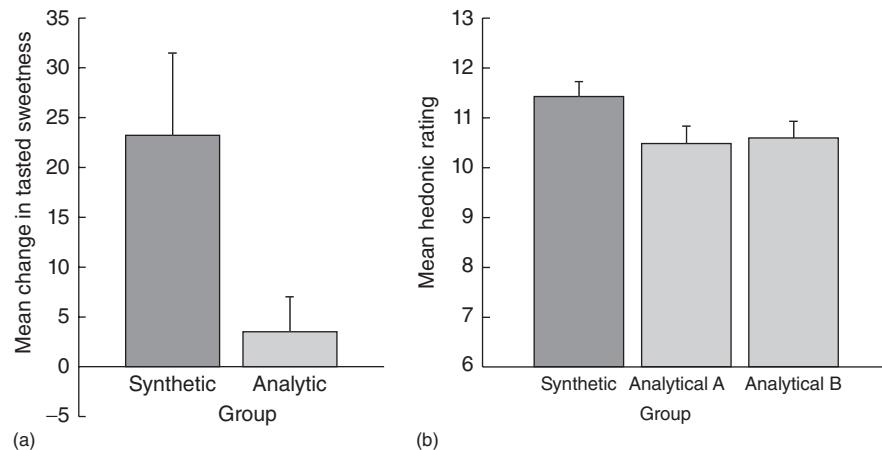

Such learning should be sensitive to manipulations in which attention is directed either towards the identity of their constituent elements (an analytical strategy) or to the configural as a whole (a synthetic strategy) during the pairing of odors and tastes, or in subsequent judgments of the odor/taste mixtures. An analytical strategy should inhibit increases in the taste properties of the odor, and the subsequent ability of the odor to influence tastes in solution. In contrast, treating the elements as a synthetic whole is likely to encourage the blurring of the perceptual boundaries, fostering subsequent odor/taste interactions.

Consistent with this, pre-exposure of the elements of the specific odor-taste flavor compounds that were

later repeatedly associated – in Pavlovian terms, US or CS pre-exposure – significantly reduced any change in odor perceptual qualities following the pairing with tastes (Stevenson and Case, 2003). Similarly, prior analytical training in which attention was explicitly directed towards the individual elements in an odor and sweet taste mixture was shown to inhibit the development of a sweet-smelling odor (Prescott and Murphy, 2009). The fact that the training used different odor/taste combinations than were later used in the conditioning procedure suggests that an attentional focus (analytical or synthetic) induced during training was then applied to *new* odor/taste combinations during conditioning. This study also showed identical effects of such a focus on the hedonic value of a flavor – only those odors paired under synthetic conditions showed conditioned liking. A similar inhibition of changes in smelled sweetness of novel odors was also reported by Labbe and Martin (2009) following sensory profiling of the odors in mixtures with sweet tastes during exposure (analytical condition), whereas increases in odor sweetness were found in a condition that used a synthetic mock-discrimination task similar to that of Prescott and Murphy (2009).

The findings from these studies have important theoretical implications in that their results are clearly consistent with configural accounts of perceptual odor-taste learning and flavor representation (Stevenson and Boakes, 2004; Stevenson et al., 1998). Under conditions where attention is directed towards individual stimulus elements during conditioning, the separate representation of these elements may be incompatible with learning of a configural representation that includes both taste and odor properties (see Figure 45.4). This explanation is supported by the demonstration that an analytical approach also acted to inhibit a sweet-smelling odor's ability to enhance a sweet taste when the odor/taste combination was evaluated in solution following repeated pairing (Prescott et al., 2004). In other words, an analytical attentional strategy can be shown to interfere with either the development of a flavor configuration resulting from associative learning, or the subsequent ability of this configuration to combine with a physically present tastant. While contrasting analytical and synthetic attentional approaches therefore appear to support a configurational explanation of flavor formation, it should be nevertheless noted that the presence of negative findings following such manipulations on odor-taste learning (Stevenson and Mahmut, 2011b) means that our understanding of the role of experimental tasks in inducing different attentional approaches remains limited.

Analytical approaches to perception appear to be inhibitory to liking even once that liking has been established. Commercial tea drinks were evaluated by consumers in one of two contexts. One group was asked only to rate their liking for the drink once it had been tasted;

**Figure 45.4** The impact of synthetic and analytical approaches to configural stimuli. (a) Mean (+SEM) ratings of the sweetness of a flavor comprised of sucrose in solution together with an odor that has previously been conditioned with this taste so that it smells sweet. Despite this, the enhancement is evident only in a group that treated the elements synthetically during their association. Figure adapted from data reported in Prescott, J., Johnstone, V. and Francis, J. (2004) Odor/taste interactions: Effects of different attentional strategies during exposure. *Chemical Senses*, 29, 331–334. (b) Mean (+SEM) ratings of overall flavour liking for a beverage sample in the synthetic (overall liking only) and the two analytical (overall liking plus attributes) groups. Reprinted with modification from *Food Quality and Preference*, 22, J. Prescott, S. M. Lee, K-O, Kim, Analytic approaches to evaluation modify hedonic responses, pp. 391–393, Copyright (2011), with permission from Elsevier.

two other groups were given this same task but their rating of liking was followed by a series of ratings of different aspects of the drink's flavor (Prescott et al., 2011). This suggests that an analytical attentional strategy was induced by knowledge that the flavor was to be perceptually analyzed, inhibiting the configuration process responsible for the transfer of hedonic properties (see Figure 45.4).

## 45.5 CLINICAL AND APPLIED ISSUES IN FLAVOR PERCEPTION

### 45.5.1 Perceptual Loss

Several studies have now examined the impact on eating behavior from damaging one of the three senses involved in oral flavor perception. Impacts have been well documented for olfaction (Aschenbrenner et al., 2008) and somewhat less so for taste (Welge-Lussen et al., 2011), but there is little information on damage to oral somatosensation. Olfactory loss is usually reported at first as a “loss of taste” with the person presenting with both taste and olfactory impairment (e.g., Deems et al., 1991). Clinical testing usually confirms that the loss is restricted to olfaction. The functional impact can be profound, with a loss of enjoyment of food, changes in food preferences, and alteration of body weight (Aschenbrenner et al., 2007). Body weight changes vary, and this may depend upon whether the anosmia is accompanied by parosmia (unpleasant olfactory distortion), which appears to be associated with weight loss (Mattes et al., 1990).

Complete loss of taste is rare, although significant general impairment can occur as a consequence of chemotherapy, radiotherapy, and some drugs (e.g., Zabernigg et al., 2010). This has a similar impact to anosmia, altering food preferences and body weight (Porter et al., 2010). Where taste loss is restricted to just one area of the tongue, this may not be noticed because of the redundancy of the taste afferents and the somatosensory referral of gustatory information across the “missing” taste region (Todrank and Bartoshuk, 1991). In addition, if the loss is restricted to one side, disinhibition may occur on the other, increasing sensitivity that further compensates for partial loss. For somatosensory loss, there are no documented reports other than temporary loss produced by local anaesthesia. This can be sufficiently profound, however, to prevent a person from recognizing the flavor of a common food (Kutter et al., 2011).

The most clinically significant manifestation of sensory loss in flavor is in the elderly, as they may experience independent reductions in their capacity to detect, identify and discriminate both tastes and smells (Hickson, 2005). This can be of major significance in the frail elderly, as poor appetite driven in part by sensory loss, may contribute to reduced food intake, weight loss, and increased risk of dying (Hickson, 2005). A similar albeit less dramatic relationship holds true in the healthy elderly, where reduced appetite may contribute to suboptimal nutrition. This was investigated by Schiffman (1992) who found that augmenting the olfactory and the gustatory components of food boosted intake and enjoyment in this population.

### 45.5.2 Flavor, Appetite, and Obesity

Shepherd (2006) has argued that a greater understanding of flavor perception can help tackle the obesity epidemic. To date four obesity-flavor perception relationships have emerged. The first concerns changes in flavor hedonics across the course of meal, which act to reduce food intake prior to the onset of physiological signals – sensory specific satiety (Hetherington, 1996; Rolls, Rowe, and Rolls, 1982). Normally the hedonic response to a particular food flavor will decline while consuming that food (e.g., Rolls and Rolls, 1997). One obvious possibility is that this process may be less efficient in obese relative to lean individuals leading them to eat more. However, in the two studies that have investigated this, neither found any significant influences of body mass on sensory specific satiety (Brondel et al., 2007; Snoek et al., 2004).

The second flavor-obesity link concerns preference for high-energy foods. Interest in this arose from a study by Drewnowski et al. (1985) that investigated fat/sugar preferences using real fat/sugar mixes in lean, obese and recovered obese female participants. They found that obese and recovered obese women had much higher fat preferences than lean women, suggesting this might contribute to poorer nutritional choices and weight gain, although sweetness differences were less evident. A more recent study of African-American adults examined whether differences in fat perception might predict food preferences and dietary choice (Liang et al., 2012). Those participants with the poorest ability to discriminate fat content expressed greater preference for fatty foods, and had more abdominal fat, than participants best able to discriminate the fat content of a set of test foods. Whether the differences in fat perception in these studies are a product or a consequence of weight gain is not currently known.

The third flavor-obesity relationship concerns taste. Bartoshuk et al. (2006) found that participants with more taste buds tend to be leaner. In a similar vein obese individuals appear to find the same sweet taste less intense than do lean persons, and they seem to enjoy increases in sweetness intensity in a way that lean participants do not. These differences in perception may again contribute to greater preferences for, and intake of, energy dense food.

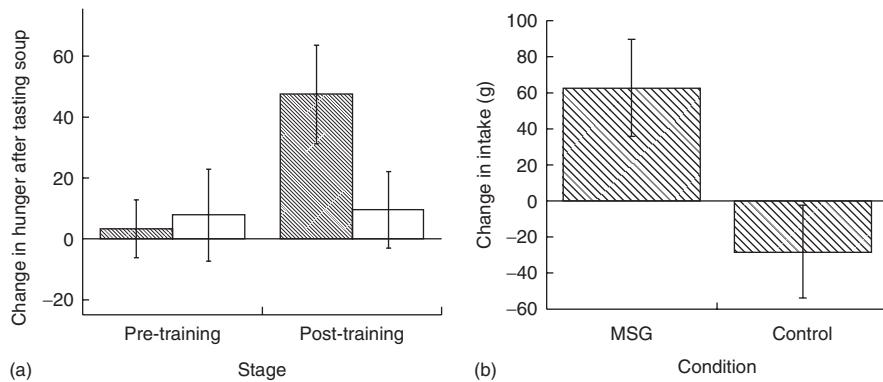

The final flavor-obesity link emerged from the claim that patients who have undergone gastric bypass surgery for weight loss seem to experience long-lasting reductions in preference for fatty and sweet foods (e.g., Miras and le Roux, 2010). Animal models (receiving gastric bypass vs. placebo treatment) confirmed that changes in fat and sugar preference do occur, but tests in humans who have undergone gastric bypass surgery reveal only modest differences in sensory and hedonic perception of flavor stimuli (Bueter

et al., 2011; le Roux et al., 2011). If these preference shifts are of sufficient magnitude to drive a reduction in energy intake, then they are of great interest, especially if the mechanism can be induced without the need for surgery.

Understanding how flavor perceptions and preferences are formed may help to provide insight into behaviors that promote obesity. As noted earlier, odor-taste pairings can produce learned flavor preferences when the pairing is accompanied by ingestion of valued nutrients. The distinction between this form of learning and flavor-flavor learning (in which a liked stimulus, such as a sweet taste, may not be accompanied by calories) can be seen in terms of the distinction between, respectively, conditioned wanting versus conditioned liking (Winkielman and Berridge, 2003). In the former, the effects of the learning can be measured in appetitive terms using measures of intake and hunger, rather than simply measures of liking. Hence, it has been recently demonstrated in humans that a novel soup flavor paired with ingested monosodium glutamate (MSG) not only increased in rated liking, even when tested without added MSG, but also, relative to a non-MSG control, produced behavioral changes including increases in *ad libitum* food intake and rated hunger following an initial tasting of the flavor (Yeomans et al., 2008b). In other words, the soup flavor became a cue that motivated the desire or want for consumption of the soup (see Figure 45.5).

This research points to an origin for the triggers to unrestrained eating that represents a risk for obesity. Via this same process seen with MSG conditioning, flavors not only become liked by pairing with energy, but also become cues that engage wanting for foods, in particular palatable (often high sugar, high fat) foods, since these are both common and effective sources of energy. For the obese, the sensory cues for the presence of energy may be especially powerful in triggering the desire to eat (Hofmann et al., 2010).

There have been some recent attempts to explore other practical implications of odor-taste learning, opening opportunities to perhaps exploit its consequences for healthier eating. It has been shown, for example, that the enhancement of tastes by congruent odors seen in model systems (that is, solutions) also occurs in foods, with bitter- and sweet-smelling odors enhancing their respective congruent tastes in milk drinks (Labbe et al., 2006). Most recently, an examination of the potential for odors from a range of salty foods to enhance saltiness in solution (Lawrence et al., 2009) and model foods (Batenburg and van der Velden, 2011) raise the possibility that such odors could be used to effectively reduce the sodium content of foods, without the typical concurrent loss of acceptability that occurs (Girgis et al., 2003). Similarly, the finding that odors can take on fat-like properties following associative pairing with fats (Sunqvist et al., 2006) might allow odors

**Figure 45.5** Mean ( $\pm$  SEM) change in (a) hunger ratings and (b) intake of soup (pre- and post-pairing data shown), following tasting a soup that had previously been repeatedly paired with monosodium glutamate (MSG; cross-hatched bar in (a)) or a control soup that had previously had no added MSG. Reprinted from *Physiology & Behavior*, 93, M. R. Yeomans, N. J. Gould, S. Mobini, J. Prescott, Acquired flavor acceptance and intake facilitated by monosodium glutamate in humans, pp. 958–966, Copyright (2008b), with permission from Elsevier.

to partially substitute for actual fat content in foods. These studies therefore point to an exciting prospect, in which research aimed at understanding multisensory processes in flavor perception may lead to applications that ultimately have important public health consequences.

### 45.5.3 Implications for the Measurement of Sensory Qualities

A configural view of flavor perception generates important implications for the measurement of sensory qualities. The differing task requirements, which appear to disrupt the fusion of distinct sensory inputs, map very well on to real distinctions that exist between consumer and trained or “expert” perceptions of food and beverage flavors. Without motivation to do otherwise, consumers will naturally integrate sensory information, thereby producing a response (typically hedonic) to the whole food or beverage. On the other hand, trained analytical panels and other experts (wine judges, and so on) are not only trained to view complex flavors as a set of individual elements, but the tasks typically required of them also involve assessment of multiple sensory attributes, each assumed to be independent.

As has been discussed in this chapter, many such attributes are not independent, even though they may be derived from distinct physiological sources. As noted earlier, Bingham et al (1990) showed that consumers, but not trained panels, showed sweetness enhancement effects by maltol odor. Prescott et al., (2011) provided evidence that analytical approaches to judging products can inhibit liking in consumers. Beyond that, there are few “real-world” data addressing this issue.

It is clear that the type of questions that are asked of consumers or subjects determine how perceptually

similar flavor qualities are combined or separated. This has obvious consequences for the psychophysical and hedonic evaluation of sensory qualities, and raises the question of what qualities *should* be measured in evaluations of food/beverage flavors. Thus, in a complex mixture such as a sweet food, which part is the “real sweetness”? Clearly, it depends on whether it is important to know about the sweetness of the flavor, or the sweetness associated with the odor or produced by the taste. However, the distinction between odor sweetness and taste sweetness may be artificial if one is evaluating flavors, since the sweetness of the flavor components may be represented cognitively, and even perhaps neurally, as equivalent. They may be functionally equivalent, as well. As noted earlier, odor sweetness can suppress tasted sourness, just as a sweetener such as sucrose does (Stevenson et al., 1999). Frank et al. (1993) suggest that the question might be an empirical one, especially for consumers. That is, what form of sweetness best predicts overall responses to foods? In this regard, overall flavor sweetness may be the most ecologically valid measure. In the case of trained panels, the whole point of descriptive analysis techniques is to deconstruct compound stimuli into their constituent parts. The question might arise therefore of whether information is being lost by relying on the physiological origin of sensory qualities (e.g., taste qualities perceived via taste receptors), rather than on their functional perceptual representations (e.g., taste as a cognitive representation). Moreover, it assumes that a particular stimulus is driving what is perceived. As shown by Davidson et al. (1999) in their study of the interaction of menthone and sweetness in chewing gum, it was the taste that determined overall flavor rather than the odor. These issues may be especially pertinent if trained panel data are being used to interpret and explain consumer responses.

## 45.6 CONCLUSION: BETTER LIVING THROUGH CHEMOSENSORY SCIENCE!

Interest in the nature and origin of flavor perceptions has recently migrated from the laboratory into the culinary world. The rise of molecular or “modernist” cuisine has been based to a large extent on understanding and utilizing the experience-dependent interactions that have been discussed in this chapter (Prescott, 2012). Chefs practicing this form of cuisine make use of the ability of sensory signals to enhance one another. For example, diners are presented with auditory and visual stimuli that are congruent with the food they are eating, presumably in an attempt to make the flavor experience more immersive. One famous example is the use of the sound of waves on the shore (via an iPod hidden in a conch shell) to accentuate the visual presentation of seafood on a tapioca-based “sandy beach,” with a vegetable and seafood based foam as the rolling waves. Other dishes take advantage of well-known perceptual biases based on visual primacy, as well as our poor ability at olfactory recognition. Hence, apparently simple tastes such as an orange flavored jelly coloured a deep red paired with a beetroot flavored jelly coloured orange can arouse surprise, if not confusion in the diner, because of the conflict between what is seen and what is tasted. Perhaps most interesting, however, are attempts to isolate the experience of flavor for the diner. The British chef Heston Blumenthal creates a dish that consists of a tactile stimulus, hardened, whipped egg white minimally-flavored with powdered green tea, but accompanied by a fine mist of lime odor sprayed into the air above the diner. The hidden surprise in this dish is the effortless way in which the textural and taste sensory properties of the “mousse” are combined with the lime odor to produce an integrated flavor. The diner receives a dramatic demonstration of a simple, but genuine, multisensory experience. And while the overall effect is also presented for its hedonic properties (that is, it is meant to be delicious), it has no purpose beyond this and no real nutritional value. It is as close as most diners have ever come to experiencing a flavor without a food. Whether such “experiments” with flavor and foods become merely a culinary footnote remains to be seen, but they are evidence that research on flavor is seeping into the “real world”.

## Neural Integration of Taste, Smell, Oral Texture, and Visual Modalities

EDMUND T. ROLLS

### 46.1 INTRODUCTION

#### 46.1.1 Introduction and Overview

The aims of this chapter are to describe how taste, olfactory, visual, oral sensory, and other sensory inputs are combined in the brain, how a representation of reward value is produced, and how cognition and selective attention influence this processing.

Complementary neuronal recordings in primates, and functional neuroimaging in humans, show that the primary taste cortex in the anterior insula provides separate and combined representations of the taste, temperature, and texture (including fat texture) of food in the mouth independently of hunger and thus of reward value and pleasantness. One synapse on, in the orbitofrontal cortex, these sensory inputs are for some neurons combined by associative learning with olfactory and visual inputs, and these neurons encode food reward in that they only respond to food when hungry, and in that activations correlate with subjective pleasantness. Cognitive factors, including word-level descriptions, and selective attention to affective value, modulate the representation of the reward value of taste and olfactory stimuli in the orbitofrontal cortex and a region to which it projects, the anterior cingulate cortex, a tertiary taste cortical area. The food reward representations formed in this way play an important role in the control of appetite, food intake. Individual differences in these reward representations may contribute to obesity.

#### 46.1.2 Food Reward and Appetite

A reason why it is important to understand the brain systems for food reward is that the reward value of food (i.e., whether we will work for a food), measures our appetite for a food, and whether we will eat a food. Thus normally we want food (will work for it, and will eat it) when we like it. “We want because we like”: the goal value, the food reward value, makes us want it. For example, neurons in the orbitofrontal cortex and lateral hypothalamus described below respond to the reward value of a food when it is, for example, shown, and these neuronal responses predict whether that food will be eaten (Rolls, 1981, 2005a, 2014; Rolls et al., 1986, 1989). Similarly, in a whole series of studies on sensory-specific satiety in humans based on these discoveries, the reported pleasantness in humans of a food is closely correlated with whether it will then be eaten, and even with how much is eaten (Rolls et al., 1981b, 1983b, 1984). The situation when it has been suggested that wanting is not a result of liking (Berridge et al., 2009), is when behavior becomes a habit. A habit is a stimulus-response type of behavior that is no longer under control of the goal, but is under the control of an overlearned conditioned stimulus (Rolls, 2005a, 2014). The concept here is that food reward normally drives appetite and eating, and it is therefore important to understand the brain mechanisms involved in food reward, in order to understand the control of appetite and food intake.

### 46.1.3 Investigations in Primates including Humans

The focus of the approach taken here is on complementary neurophysiological investigations in macaques and functional neuroimaging in humans. There are a number of reasons for this focus.

First, there are major anatomical differences in the neural processing of taste in rodents and primates (Rolls and Scott, 2003; Scott and Small, 2009; Small and Scott, 2009). In rodents (and also in primates) taste information is conveyed by cranial nerves 7, 9, and 10 to the rostral part of the nucleus of the solitary tract (NTS) (Norgren and Leonard, 1971; Norgren and Leonard, 1973; Norgren, 1990) (see Figure 46.1). However, although in primates the NTS projects to the taste thalamus and thus to the cortex (Figure 46.1), in rodents the majority of NTS taste neurons responding to stimulation of the taste receptors of the anterior tongue project to the ipsilateral medial aspect of the pontine parabrachial nucleus (PbN), the rodent “pontine taste area” (Cho et al., 2002; Small and Scott, 2009). The remainder project to adjacent regions of the medulla. From the PbN the rodent gustatory pathway bifurcates into two pathways: (1) a ventral “affective” projection to the hypothalamus, central gray, ventral striatum, bed nucleus of the stria terminalis and amygdala; and (2) a dorsal “sensory” pathway, which first synapses in the thalamus and then the agranular and dysgranular insular gustatory cortex (Norgren and Leonard, 1971; Norgren, 1974, 1976, 1990). These regions, in turn, project back to the PbN in rodents to sculpt the gustatory code and guide complex feeding behaviors (Norgren, 1976; Di Lorenzo, 1990; Norgren, 1990; Li et al., 2002; Lundy and Norgren, 2004).

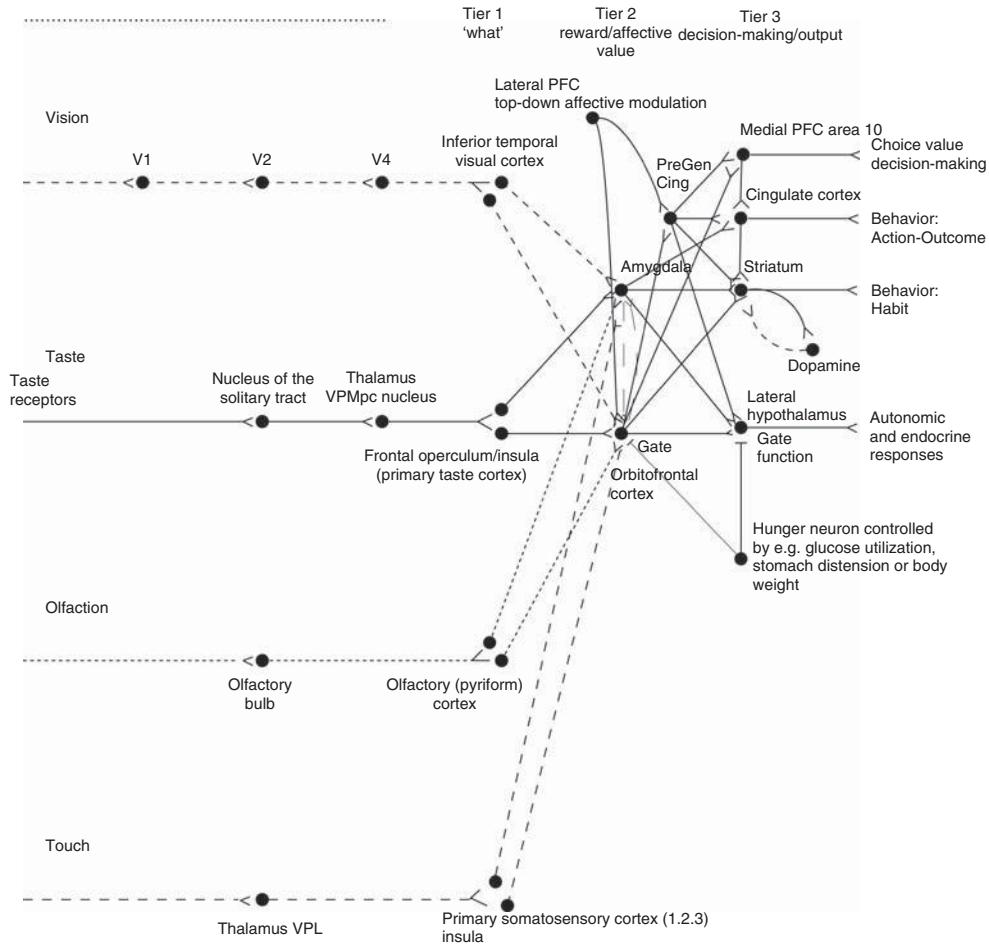

In contrast, in primates (including humans) there is strong evidence to indicate that the PbN gustatory relay is absent (Small and Scott, 2009): (1) Second-order gustatory projections that arise from rostral NTS appear not to synapse in the PbN and instead join the central tegmental tract and project directly to the taste thalamus in primates (Beckstead et al., 1980; Pritchard et al., 1989); (2) Despite several attempts, no one has successfully isolated taste responses in the monkey PbN (Norgren, 1990; Small and Scott, 2009) (the latter cite Ralph Norgren, personal communication and Tom Pritchard, personal communication); (3) In monkeys the projection arising from the PbN does not terminate in the region of ventral basal thalamus that contains gustatory responsive neurons (Pritchard et al., 1989).

Second, a functional difference of rodent taste processing from that of primates is that physical and chemical signals of satiety have been shown to reduce the taste responsiveness of neurons in the nucleus in the solitary tract, and the pontine taste area, of the rat, with decreases in the order of 30%, as follows (Rolls and Scott, 2003; Scott and Small, 2009). Gastric distension by air or with 0.3 M

NaCl suppress responses in the NTS, with the greatest effect on glucose (Gleen and Erickson, 1976). Intravenous infusions of 0.5 g/kg glucose (Giza and Scott, 1983), 0.5 U/kg insulin (Giza and Scott, 1987b), and 40 µg/kg glucagon (Giza et al., 1993), all cause reductions in taste responsiveness to glucose in the NTS. The intraduodenal infusion of lipids causes a decline in taste responsiveness in the PbN, with the bulk of the suppression borne by glucose cells (Hajnal et al., 1999). The loss of signal that would otherwise be evoked by hedonically positive tastes implies that the reward value that sustains feeding is reduced at the brainstem level, making termination of a meal more likely (Giza et al., 1992). Further, if taste activity in NTS is affected by the rat’s nutritional state, then intensity judgements in rats should change with satiety. There is evidence that they do. Rats with conditioned aversions to 1.0 M glucose show decreasing acceptance of glucose solutions as their concentrations approach 1.0 M. This acceptance gradient can be compared between euglycemic rats and those made hyperglycemic through intravenous injections (Scott and Giza, 1987). Hyperglycemic rats showed greater acceptance at all concentrations from 0.6 to 2.0 M glucose, indicating that they perceived these stimuli to be less intense than did conditioned rats with no glucose load (Giza and Scott, 1987a).

In contrast, in primates, the reward value of taste is represented in the orbitofrontal cortex in that the responses of orbitofrontal taste neurons are modulated by hunger in just the same way as is the reward value or palatability of a taste. In particular, it has been shown that orbitofrontal cortex taste neurons stop responding to the taste of a food with which a monkey is fed to satiety, and that this parallels the decline in the acceptability of the food (Rolls et al., 1989; Critchley and Rolls, 1996c). In contrast, the representation of taste in the primary taste cortex of primates (Scott et al., 1986; Yaxley et al., 1990) is not modulated by hunger (Rolls et al., 1988; Yaxley et al., 1988). Thus in the primary taste cortex of primates (and at earlier stages of taste processing including the nucleus of the solitary tract (Yaxley et al., 1985)), the reward value of taste is not represented, and instead the identity of the taste is represented (Rolls, 2014).

The importance of cortical processing of taste in primates, first for identity and intensity in the primary taste cortex, and then for reward value in the orbitofrontal cortex, is that both types of representation need to be interfaced to visual and other processing that requires cortical computation. For example, it may have adaptive value to be able to represent exactly what taste is present, and to link it by learning to the sight and location of the source of the taste, even when hunger and reward is not being produced, so that the source of that taste can be found in future, when it may have reward value. In line with cortical processing to dominate the processing of taste in primates, there is no

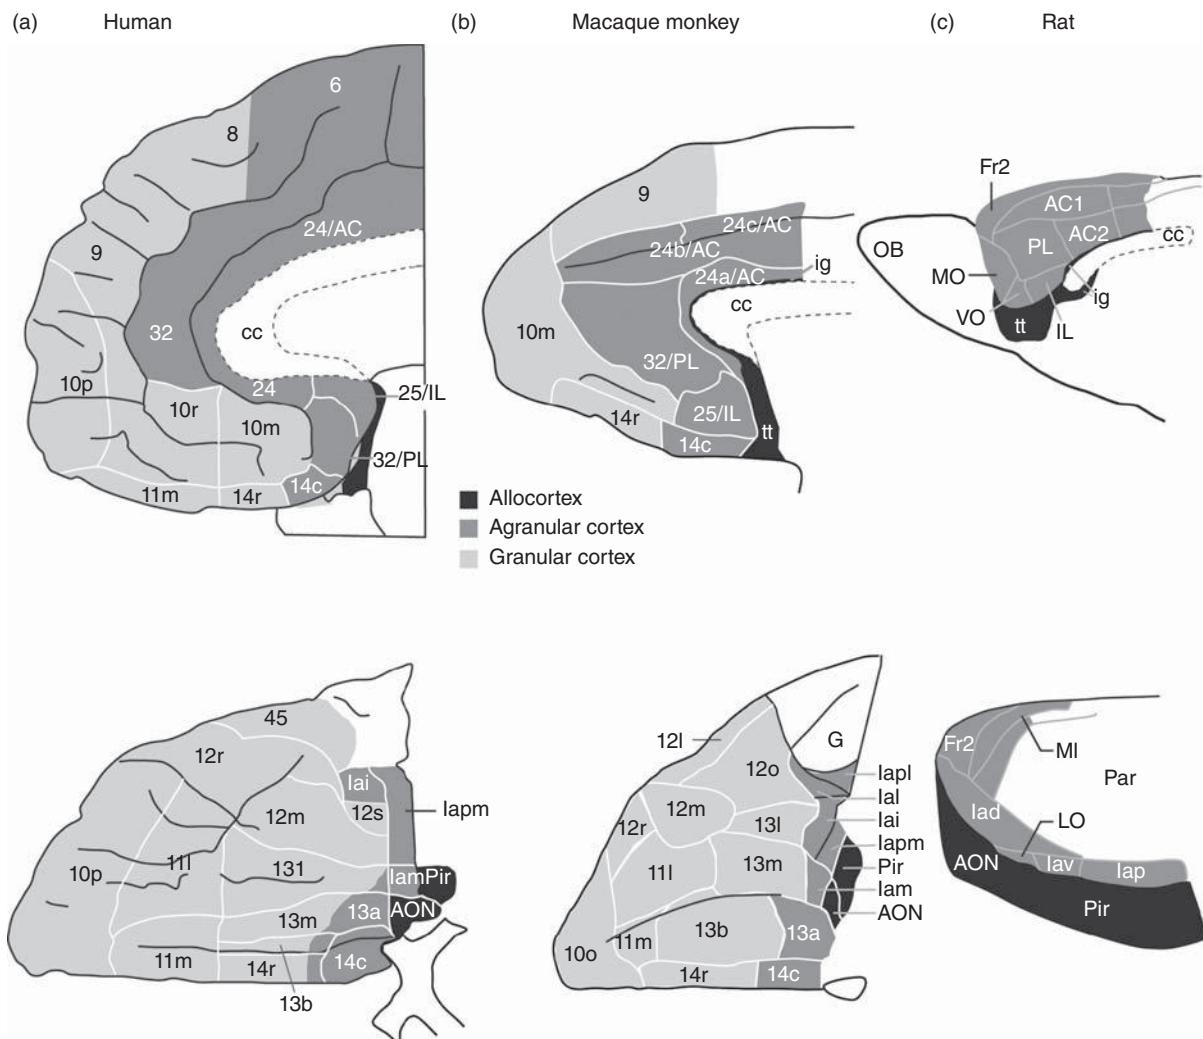

**Figure 46.1** Schematic diagram showing some of the gustatory, olfactory, visual and somatosensory pathways to the orbitofrontal cortex, and some of the outputs of the orbitofrontal cortex, in primates. The secondary taste cortex, and the secondary olfactory cortex, are within the orbitofrontal cortex. V1 - primary visual cortex. V4 - visual cortical area V4. PreGen Cing – pregenual cingulate cortex. “Gate” refers to the finding that inputs such as the taste, smell, and sight of food in some brain regions only produce effects when hunger is present (Rolls, 2005a). Tier 1: the column of brain regions including and below the inferior temporal visual cortex represents brain regions in which “what” stimulus is present is made explicit in the neuronal representation, but not its reward or affective value which are represented in the next tier of brain regions (Tier 2), the orbitofrontal cortex and amygdala, and in the anterior cingulate cortex. In Tier 3 areas beyond these such as medial prefrontal cortex area 10, choices or decisions about reward value are taken, with the mechanisms described elsewhere (Rolls, 2008a; Rolls and Deco, 2010; Rolls, 2014). Top-down control of affective response systems by cognition and by selective attention from the dorsolateral prefrontal cortex is also indicated. Medial PFC area 10 – medial prefrontal cortex area 10; VPMpc – ventralposteriormedial thalamic nucleus.

modulation of taste responsiveness at or before the primary taste cortex, and the pathways for taste are directly from the nucleus of the solitary tract in the brainstem to the taste thalamus and then to the taste cortex (Figure 46.1) (Rolls, 2014).

The implication is that taste, and the closely related olfactory and visual processing that contribute to food reward, are much more difficult to understand in rodents than in primates, partly because there is less segregation of “what” (identity and intensity) from hedonic processing in rodents, and partly because of the more serial hierarchical processing in primates (Figure 46.1).

Third, the prefrontal cortex (and for that matter the temporal lobe visual cortical areas) have also undergone great development in primates, and one part of the prefrontal cortex, the orbitofrontal cortex, is very little developed in rodents, yet is one of the major brain areas involved in taste and olfactory processing, and emotion and motivation, in primates including humans. Indeed, it has been argued (on the basis of cytoarchitecture, connections, and functions) that the granular prefrontal cortex is a primate innovation, and the implication of the argument is that any areas that might be termed orbitofrontal cortex in rats (Schoenbaum et al., 2009) are homologous only

**Figure 46.2** Comparison of the orbitofrontal (below) and medial prefrontal (above) cortical areas in humans, macaque monkeys, and rats. (a) Medial (top) and orbital (bottom) areas of the human frontal cortex (Öngür et al. (2003)). (b) Medial (top) and orbital (bottom) areas of the macaque frontal cortex (Carmichael and Price (1994)). (c) Medial (top) and lateral (bottom) areas of rat frontal cortex (Palomero-Gallagher and Zilles (2004)). Rostral is to the left in all drawings. Top row: dorsal is up in all drawings. Bottom row: in (a) and (b), lateral is up; in (c), dorsal is up. Not to scale. Abbreviations: AC, anterior cingulate cortex; AON, anterior olfactory ‘nucleus’; cc, corpus callosum; Fr2 second frontal area; Ia, agranular insular cortex; ig, induseum griseum; IL, infralimbic cortex; LO, lateral orbital cortex; MO, medial orbital cortex; OB, olfactory bulb; Pr, piriform (olfactory) cortex; PL, prelimbic cortex; tt, tenia tecta; VO, ventral orbital cortex; Subdivisions of areas are labelled caudal (c); inferior (i), lateral (l), medial (m); orbital (o), posterior or polar (p), rostral (r), or by arbitrary designation (a, b). to the agranular parts of the primate orbitofrontal cortex (shaded mid gray in Figure 46.2), that is to areas 13a, 14c, and the agranular insular areas labelled Ia in Figure 46.2 (Passingham and Wise, 2012). It follows from that argument that for most areas of the orbitofrontal and medial prefrontal cortex in humans and macaques (those shaded light gray in Figure 46.2), special consideration must be given to research in macaques and humans. As shown in Figure 46.2, there may be no cortical area in rodents that is homologous to most of the primate including human

orbitofrontal cortex (Preuss, 1995; Wise, 2008; Passingham and Wise, 2012).

## 46.2 TASTE PROCESSING IN THE PRIMATE BRAIN

### 46.2.1 Pathways

A diagram of the taste and related olfactory, somatosensory, and visual pathways in primates is shown in Figure 46.1.

The multimodal convergence that enables single neurons to respond to different combinations of taste, olfactory, texture, temperature, and visual inputs to represent different flavors produced often by new combinations of sensory input is a theme of that will be addressed.

### 46.2.2 The Insular Primary Taste Cortex

Rolls and colleagues have shown that the primary taste cortex in the primate anterior insula and adjoining frontal operculum contains not only taste neurons tuned to sweet, salt, bitter, sour (Scott et al., 1986; Yaxley et al., 1990; Scott and Plata-Salaman, 1999; Rolls and Scott, 2003), and umami as exemplified by monosodium glutamate (Baylis and Rolls, 1991; Rolls et al., 1996b), but also other neurons that encode oral somatosensory stimuli including viscosity, fat texture, temperature, and capsaicin (Verhagen et al., 2004). Some neurons in the primary taste cortex respond to particular combinations of taste and oral texture stimuli, but do not respond to olfactory stimuli or visual stimuli such as the sight of food (Verhagen et al., 2004). Neurons in the primary taste cortex do not represent the reward value of taste, that is the appetite for a food, in that their firing is not decreased to zero by feeding the taste to satiety (Rolls et al., 1988; Yaxley et al., 1988).

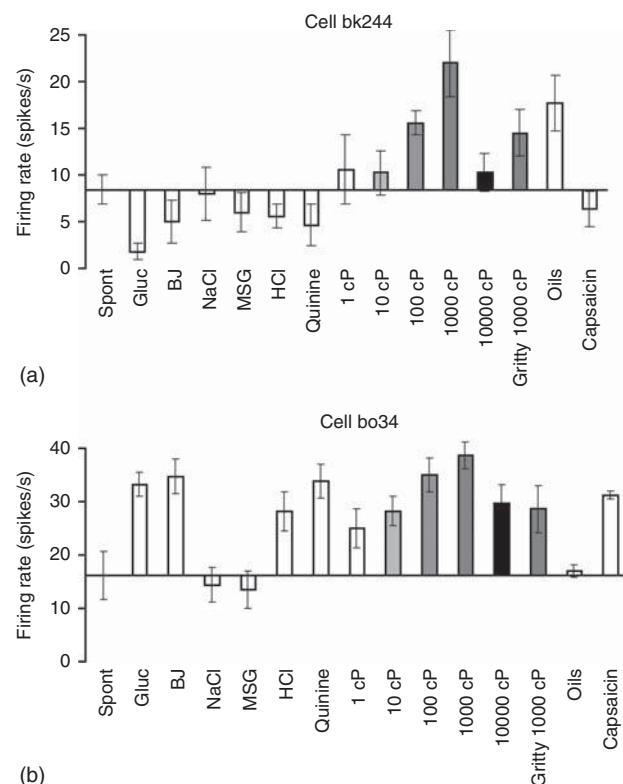

Parts of the insula can be activated by visual stimuli related to disgust, such as a face expression of disgust (Phillips et al., 2004), and this could reflect the fact that parts of the insula are part of the visceral efferent system involved in autonomic responses (Critchley, 2005) (and may even overlap partly with the taste-responsive areas (Simmons et al., 2013)).

### 46.2.3 The Secondary Taste Cortex in the Orbitofrontal Cortex

A secondary cortical taste area in primates was discovered by Rolls and colleagues (Thorpe et al., 1983; Rolls et al., 1989; Rolls et al., 1990) in the orbitofrontal cortex, extending several mm in front of the primary taste cortex. This is defined as a secondary cortical taste area, for it receives direct inputs from the primary taste cortex, as shown by a combined neurophysiological and anatomical pathway tracing investigation (Baylis et al., 1995). Different neurons in this region respond not only to each of the four classical prototypical tastes sweet, salt, bitter, and sour (Rolls et al., 1990, 2003a; Rolls, 1997; Verhagen et al., 2003; Kadohisa et al., 2005b), but also to umami tastants such as glutamate (which is present in many natural foods such as tomatoes, mushrooms, and milk) (Baylis and Rolls, 1991) and inosine monophosphate (which is present in meat and some fish such as tuna) (Rolls et al., 1996b). This evidence,

taken together with the identification of glutamate taste receptors (Zhao et al., 2003; Maruyama et al., 2006), leads to the view that there are five prototypical types of taste information channels, with umami contributing, often in combination with corresponding olfactory inputs (Rolls et al., 1998; McCabe and Rolls, 2007; Rolls, 2009a), to the flavor of protein. In addition, other neurons respond to water (Rolls et al., 1990), and others to somatosensory stimuli including astringency as exemplified by tannic acid (Critchley and Rolls, 1996a), and capsaicin (Rolls et al., 2003a; Kadohisa et al., 2004).

Some of the coding principles are illustrated by the two neurons shown in Figure 46.3. The two neurons each

**Figure 46.3** Taste and oral somatosensory inputs to orbitofrontal cortex neurons. (a) Firing rates (mean  $\pm$  sem) of viscosity-sensitive neuron bk244 which did not have taste responses, in that it did not respond differentially to the different taste stimuli. The firing rates are shown to the viscosity series (carboxymethylcellulose 1 – 10,000 centipoise, to the gritty stimulus (1,000 cP carboxymethylcellulose with Fillrite microspheres), to the taste stimuli 1 M glucose (Gluc), 0.1 M NaCl, 0.1 M MSG, 0.01 M HCl and 0.001 M QuinineHCl, and to fruit juice (BJ). Spont = spontaneous firing rate. (b) Firing rates (mean  $\pm$  sem) of viscosity-sensitive neuron bo34 which had no response to the oils (mineral oil, vegetable oil, safflower oil and coconut oil, which have viscosities that are all close to 50 cP). The neuron did not respond to the gritty stimulus in a way that was unexpected given the viscosity of the stimulus, was taste tuned, and did respond to capsaicin. (After Rolls, Verhagen and Kadohisa, 2003).

have their independent tuning to the set of stimuli. It is this independent tuning or coding that underlies the ability of the brain to represent the exact nature of a stimulus or event, and this applies to taste in addition to other sensory modalities (Rolls et al., 2010d; Rolls and Treves, 2011). The encoding of information in the brain can of course not be captured by functional neuroimaging, because that takes an average of the activity of tens of thousands of neurons, whereas each neuron conveys information that is to a considerable extent independent of the information encoded by other neurons (Rolls et al., 2009; Rolls et al., 2010d; Rolls and Treves, 2011).

Taste responses are found in a large mediolateral extent of the orbitofrontal cortex (Critchley and Rolls, 1996a; Pritchard et al., 2005; Rolls, 2008b; Rolls and Grabenhorst, 2008). Indeed, taste neurons have been shown to extend throughout area 13 in a region that is approximately 7–12 mm from the midline (Rolls and Baylis, 1994; Critchley and Rolls, 1996a; Rolls et al., 1996b; Rolls, 2008b), the exact area in which Pritchard et al. (2005) also found a population of taste neurons (see Figure 46.3 with cytoarchitectonic areas indicated after Carmichael and Price, 1994; Öngür and Price, 2000; Petrides and Pandya, 2001; Öngür et al., 2003). We showed in our previous studies that these taste neurons extend from approximately 4 mm anterior to the clinoid process of the sphenoid bone to 12 mm anterior. Pritchard et al. (2005) focused their investigation on a region 5–9 mm anterior to the sphenoid. Although Pritchard et al. (2005) commented that in their study there was a good proportion of taste neurons in this area, we, in comparing the proportions of taste neurons in different parts of the orbitofrontal cortex extending out laterally through area 12, find similar proportions of taste neurons throughout this mediolateral extent (from 7 mm to 20 mm lateral) (Rolls et al., 1989, 1990, 1996b, 2003a; Rolls and Baylis, 1994; Critchley and Rolls, 1996a; Verhagen et al., 2003; Kadohisa et al., 2004, 2005b). Moreover, even in area 13m, in the region 7–12 mm lateral where Pritchard et al. (2005) found taste neurons, we know that many other properties are represented, including oral texture as exemplified by astringency and fat texture (Critchley and Rolls, 1996a; Rolls et al., 1999); and olfactory properties (Critchley and Rolls, 1996b, c; Rolls et al., 1996) which can become associated by learning with taste stimuli (Rolls et al., 1996c). Thus area 13m contains taste, oral texture, and olfactory representations. Some of these cells are multimodal in these modalities (Rolls and Baylis, 1994; Critchley and Rolls, 1996a; Rolls et al., 1996c), and the majority of these neurons have their responses to taste and/or olfactory stimuli modulated by hunger (Critchley and Rolls, 1996c). In a more recent investigation, Rolls,

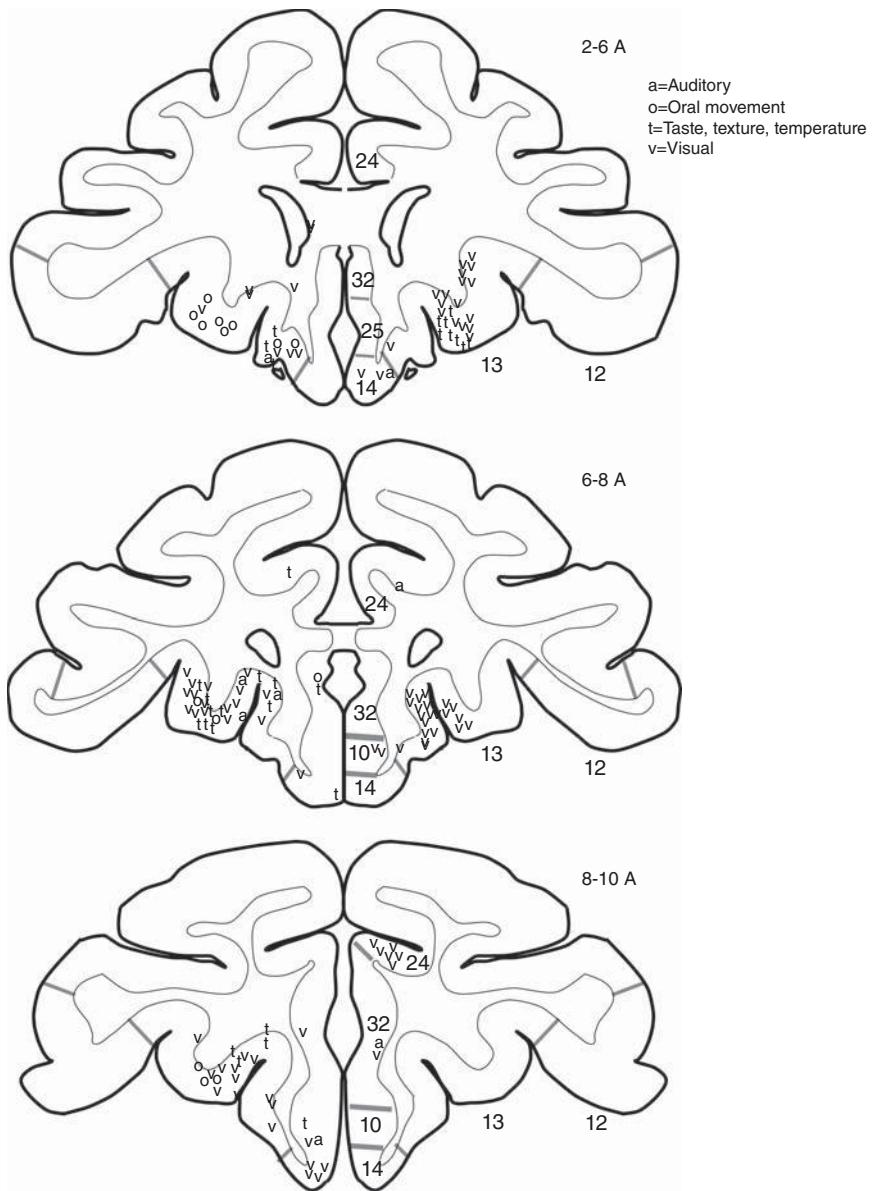

Verhagen, Gabbott, and Kadohisa measured the responses of 1753 neurons in rhesus macaques, and found taste neurons in the mid and medial orbitofrontal cortex region extending to within approximately 7 mm of the midline in area 13m, but very few in the more medial areas 10, 14, and 25, as illustrated in Figure 46.4 (Rolls, 2008b).

#### **46.2.4 The Anterior Cingulate Cortex: A Tertiary Taste Cortical Area**

The orbitofrontal cortex, including the extensive areas where taste neurons noted above are found, projects to the pregenual cingulate cortex area 32 (Carmichael and Price, 1996). Human imaging studies have shown that reward-related stimuli, such as the taste of sucrose and the texture of oral fat, activate the pregenual cingulate cortex (de Araujo and Rolls, 2004; Rolls, 2005a; Rolls and Grabenhorst, 2008; Rolls, 2009b; Grabenhorst and Rolls, 2011). However, little is known at the neuronal level of whether the responses of single neurons in the pregenual cingulate cortex are tuned to taste stimuli and respond differentially to different taste stimuli. Rolls, Gabbott, Verhagen, and Kadohisa therefore recorded from single neurons in the macaque pregenual cingulate cortex, in order to obtain evidence on these issues (Rolls et al., 2008b).

The responses of a pregenual cingulate cortex neuron with taste responses are shown in Figure 46.5. The neuron increased its firing rate primarily to glucose, fruit juice and cream, with some response to the oily texture of silicone oil, to monosodium glutamate, and to quinine. When the macaque was fed to satiety with glucose, the neuron showed a sensory-specific decrease in its response to the taste of glucose (Rolls, 2008b).

The data for the pregenual cingulate cortex and adjacent areas were obtained by Rolls, Gabbott, Verhagen, and Kadohisa (Rolls, 2008b) in two rhesus macaques in recordings that extended from approximately 10 mm anterior with respect to the sphenoid reference to approximately 13 mm anterior, with the recording sites of the neurons shown in Figure 46.6 (Rolls, 2008b). As shown, most of these neurons were in area 32, with one taste neuron in area 10. Although a small proportion of the neurons were classified as responding to taste, this proportion is not out of line with the proportion of taste neurons recorded with identical techniques in the same laboratory in the primary taste cortex in the macaque anterior insula and adjoining frontal opercular cortex. Of the 12 responsive neurons in the medial wall cortex, 11 had best responses to sweet stimuli (glucose and/or fruit juice, as illustrated in Figure 46.5), and one had best responses to quinine and NaCl. The spontaneous firing rates of neurons in the

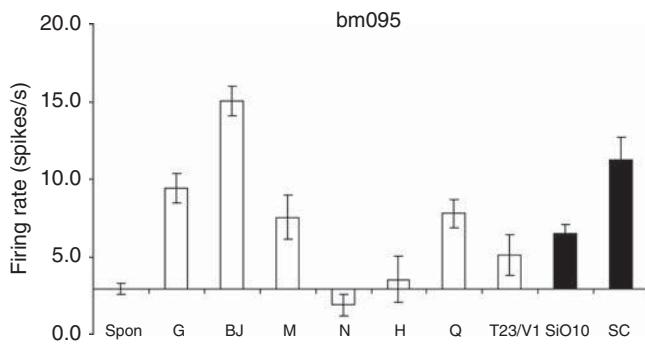

**Figure 46.4** The reconstructed positions of the neurons in the medial orbitofrontal cortex with different types of response, with the cytoarchitectonic boundaries determined after Carmichael and Price (1994). The neurons within different planes at distances in mm anterior (a) to the sphenoid reference point are shown on the coronal sections. (Data from Rolls, Verhagen, Gabbott and Kadohisa, 2008; see Rolls, 2008b).

pregenual cingulate cortex were typically in the range 0–5 spikes/s, which increased significantly to 20–30 spikes/s when the neurons were responding selectively to specific taste stimuli.

The presence of a neuronal representation of a primary (unlearned) reinforcer, taste, in the pregenual cingulate cortex is of importance for understanding the functions more generally of the anterior cingulate cortex in complex reward-related learning (Amiez et al., 2006), and in action selection (Grabenhorst and Rolls, 2011; Rushworth et al., 2011), for this evidence shows that primary rewards are represented in at least one part of the anterior cingulate cortex – the pregenual cingulate cortex area 32 (Rolls, 2008b; Rolls, 2009b). Neurons responding to fruit juice used as a

reinforcer in saccade countermanding have been found in the dorsal part of the anterior cingulate sulcus area 24c (Ito et al., 2003), and the pregenual cingulate cortex provides a source of inputs to area 24 (Carmichael and Price, 1996). Indeed, establishing that the pregenual cingulate cortex contains a representation of a primary reinforcer, in this case a taste, is of importance more generally in relation to understanding the functions of the pregenual cingulate cortex in emotion (Rolls and Grabenhorst, 2008; Rolls, 2009b; Grabenhorst and Rolls, 2011), in that for example some disorders of emotion in humans produced by anterior cingulate damage include deficits in responding to what are probably other primary reinforcers, face and voice expression (Hornak et al., 2003; Rolls, 2005a, 2014).

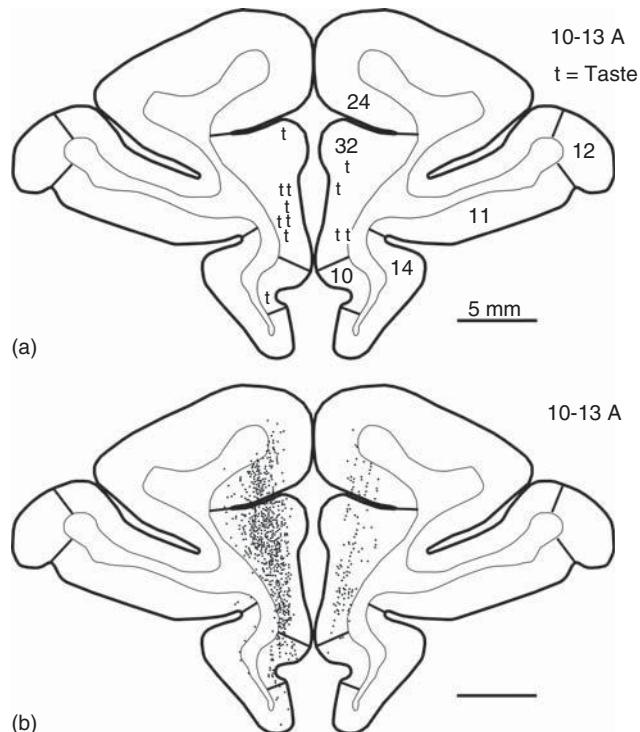

**Figure 46.5** Responses of a pregenual cingulate cortex neuron (bm095) with differential responses to tastes and oral fat texture stimuli. The mean ( $\pm$ sem) firing rate responses to each stimulus calculated in a 5 s period over several trials are shown. The spontaneous (Spon) firing rate of 3 spikes/s is shown by the horizontal line, with the responses indicated relative to this line. The taste stimuli were 1 M glucose (G), blackcurrant fruit juice (BJ), 0.1 M NaCl (N), 0.1 M MSG (M), 0.01 M HCl (H) and 0.001 M QuinineHCl (Q); water (T23/V1); single cream (SC); and silicone oil with a viscosity of 10 cP (SiO10). The neuron had significantly different responses to the different stimuli as shown by a one-way ANOVA ( $F[9,46]=17.7$ ,  $p<10^{-10}$ ). (Data from Rolls, Gabbott, Verhagen, and Kadohisa; see Rolls, 2008b).

#### 46.2.5 The Pleasantness of the Taste of Food, Sensory-Specific Satiety, and the Effects of Variety on Food Intake

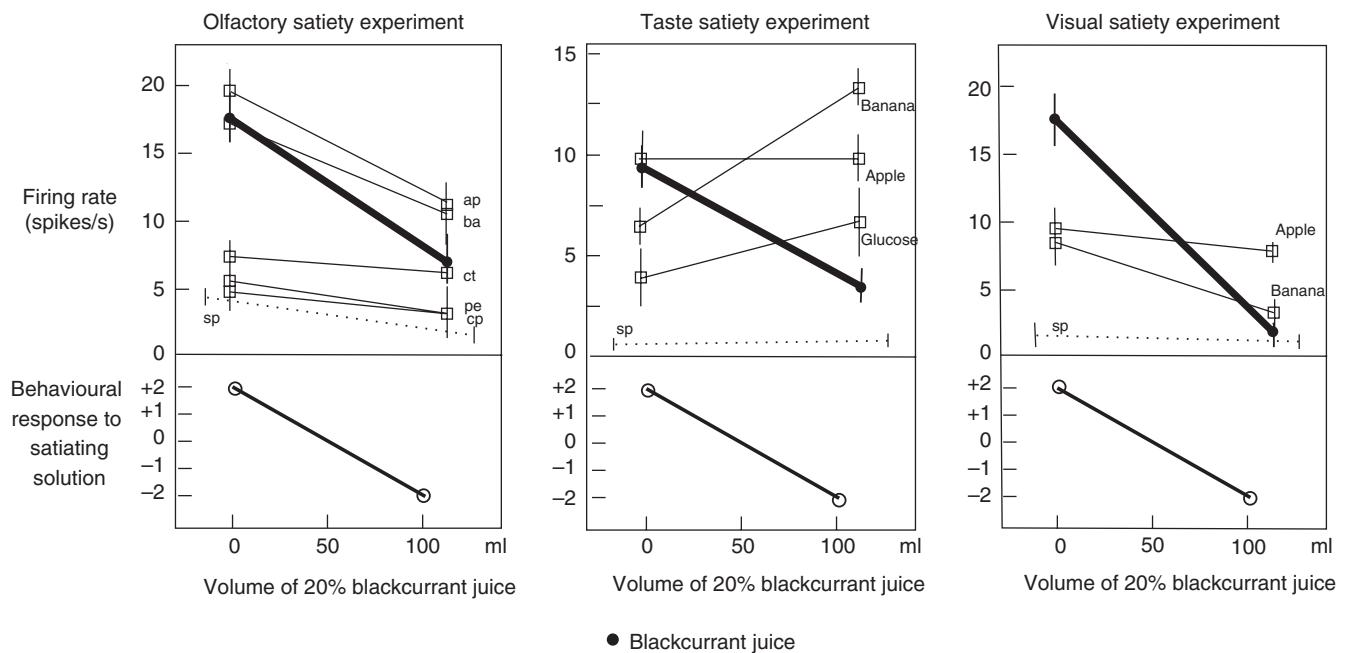

The modulation of the reward value of a sensory stimulus such as the taste of food by motivational state, for example hunger, is one important way in which motivational behavior is controlled (Rolls, 2005a, 2007, 2014). The subjective correlate of this modulation is that food tastes pleasant when hungry, and tastes hedonically neutral when it has been eaten to satiety. Following Edmund Rolls' discovery of sensory-specific satiety revealed by the selective reduction in the responses of lateral hypothalamic neurons to a food eaten to satiety (Rolls, 1981; Rolls et al., 1986), it has been shown that this is implemented by neurons in a region that projects to the hypothalamus, the orbitofrontal (secondary taste) cortex, for the taste, odor, and sight of food (Rolls et al., 1989; Critchley and Rolls, 1996c) (Figure 46.7).

This evidence shows that the reduced acceptance of food that occurs when food is eaten to satiety, the reduction in the pleasantness of its taste and flavor, and the effects of variety to increase food intake (Cabanac, 1971; Rolls and Hetherington, 1989; Rolls and Rolls, 1977, 1982, 1997; Rolls et al., 1981a, b, 1982, 1983a, b, 1984; Hetherington, 2007), are produced in the primate orbitofrontal cortex, but not at earlier stages of processing

**Figure 46.6** The reconstructed positions of the anterior cingulate neurons with taste (t) responses, together with the cytoarchitectonic boundaries determined by Carmichael and Price (1994). Most (11/12) of the taste neurons were in the pregenual cingulate cortex (area 32), as shown. The neurons are shown on a coronal section at 12 mm anterior (a) to the sphenoid reference point. The recording sites were reconstructed using X-radiographs made on every track and subsequent histology using the methods described by Rolls et al., (2003a). (b). The locations of all the 749 neurons recorded in the anterior cingulate region in this study are indicated to show the regions sampled. (Data from Rolls, Gabbott, Verhagen, and Kadohisa; see Rolls, 2008b).

including the insular-opercular primary taste cortex (Rolls et al., 1988; Yaxley et al., 1988) and the nucleus of the solitary tract (Yaxley et al., 1985), where the responses reflect factors such as the intensity of the taste, which is little affected by satiety (Rolls et al., 1983c; Rolls and Grabenhorst, 2008). In addition to providing an implementation of sensory-specific satiety (probably by adaptation of the synaptic afferents to orbitofrontal neurons with a time course of the order of the length of a course of a meal), it is likely that visceral and other satiety-related signals reach the orbitofrontal cortex (as indicated in Figure 46.1) (from the nucleus of the solitary tract, via thalamic and possibly hypothalamic nuclei) and there modulate the representation of food, resulting in an output that reflects the reward (or appetitive) value of each food (Rolls, 2014).

**Figure 46.7** Orbitofrontal cortex neuron with visual, olfactory and taste responses, showing the responses before and after feeding to satiety with blackcurrant juice. The solid circles show the responses to blackcurrant juice. The olfactory stimuli included apple (ap), banana (ba), citral (ct), phenylethanol (pe), and caprylic acid (cp). The spontaneous firing rate of the neuron is shown (sp). The taste panel is for the flavor of food in the mouth. Below the neuronal response data for each experiment, the behavioral measure of the acceptance or rejection of the solution on a scale from +2 to -2 is shown. The values shown are the mean firing rate and its s.e. (After Critchley and Rolls, 1996c).

#### 46.2.6 The Representation of Flavor: Convergence of Olfactory, Taste, and Visual Inputs in the Orbitofrontal Cortex and Related Areas Including the Amygdala and Hippocampus

Taste and olfactory pathways are brought together in the orbitofrontal cortex where flavor is formed by learned associations at the neuronal level between these inputs (see Figure 46.1) (Rolls and Baylis, 1994; Critchley and Rolls, 1996b; Rolls et al., 1996). Visual inputs also become associated by learning in the orbitofrontal cortex with the taste of food to represent the sight of food and contribute to flavor (Thorpe et al., 1983; Rolls et al., 1996c). The visual and olfactory as well as the taste inputs represent the reward value of the food, as shown by sensory-specific satiety effects (Critchley and Rolls, 1996c). Olfactory-to-taste associative learning by these orbitofrontal cortex neurons may take 30–40 trials to reverse in an olfactory-to-taste discrimination task, and this may help to make a flavor stable (Rolls et al., 1996c). Olfactory neurons are found in a considerable anterior-posterior extent of the primate orbitofrontal cortex, extending far into areas 11 and 14 (Rolls and Baylis, 1994; Critchley and Rolls, 1996b, c; Rolls et al., 1996c, 1996), and are not restricted to a

posterior region as some have thought (Gottfried and Zald, 2005).

Visual-to-taste association learning and its reversal by neurons in the orbitofrontal cortex can take place in as little as one trial (Thorpe et al., 1983; Rolls et al., 1996c; Deco and Rolls, 2005a). This has clear adaptive value in enabling particular foods with a good or bad taste to be learned and recognized quickly, important in foraging and in food selection for ingestion. The visual inputs reach the orbitofrontal cortex from the inferior temporal visual cortex, where neurons respond to objects independently of their reward value (e.g., taste), as shown by satiety and reversal learning tests (Rolls et al., 1977; Rolls, 2008a, 2012c). The visual-to-taste associations are thus learned in the orbitofrontal cortex (Rolls, 2014). These visual–taste neurons thus respond to expected value (and in humans different orbitofrontal cortex neurons signal expected monetary value (Rolls et al., 2008a)).

Different neurons in the orbitofrontal cortex respond when a visually signalled expected taste reward is not obtained, that is, to negative reward prediction error (Thorpe et al., 1983; Rolls and Grabenhorst, 2008). There is evidence that dopamine neurons in the ventral tegmentum respond to positive reward prediction error (Schultz, 2007), and as such, they do not respond to taste reward (Rolls,

2014). The inputs to the dopamine neurons may originate from structures such as the orbitofrontal cortex, where expected value, reward outcome (e.g., taste), and negative reward prediction error are represented (Rolls, 2014).

The amygdala also contains neurons that respond to taste and oral texture (Sanghera et al., 1979; Scott et al., 1993; Kadohisa et al., 2005b, 2005a). Some neurons in the primate amygdala respond to visual stimuli associated with reinforcers such as taste, but do not reflect the reinforcing properties very specifically, do not rapidly learn and reverse visual-to-taste associations, and are much less affected by reward devaluation by feeding to satiety than are orbitofrontal cortex neurons (Sanghera et al., 1979; Yan and Scott, 1996; Kadohisa et al., 2005a, b; Wilson and Rolls, 2005; Rolls, 2014). The primate orbitofrontal cortex appears to be much more closely involved in flexible (rapidly learned, and affected by reward devaluation) representations than is the primate amygdala (Rolls, 2014).

The primate hippocampus contains neurons that respond to the sight of locations in spatial scenes where taste rewards are found, but not to the sight of objects associated with taste reward (Rolls and Xiang, 2005), and this is part of the evidence for understanding the functions of the hippocampus in episodic memory (Rolls, 2008a, 2010b).

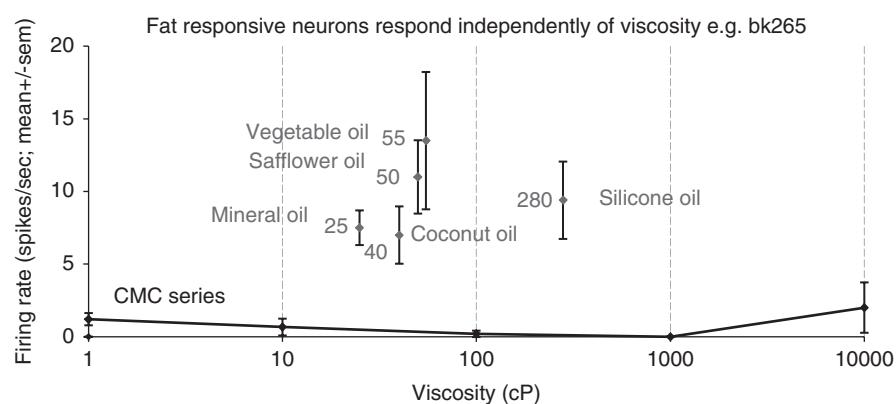

## 46.2.7 The Texture of Food, Including Fat Texture

### 46.2.7.1 Viscosity, Particulate Quality, and Astringency.

Some orbitofrontal cortex neurons have oral texture-related responses that encode parametrically

the viscosity of food in the mouth (shown using a methyl cellulose series in the range 1–10,000 centiPoise), and others independently encode the particulate quality of food in the mouth, produced quantitatively, for example by adding 20–100  $\mu\text{m}$  microspheres to methyl cellulose (Rolls et al., 2003a) (see Figure 46.3). Somatosensory signals that transmit information about capsaicin (chilli) and astringency are also reflected in neuronal activity in these cortical areas (Critchley and Rolls, 1996a; Kadohisa et al., 2004, 2005b).

**46.2.7.2 Oral Fat Texture.** Texture in the mouth is an important indicator of whether *fat* is present in a food, which is important not only as a high value energy source, but also as a potential source of essential fatty acids. In the orbitofrontal cortex, Rolls, Critchley et al., (1999) have found a population of neurons that responds when fat is in the mouth. The fat-related responses of these neurons are produced at least in part by the texture of the food rather than by chemical receptors sensitive to certain chemicals, in that such neurons typically respond not only to foods such as cream and milk containing fat, but also to paraffin oil (which is a pure hydrocarbon) and to silicone oil [ $\text{Si}(\text{CH}_3)_2\text{O}_n$ ]. Moreover, the texture channels through which these fat-sensitive neurons are activated are separate from viscosity sensitive channels, in that the responses of these neurons cannot be predicted by the viscosity of the oral stimuli, as illustrated in Figure 46.8 (Verhagen et al., 2003; Rolls, 2011a). The responses of these oral fat-encoding neurons are not related to free fatty acids such as linoleic or lauric acid (Verhagen et al., 2003; Kadohisa et al., 2005b; Rolls, 2011a), and the fat responsiveness of these primate orbitofrontal cortex

**Figure 46.8** A neuron in the primate orbitofrontal cortex responding to the texture of fat in the mouth independently of viscosity. The cell (bk265) increased its firing rate to a range of fats and oils (the viscosity of which is shown in centipoise). The information that reaches this type of neuron is independent of a viscosity sensing channel, in that the neuron did not respond to the methyl cellulose (CMC) viscosity series. The neuron responded to the texture rather than the chemical structure of the fat in that it also responded to silicone oil ( $\text{Si}(\text{CH}_3)_2\text{O}_n$ ) and paraffin (mineral) oil (hydrocarbon). Some of these neurons have taste inputs. (After Verhagen, Rolls and Kadohisa, 2003).

neurons is therefore not related to fatty acid sensing (Gilbertson et al., 1997; Gilbertson, 1998), but instead to oral texture sensing (Rolls, 2011a; Rolls, 2012b). This has I believe very important implications for the development of foods with the mouth feel of fat, but low energy content (Rolls, 2011a, 2012b). A few neurons do have responses to linoleic and/or lauric acid, but these neurons do not respond to fat in the mouth, and may reflect the bad taste that rancid fats may have (Verhagen et al., 2003; Rolls, 2011a). Some of the fat texture-related orbitofrontal cortex neurons do though have convergent inputs from the chemical senses, in that in addition to taste inputs, some of these neurons respond to the odour associated with a fat, such as the odour of cream (Rolls et al., 1999). Feeding to satiety with fat (e.g., cream) decreases the responses of these neurons to zero on the food eaten to satiety, but if the neuron receives a taste input from for example glucose taste, that is not decreased by feeding to satiety with cream (Rolls et al., 1999). Thus there is a representation of the macronutrient fat in this brain area, and the activation produced by fat is reduced by eating fat to satiety.

Fat texture, oral viscosity, and temperature, for some neurons in combination with taste, are represented in the macaque primary taste cortex in the rostral insula and adjoining frontal operculum (Verhagen et al., 2004), which provides a route for this information to reach the orbitofrontal cortex.

These oral sensory properties of food, and also the sight and smell of food, are also represented in the primate amygdala (Rolls, 2000; Rolls and Scott, 2003; Kadohisa et al., 2005a, 2005b). Interestingly, the responses of these amygdala neurons do not correlate well with the preferences of the macaques for the oral stimuli (Kadohisa et al., 2005b), and feeding to satiety does not produce the large reduction in the responses of amygdala neurons to food (Rolls, 2000; Rolls and Scott, 2003) that is typical of orbitofrontal cortex neurons.

**46.2.7.3 Oral Temperature.** In addition, we have shown that some neurons in the insular cortex, orbitofrontal cortex, and amygdala reflect the temperature of substances in the mouth, and that this temperature information is represented independently of other sensory inputs by some neurons, and in combination with taste or texture by other neurons (Kadohisa et al., 2004, 2005a, b; Verhagen et al., 2004). Somatosensory signals that transmit information about capsaicin (chili) are also reflected in neuronal activity in these brain areas (Kadohisa et al., 2004, 2005b). Activations in the human orbitofrontal and insular taste cortex also reflect oral temperature (Guest et al., 2007).

## 46.3 IMAGING STUDIES IN HUMANS

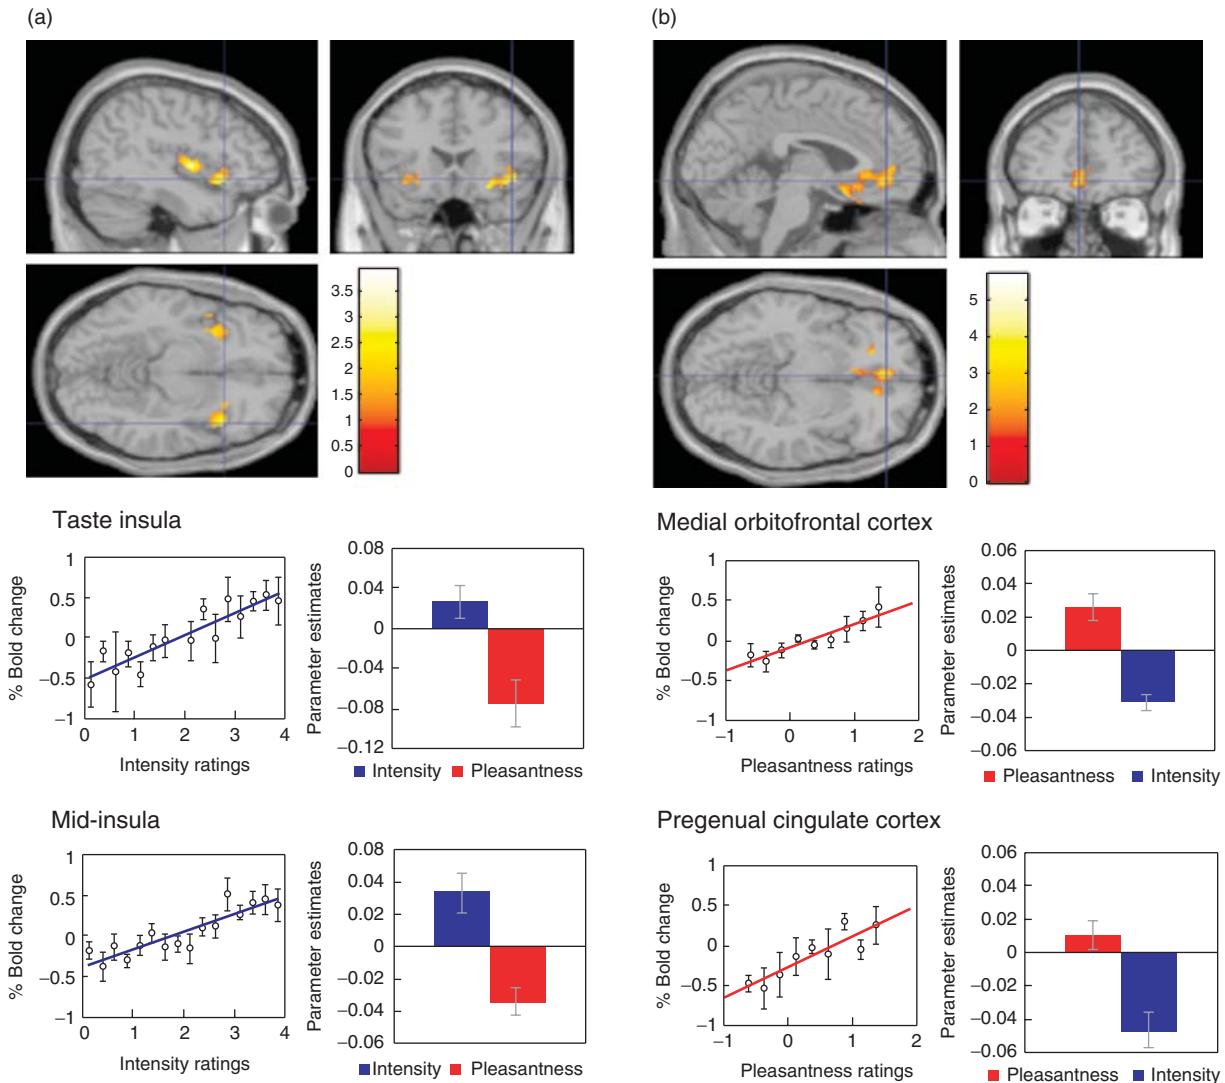

### 46.3.1 Taste

In humans it has been shown in neuroimaging studies using functional Magnetic Resonance Imaging (fMRI) that taste activates an area of the anterior insula/frontal operculum, which is probably the primary taste cortex (O'Doherty et al., 2001; de Araujo et al., 2003b; Small, 2010), and part of the orbitofrontal cortex, which is probably the secondary taste cortex (Francis et al., 1999; O'Doherty et al., 2001; de Araujo et al., 2003b; Rolls, 2005b, 2008b). We pioneered the use of a tasteless control with the same ionic constituents as saliva (O'Doherty et al., 2001; de Araujo et al., 2003b), as water can activate some neurons in cortical taste areas (Rolls et al., 1990) and can activate the taste cortex (de Araujo et al., 2003b). Within individual subjects separate areas of the orbitofrontal cortex are activated by sweet (pleasant) and by salt (unpleasant) tastes (O'Doherty et al., 2001).

The primary taste cortex in the anterior insula of humans represents the identity and intensity of taste in that activations there correlate with the subjective intensity of the taste, and the orbitofrontal and anterior cingulate cortex represents the reward value of taste, in that activations there correlate with the subjective pleasantness of taste (Grabenhorst and Rolls, 2008; Grabenhorst et al., 2008a) (Figure 46.9).

We also found activation of the human amygdala by the taste of glucose (Francis et al., 1999). Extending this study, O'Doherty et al., (2001) showed that the human amygdala was as much activated by the affectively pleasant taste of glucose as by the affectively negative taste of NaCl, and thus provided evidence that the human amygdala is not especially involved in processing aversive as compared to rewarding stimuli. Zald et al. (1998, 2002) also showed that the amygdala, as well as the orbitofrontal cortex, respond to aversive (e.g., quinine) and to sucrose taste stimuli.

Umami taste stimuli, of which an exemplar is monosodium glutamate (MSG) and which capture what is described as the taste of protein, activate the insular (primary), orbitofrontal (secondary), and anterior cingulate (tertiary (Rolls, 2008b)) taste cortical areas (de Araujo et al., 2003a). When the nucleotide 0.005 M inosine 5'-monophosphate (IMP) was added to MSG (0.05 M), the BOLD (blood oxygenation-level dependent) signal in an anterior part of the orbitofrontal cortex showed supralinear additivity, and this may reflect the subjective enhancement of umami taste that has been described when IMP is added to MSG (Rolls, 2009a). (The supra-linear additivity refers to a greater activation to the combined

**Figure 46.9** Effect of paying attention to the pleasantness vs the intensity of a taste stimulus. (a) Top: A significant difference related to the taste period was found in the taste insula at [42 18–14]  $z=2.42$   $p<0.05$  (indicated by the cursor) and in the mid insula at [40–2 4]  $z=3.03$   $p<0.025$ . Middle: Taste Insula. Right: The parameter estimates (mean  $\pm$  sem across subjects) for the activation at the specified coordinate for the conditions of paying attention to pleasantness or to intensity. The parameter estimates were significantly different for the taste insula  $t=4.5$ ,  $df=10$ ,  $p=0.001$ . Left: The correlation between the intensity ratings and the activation (% BOLD change) at the specified coordinate ( $r=0.91$ ,  $df=14$ ,  $p<<0.001$ ). Bottom: Mid Insula. Right: The parameter estimates (mean  $\pm$  sem across subjects) for the activation at the specified coordinate for the conditions of paying attention to pleasantness or to intensity. The parameter estimates were significantly different for the mid insula  $t=5.02$ ,  $df=10$ ,  $p=0.001$ . Left: The taste stimulus, monosodium glutamate, was identical on all trials. (b) Top: A significant difference related to the taste period was found in the medial orbitofrontal cortex at [-6 14–20]  $z=3.81$ ,  $p<0.003$  (towards the back of the area of activation shown) and in the pregenual cingulate cortex at [-4 46–8]  $z=2.90$ ,  $p<0.04$  (at the cursor). Middle: Medial orbitofrontal cortex. Right: The parameter estimates (mean  $\pm$  sem across subjects) for the activation at the specified coordinate for the conditions of paying attention to pleasantness or to intensity. The parameter estimates were significantly different for the orbitofrontal cortex  $t=7.27$ ,  $df=11$ ,  $p<10^{-4}$ . Left: The correlation between the pleasantness ratings and the activation (% BOLD change) at the specified coordinate ( $r=0.94$ ,  $df=8$ ,  $p<<0.001$ ). Bottom: Pregenual cingulate cortex. Conventions as above. Right: The parameter estimates were significantly different for the pregenual cingulate cortex  $t=8.70$ ,  $df=11$ ,  $p<10^{-5}$ . Left: The correlation between the pleasantness ratings and the activation (% BOLD change) at the specified coordinate ( $r=0.89$ ,  $df=8$ ,  $p=0.001$ ). The taste stimulus, 0.1 M monosodium glutamate, was identical on all trials. (After Grabenhorst and Rolls, 2008). (See plate section for color version.)

stimulus MSG+IMP than to the sum of the activations to MSG and IMP presented separately. This evidence that the effect of the combination is greater than the sum of its parts indicates an interaction between the parts to form in this case an especially potent taste of umami, which is part of what can make a food taste delicious (Rolls, 2009a.) Overall, these results illustrate that the responses of the brain can reflect inputs produced by particular combinations of sensory stimuli with supralinear activations, and that the combination of sensory stimuli may be especially represented in particular brain regions, and may help to make the food pleasant.

### 46.3.2 Odor

In humans, in addition to activation of the pyriform (olfactory) cortex (Zald and Pardo, 1997; Sobel et al., 2000; Poellinger et al., 2001), there is strong and consistent activation of the orbitofrontal cortex by olfactory stimuli (Zatorre et al., 1992; Francis et al., 1999; Rolls et al., 2003b). This region appears to represent the pleasantness of odor, as shown by a sensory-specific satiety experiment with banana vs vanilla odor (O'Doherty et al., 2000), and this has been confirmed by Gottfried et al. (personal communication, see Gottfried, 2013), who also showed that activations in the pyriform (primary olfactory) cortex were not decreased by odor devaluation by satiety. Further, pleasant odors tend to activate the medial, and unpleasant odors the more lateral, orbitofrontal cortex (Rolls et al., 2003b), adding to the evidence that it is a principle that there is a hedonic map in the orbitofrontal cortex, and also in the anterior cingulate cortex, which receives inputs from the orbitofrontal cortex (Rolls and Grabenhorst, 2008; Grabenhorst and Rolls, 2011). The primary olfactory (pyriform) cortex represents the identity and intensity of odor in that activations there correlate with the subjective intensity of the odor, and the orbitofrontal and anterior cingulate cortex represents the reward value of odor, in that activations there correlate with the subjective pleasantness (medially) or unpleasantness (laterally) of odor (Rolls et al., 2003b, 2008c, 2009; Grabenhorst et al., 2007; Rolls and Grabenhorst, 2008; Rolls et al., 2008c; Rolls et al., 2009; Grabenhorst and Rolls, 2011).

### 46.3.3 Olfactory-Taste Convergence to Represent Flavor, and the Influence of Satiety on Flavor Representations

Taste and olfactory conjunction analyses, and the measurement of supradditive effects indicating convergence and interactions, showed convergence for taste (sucrose) and odor (strawberry) in the orbitofrontal and anterior cingulate cortex, and activations in these regions were correlated

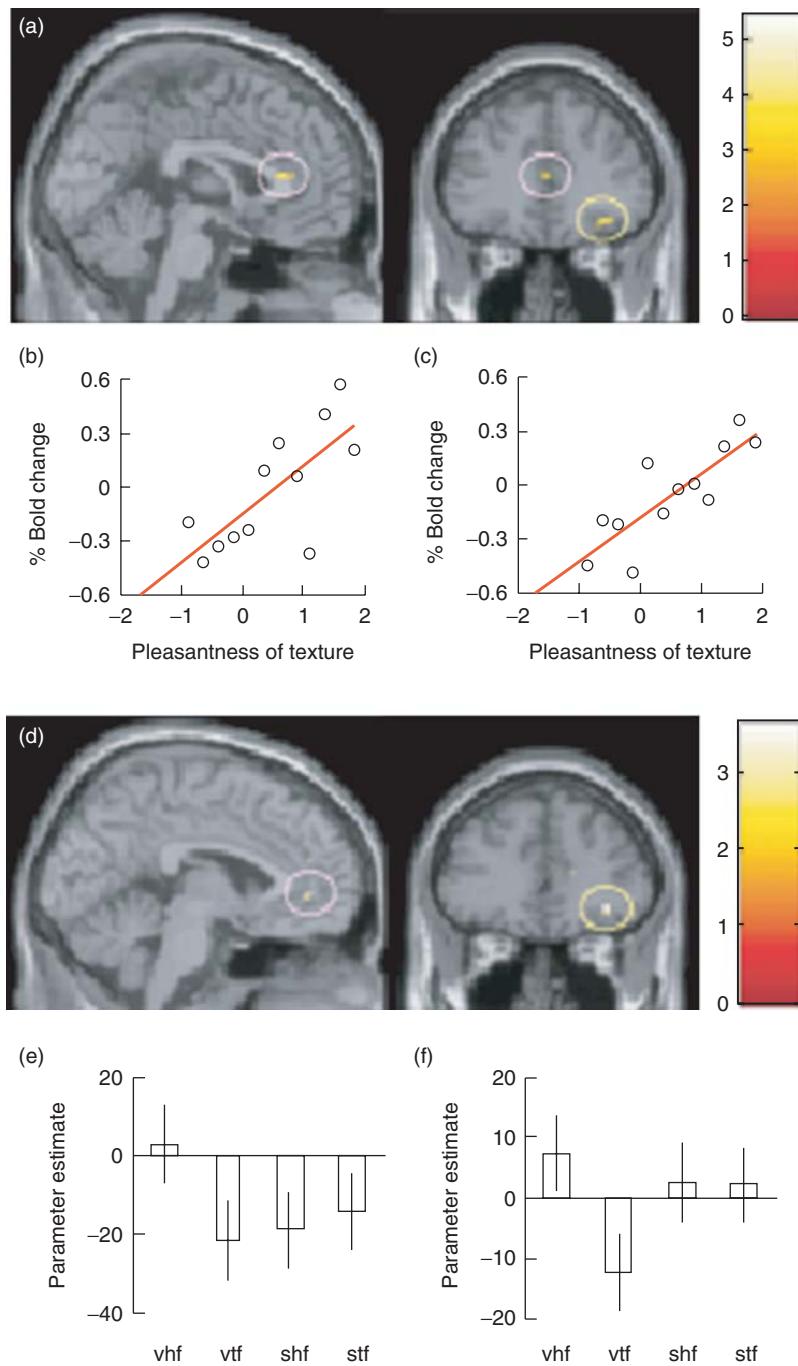

with the pleasantness ratings given by the participants (de Araujo et al., 2003c; Small et al., 2004; Small and Prescott, 2005). These results provide evidence on the neural substrate for the convergence of taste and olfactory stimuli to produce flavor in humans, and where the pleasantness of flavor is represented in the human brain. The first region where the effects of this convergence are found is in an agranular part of what cytoarchitecturally is the insula (Ia, at Y=15) that is topologically found in the posterior orbitofrontal cortex, though it is anterior to the insular taste cortex, and posterior to the granular orbitofrontal cortex (see Figure 46.2) (de Araujo et al., 2003c).

McCabe and Rolls (2007) have shown that the convergence of taste and olfactory information appears to be important for the delicious flavor of umami. They showed that when glutamate is given in combination with a consonant, savory, odor (vegetable), the resulting flavor can be much more pleasant than the glutamate taste or vegetable odour alone, and that this reflected activations in the pregenual cingulate cortex and medial orbitofrontal cortex. The principle is that certain sensory combinations can produce very pleasant food stimuli, which may of course be important in driving food intake; and that these combinations are formed in the brain far beyond the taste or olfactory receptors (Rolls, 2009a).

To assess how satiety influences the brain activations to a whole food which produces taste, olfactory, and texture stimulation, we measured brain activation by whole foods before and after the food is eaten to satiety. The foods eaten to satiety were either chocolate milk, or tomato juice. A decrease in activation by the food eaten to satiety relative to the other food was found in the orbitofrontal cortex (Kringelbach et al., 2003) but not in the primary taste cortex. This study provided evidence that the pleasantness of the flavor of food, and sensory-specific satiety, are represented in the orbitofrontal cortex.

### 46.3.4 Oral Viscosity and Fat Texture

The viscosity of food in the mouth is represented in the human primary taste cortex (in the anterior insula), and also in a mid-insular area that is not taste cortex, but which represents oral somatosensory stimuli (de Araujo and Rolls, 2004). Oral viscosity is also represented in the human orbitofrontal and perigenual cingulate cortices, and it is notable that the perigenual cingulate cortex, an area in which many pleasant stimuli are represented, is strongly activated by the texture of fat in the mouth and also by oral sucrose (de Araujo and Rolls, 2004). We have shown that the pleasantness and reward value of fat texture is represented in the mid-orbitofrontal and anterior cingulate cortex, where activations are correlated with the subjective pleasantness of oral fat texture (Rolls, 2009a; Grabenhorst

**Figure 46.10** Brain regions in which the activations were correlated with the subjective pleasantness of fat texture: Mid-orbitofrontal cortex ( $[32\ 34-14]\ z=3.38\ p=0.013$ ) (a, yellow circle, c showing the relation between the % change in the BOLD signal and the rating of the pleasantness of the texture) and anterior cingulate cortex ( $[2\ 30\ 14]\ z=3.22,\ p=0.016$ ) (a, pink circles, and b). (After Grabenhorst et al., 2010). (See plate section for color version.)

et al., 2010; Rolls, 2010a) (Figure 46.10). This provides a foundation for studies of whether activations in the fat reward system are heightened in people who tend to become obese (Rolls, 2012a). Interestingly, high fat stimuli with a pleasant flavor increase the coupling of activations between the orbitofrontal cortex and somatosensory cortex, suggesting a role for the somatosensory cortex in processing the sensory properties of food in the mouth (Grabenhorst and Rolls, 2013).

### 46.3.5 The Sight of Food

O'Doherty et al., (2002) showed that visual stimuli associated with the taste of glucose activated the orbitofrontal cortex and some connected areas, consistent with the primate neurophysiology. Simmons, Martin and Barsalou (2005) found that showing pictures of foods, compared to pictures of places, can also activate the orbitofrontal cortex. Similarly, the orbitofrontal cortex and connected

areas were also found to be activated after presentation of food stimuli to food-deprived subjects (Wang et al., 2004).

### 46.3.6 Top-Down Cognitive Effects on Taste, Olfactory, and Flavor Processing

To what extent does cognition influence the hedonics of food-related stimuli, and how far down into the sensory system does the cognitive influence reach? To address this, we performed an fMRI investigation in which the delivery of a standard test odor (isovaleric acid combined with cheddar cheese odour, presented orthonasally using an olfactometer) was paired with a descriptor word on a screen, which on different trials was “Cheddar cheese” or “Body odor.” Participants rated the affective value of the test odor as significantly more pleasant when labeled “Cheddar Cheese” than when labeled “Body odour,” and these effects reflected activations in the medial orbitofrontal cortex (OFC)/rostral anterior cingulate cortex (ACC) that had correlations with the pleasantness ratings (de Araujo et al., 2005). The implication is that cognitive factors can have profound effects on our responses to the hedonic and sensory properties of food, in that these effects are manifest quite far down into sensory and hedonic processing (in the orbitofrontal cortex, see Figure 46.1), so that hedonic representations of odors are affected (de Araujo et al., 2005).

Similar cognitive effects and mechanisms have now been found for the taste and flavor of food, where the cognitive word level descriptor was for example “rich delicious flavor” and activations to flavor were increased in the orbitofrontal cortex and regions to which it projects including the pregenual cingulate cortex and ventral striatum, but were not influenced in the insular primary taste cortex where activations reflected the intensity (concentration) of the stimuli (Grabenhorst et al., 2008a) (see Figure 46.11).

### 46.3.7 Effects of Selective Attention to Affective Value Versus Intensity on Representations of Taste, Olfactory, and Flavor Processing

We have found that with taste, flavor, and olfactory food-related stimuli, selective attention to pleasantness modulates representations in the orbitofrontal cortex (see Figure 46.9), whereas selective attention to intensity modulates activations in areas such as the primary taste cortex (Grabenhorst and Rolls, 2008; Rolls et al., 2008c). Thus, depending on the context in which tastes and odors are presented and whether affect is relevant, the brain responds to a taste, odor or flavor differently. These findings show that when attention is paid to affective value, the brain systems engaged to represent the stimulus are different from

those engaged when attention is directed to the physical properties of a stimulus such as its intensity.

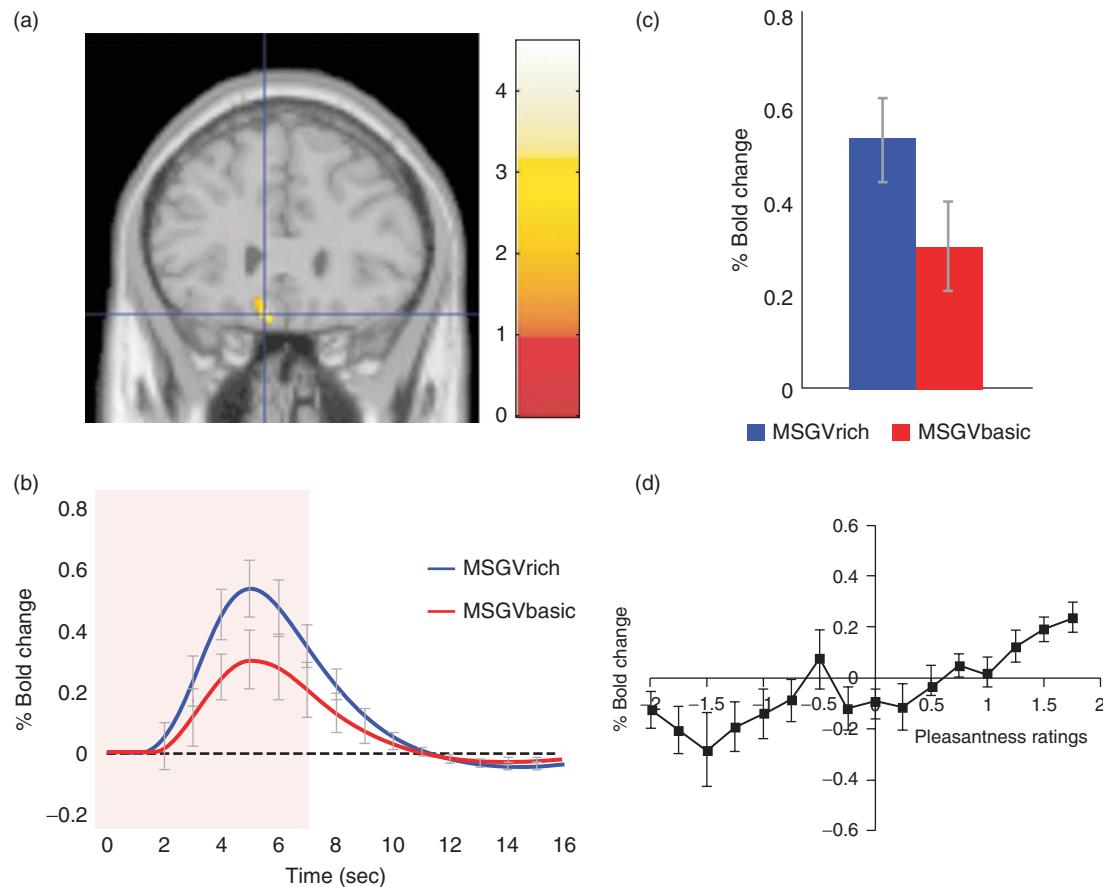

The source of the top-down modulation by attention of the orbitofrontal cortex appears to be the lateral prefrontal cortex, as shown by PPI (psychophysiological interaction) analyses (Grabenhorst and Rolls, 2010), and by Granger causality analyses (Ge et al., 2012; Luo et al., 2013). The mechanism probably involves a weak top-down biased competition effect on the taste and olfactory processing (Desimone and Duncan, 1995; Deco and Rolls, 2005b; Rolls, 2008a). Because whole streams of cortical processing are influenced (orbitofrontal and cingulate cortex, and even their coupling to the primary taste cortex, by pleasantness-related processing; and insular taste cortex and the mid-insula by intensity-related processing (Grabenhorst and Rolls, 2010; Luo et al., 2013), the process has been described as a biased activation model of attention (Grabenhorst and Rolls, 2010).

This differential biasing by prefrontal cortex attentional mechanisms (Grabenhorst and Rolls, 2010; Ge et al., 2012) of brain regions engaged in processing a sensory stimulus depending on whether the cognitive demand is for affect-related vs more sensory-related processing may be an important aspect of cognition and attention which have implications for how strongly the reward system is driven by food, and thus for eating and the control of appetite (Grabenhorst and Rolls, 2008; Rolls et al., 2008c; Grabenhorst and Rolls, 2011; Rolls, 2012a). The top-down modulations of processing have many implications for investigations of taste, olfactory, and other sensory processing, and for the development of new food and perfumery products.

### 46.3.8 Beyond Reward Value to Decision Making

Representations of the reward value of food, and their subjective correlate the pleasantness of food, are fundamental in determining appetite and processes such as economic decision making (Rolls, 2005a; Padoa-Schioppa, 2011; Padoa-Schioppa and Cai, 2011; Rolls, 2014). But after the reward evaluation, a decision has to be made about whether to seek for and consume the reward. We are now starting to understand how the brain takes decisions as described in *The Noisy Brain* (Rolls and Deco, 2010), and this has implications for whether a reward of a particular value will be selected (Rolls, 2008a; Rolls and Grabenhorst, 2008; Rolls and Deco, 2010; Grabenhorst and Rolls, 2011; Rolls, 2011b; Deco et al., 2013; Rolls, 2014).

A tier of processing beyond the orbitofrontal cortex, in the medial prefrontal cortex area 10, becomes engaged when choices are made between odor stimuli based on their pleasantness (Grabenhorst et al., 2008b; Rolls et al., 2010b, a; Rolls et al., 2010c) (tier 3 in Figure 46.1).

**Figure 46.11** Cognitive modulation of flavor reward processing in the brain. (a). The medial orbitofrontal cortex was more strongly activated when a flavor stimulus was labelled “rich and delicious flavor” (MSGVrich) than when it was labelled “boiled vegetable water” (MSGVbasic) ([−8 28–20]). (The flavor stimulus, MSGV, was the taste 0.1 M MSG + 0.005 M inosine 5’ monophosphate combined with a consonant 0.4% vegetable odor.) (b). The timecourse of the BOLD signals for the two conditions. (c). The peak values of the BOLD signal (mean across subjects  $\pm$  sem) were significantly different ( $t=3.06$ ,  $df=11$ ,  $p=0.01$ ). (d). The BOLD signal in the medial orbitofrontal cortex was correlated with the subjective pleasantness ratings of taste and flavor, as shown by the SPM analysis, and as illustrated (mean across subjects  $\pm$  sem,  $r=0.86$ ,  $p<0.001$ ). (After Grabenhorst, Rolls and Bilderbeck, 2008 (Grabenhorst et al., 2008a)). (See plate section for color version.)

The choices are made by a local attractor network in which the winning attractor represents the decision, with each possible attractor representing a different choice, and each attractor receiving inputs that reflect the evidence for that choice. (The attractor network is formed in a part of the cerebral cortex by strengthening of the recurrent collateral excitatory synapses between nearby pyramidal cells. One group of neurons with strengthened synapses between its members can form a stable attractor with high firing rates, which competes through inhibitory interneurons with other possible attractors formed by other groups of excitatory neurons (Rolls, 2008a, 2010c). The word attractor refers to the fact that inexact inputs are attracted to one of the states of high firing that are specified by the synaptic connections between the different groups of neurons. The result in this non-linear system is that one attractor wins, and this implements a mechanism for decision making with one winner

(Rolls, 2008a; Wang, 2008; Rolls and Deco, 2010; Deco et al., 2013). The decisions are probabilistic as they reflect the noise in the competitive non-linear decision-making process that is introduced by the random spiking times of neurons for a given mean rate that reflect a Poisson process (Rolls and Deco, 2010; Rolls et al., 2010a). The costs of each reward need to be subtracted from the value of each reward to produce a net reward value for each available reward before the decision is taken (Rolls, 2008a; Rolls and Grabenhorst, 2008; Grabenhorst and Rolls, 2011). The reasoning or rational system with its long-term goals (introducing evidence such as “scientific studies have shown that fish oils rich in omega 3 may reduce the probability of Alzheimer’s disease”) then competes with the rewards such as the pleasant flavor of food (which are gene-specified (Rolls, 2005a, 2014), though subject to conditioned effects

(Booth, 1985; Rolls, 2005a)) in a further decision process which may itself be subject to noise (Rolls, 2005a, 2008a; Rolls and Deco, 2010). This can be described as a choice between the selfish phene (standing for phenotype) and the selfish gene (Rolls, 2011b, 2012d, 2014). In this context, the findings described in this paper that the cognitive system can have a top-down influence on the reward system are important advances in our understanding of how these decisions are reached.

## 46.4 SYNTHESIS

These investigations show that a principle of brain function is that representations of the reward / hedonic value and pleasantness of sensory including food-related stimuli are formed separately from representations of what the stimuli are. The pleasantness / reward value is represented in areas such as the orbitofrontal cortex and pregenual cingulate cortex, and it is here that hunger/satiety signals modulate the representations of food to make them implement reward. The satiety signals that help in this modulation may reach the orbitofrontal cortex from the hypothalamus, and in turn, the orbitofrontal cortex projects to the hypothalamus where neurons are found that respond to the sight, smell, and taste of food if hunger is present (Rolls and Grabenhorst, 2008; Rolls, 2014). We have seen above some of the principles that help to make the food pleasant, including particular combinations of taste, olfactory, texture, visual, and cognitive inputs.

A hypothesis is developed elsewhere that obesity is associated in part with overstimulation of these reward systems by very rewarding combinations of taste, odor, texture, visual, and cognitive inputs (Rolls, 2005a, 2011c, 2012a, 2014).

## Olfaction and Taste in the Food and Beverage Industries

GRAHAM A. BELL and WENDY V. PARR

### 47.1 INTRODUCTION

Chemosensory research related to food manufacturing and consumer acceptance began in circumstances hardly recognizable today, when the emphasis was on selling what you made, rather than making what would sell (Moskowitz et al., 2011). Modern chemosensory research largely stemmed from the development of the need for massive amounts of ready-made food products by the US military in World War II (Jones et al., 1955; Kamen, 1989). Applications of knowledge gained in this period were initially focused on niche markets such as institutional catering, airline food services, emergency rationing, and provisions for athletes, hikers, and campers (Lyon et al., 1992). During this early period, further developments were made in product design, quality assurance, shelf-life testing, product matching, and screening for bacteria and other pathogens.

Today commercially prepared food and beverages are largely marketed to mass consumers in developed countries, dwarfing these earlier niche markets. With consolidation of commercial markets in Europe in the past decades (Lyon, 1999), and several other major international free trade agreements, a global commercial imperative, which is measured in trillions of dollars (Deloitte, 2010), now drives the interest of the food and beverage industries in the science of olfaction and gustation. For this reason, large food companies commit millions of dollars to chemosensory science (Weller, 1999) and smaller ones maintain a close watch on the new developments of others.

What has not changed in the past century is the fact that sensory processes underpin the acceptance of food and beverage products. When questioned, consumers

report that “taste,” meaning the experience of flavor and associated sensations in the mouth, is of paramount importance in purchase decisions, particularly for fruit, dairy, and beverage items (Easton et al., 1997). Not surprisingly, smell, taste, and associated sensory modalities are regarded widely in the food and beverage industries as the major determinants of the choices people make when buying or trading for food. Added to this “core belief” is an appreciation of the sheer size of the global food and beverage markets and the involved competitive pressures.

In this chapter we address how sensory evaluation has become a key element in defining the direction modern industry takes to tailor its products to optimize success in the market place. We provide an overview of how technology and such basic factors as age and gender are becoming important to provide new products focused on specific sectors of the general population.

### 47.2 WHERE IS CHEMOSENSORY SCIENCE FOUND IN THE FOOD AND BEVERAGE INDUSTRIES?

Much of modern chemosensory science is comprised of “basic” science, including central and peripheral nervous system physiology, the molecular biology of chemoreceptors, and the chemistry of odorants and tastants. Discoveries in basic chemosensory science have led to new technologies with applications in the food and beverage industries and related industries upon which they depend (Bell, 1996). For example, it is now commonplace to identify the types of volatiles that arise from foods using gas chromatography and mass spectrometry so as to isolate

the specific chemicals critical for their flavor. All but the smallest of contemporary food and beverage companies now employ scientists and technicians specifically trained in chemistry and sensory evaluation.

Such sophistication was not always the case. In the not-too-distant past, judgment on important matters of product quality and product development was applied in a haphazard way and was often dominated by company management who would hold “organoleptic tester” sessions. Such sessions frequently consisted solely of management personnel tasting and discussing the products around a table (Jellinek, 1985). The first systematic scientific methods applied to the sensory evaluation of products were developed by such pioneers as Amerine et al., (1965), Helm and Trolle (1946), and Peryam and Swartz (1950). Rigorous scientific methodology and statistical approaches soon followed, as exemplified by studies performed by Moskowitz (1983) and Stone and Sidel (1993), and a statistics textbook focused primarily on the sensory evaluation of food (O’Mahony, 1986). Practical sensory evaluation guide books of value to in-house food technologists appeared in the 1990’s, including those of Lyon et al. (1992) and Lawless and Heymann (1998; 2010).

Many food companies outsource the specific development of flavor chemicals that are added to their foods. At the heart of the global food and beverage industries are the flavor and fragrance houses, such as International Flavors and Fragrances (IFF), Givaudan, Firmenich, Takasago, Symrise, and Quest International. These companies play an important role in the development of ingredients related to the sensory quality of food and beverages, in addition to producing fragrances for non-food purposes, including soaps, cosmetics, air fresheners and candles (Herman, 2005). They commonly make large intramural and extramural investments in analytical chemistry and in fundamental science of olfaction and gustation. As is common in private enterprise, confidentiality surrounds their in-house research. Nonetheless, an outsider can gain insight into what these companies consider important by reading the published work of institutions they support, such as the Monell Chemical Senses Center in the United States ([www.monell.org/research](http://www.monell.org/research)) and the Institut du Gout in France, which is funded in part by the European Union (EU) ([www.institutdugout.fr](http://www.institutdugout.fr)). From time to time, books appear that reveal the work of in-house flavorists and perfumers, few of whom operate in the public domain (Rowe, 2005b).

In addition to such companies, many countries have publicly funded organizations in which fundamental science is conducted on questions derived from, or of importance to, olfaction and gustation. Examples of these are the Commonwealth Scientific and Industrial Research Organisation (CSIRO) in Australia and the Institute of Plant and Food Research in New Zealand. However, the trend in the

latter institutions over the past two decades has been to publish less in the public domain and more under a veil of confidentiality for fee-paying clients or sponsors. The result is that a greater dividend from public investment passes to the “private sector partners” and the results of research remain obscured at least long enough for a commercial advantage (patents, licenses or transfer of know-how) to be gained by the fee-paying party. By comparison, knowledge transfers readily from the transparent public domain to the opaque and competitive private sector.

It is important to note that food and beverage companies are keenly interested in what is happening in public domain science. In addition to sending their R&D people to key conferences, large food companies regularly bring together leading chemosensory scientists from around the globe for seminars and conferences, where the scientists explain their latest work and discuss, under confidentiality, the possible import of the new knowledge to the inviting company. Occasionally proceedings are published (e.g., Bell and Watson, 1999). More typically, research done in-house is taken up directly by the company and seldom appears in the public domain.

### 47.3 DRIVERS OF CONSUMER BEHAVIOR

The chemical senses, along with vision and oral somatosensation, can be considered the gatekeepers for food intake (Tuorila and Monteleone, 2009), protecting us from the ingestion of inappropriate or even lethal food items and orienting our eating behaviors towards healthy and safe food items. Research aimed at providing information about how people perceive, conceptualize, judge, and otherwise respond to food and beverages has increased steadily since the 1950s. Human physiological processes, genetic differences (Bartoshuk, 1993; Prescott, 1998), and psychological processes including learning and memory (e.g., Parr et al. 2002), have received much attention. Behavioral psychology, psychometrics, and cognitive psychology have provided methodologies to quantify human responses to multiple dimensions of foods and beverages (e.g., Labbe, et al., 2006). As noted below, in recent years the sensory evaluation field has been integrated with marketing issues, including market segmentation, packaging (e.g., wine labels or bottle shape), cultural and philosophical perspectives (e.g., importance of familiarity, perceived value, geographical location, and “green” issues), and emotional responses to foods and beverages (Lundahl, 2012).

Movements in the latter directions stem from the fact that consumers rarely have the opportunity to taste a food or beverage at the point of selection or purchase. For this reason, factors other than what a food tastes or smells like play a large part in food-choice behavior. Extrinsic factors

include packaging, price, and advertisement details (Aaron et al., 1994; Lockshin et al., 2006), nutritional needs (Scott, 2001), health concerns (van Herpen et al., 2012), age- and gender-related factors (Bell and Strauss, 2007), and memories of past consuming behavior (Labbe et al., 2006). In food choice behavior, expectations are an assumed mediating variable (Deliza and MacFie, 1996).

Food and beverage companies, aiming to meet consumer expectations and demand, and to improve their market share, profit, or competitive position, have become dependent on the tools of multidisciplinary product evaluation, employing both consumers and trained panelists to make analytical judgments regarding product acceptability and other factors. The relatively recent focus on individual differences in the perception of, and preferences for, various sensory qualities involved in foods and beverages has led to the development of diversifying product qualities to cater to specific segments of the market, such as specific age groups, a process called market segmentation (Moskowitz et al., 2011).

### 47.3.1 Product Differentiation, Competitive Edge, and Quality Assurance

Manufacturers often compete in markets where success depends on creating perceived differences in the sensory quality of their products. For every market leader there are usually competitive products vying for market share either by producing a better product (in the mind of the consumer) or one that is impossible to tell apart from the leader: a “me too” (and potentially less expensive) competitor. As a product’s success in the marketplace grows, manufacturers are faced with a number of dilemmas. For example, do they tailor products for markets into which they intend to expand or do they try to achieve a universal product that overrides cultural and contextual factors in new market territories? Are the available raw materials across different locals sufficiently consistent in quality to guarantee a final product good enough to sustain demand for it and to uphold the reputation of the brand?

To address the sensory issues, panels of consumers are often recruited to undertake blind assessments of whether or not a difference can be detected between products kept in stock as “gold standards” and those containing changed ingredients or formulations. Protocols for “difference testing” have been published and are available from national standards bodies. In some cases the objective is to establish or maintain a difference between a product and its rival and in others the objective is to ensure that there is no perceivable difference between two products.

### 47.3.2 The Chemical Basis of Food Acceptance

Working closely with product developers in the food and beverage industry are various types of chemists including synthetic, analytical, organic and inorganic chemists. Their general aim is to understand everything to do with the molecules that underpin the quality of food during its transformation from raw materials to an acceptable product for consumers, and which will return a profit through that transformation in the process known as “value adding.” There is a continuing process of introducing new flavors to processed food to “extend the product line,” while removing others. Many companies are constantly motivated to find a new flavor or “concept” for a product that will increase sales that will be “the next big thing” (Moskowitz et al., 2011). Importantly, consumers demand greater degrees of safety and truth in product label information than ever before. In response, industry retains an ongoing interest in taking flavorants out of products rather than adding them. For example, manufacturers of traditionally salty products continue to be concerned with formulating reductions in components such as sodium without noticeably diminishing acceptability of the product (e.g., Liem et al., 2011; Prescott and Khu, 1995).

Bottled beverages have appeared on world markets that are clear and colourless, yet taste remarkably like familiar fruits (e.g., strawberry, grape, etc.). These illustrate the art of flavoring a product using invisible flavouring agents and the flavor chemists’ quest for “nature identical” chemical formulations. This implies the exact reconstruction of the components, often numbering in the hundreds, of the flavor compounds in the original object. However, exact replication of a chemical flavor profile is rarely needed and economic considerations come into play. Rather, one or more “key” odorant molecules are identified, by reference to chemical analysis of the original object and by methods such as split-stream gas chromatography (GC) and mass spectrometry (MS). In split-stream GC, a panel member smells each chemical component that arises from the vapors of an object sent through an absorbent column to define those chemicals that give the object its characteristic aroma or flavor. The key compounds are then purified or synthesised and, in some cases, mixed in proportions found in the sampled objects. The resulting flavor mixture is further refined until it is deemed by in-house sensory assessment to be “near enough” (for commercial purposes) to the original. The agent is then introduced into a product matrix, such as a liquid beverage or an appropriate food system, such as flavorless vegetable material. It is of interest that two Nobel Prizes have been awarded to chemists who have produced the means by which flavor or fragrance molecules can be identified (Ruzicka and Pauling, in Rowe, 2005a).

The process of identifying, isolating, purifying, and synthesizing aroma chemicals is long and hard, even before testing for safety and whether the molecule is ‘true’ to the intended or recognizable flavor. Stringent regulations, imposed recently by the European Union (EU) and driven by consumer concerns about “ingesting toxicants,” have made it harder for a number of chemicals to be allowed into food products. In addition, limitations are now imposed by regulatory bodies of many countries as to what solvents might be used to carry the aroma chemical into the product. A typical dispersion medium for key flavor molecules into a fruit juice beverage is 70% propylene glycol, 20% ethanol or isopropanol and 10% water. However, no alcohol is permitted in Halal-compliant countries and so other solutions need to be found from a very limited list of permitted solvents (Baines and Knights, 2005).

Modern chemistry has described over 20 million chemical compounds (Zviely, 2005) of which a significant, though undefined, proportion have sensory properties. The potential palette for the flavor chemist is therefore practically infinite. Molecules producing olfactory sensations are generally of low molecular weight (45–300 Da; Taylor and Hort, 2004; Turin and Yoshii, 2003) and enter the nose through the nostrils (orthonasal smelling). They are also released from food by the action of mastication and swallowing, making their way by the interior passages to the olfactory receptors through the back of the mouth and throat: retronasal smelling (Burdach and Doty, 1987; Halpern 2004, 2008). The combination of retronasal olfaction and taste perception achieved through the taste receptors in the tongue and mouth are crucial inputs to a “gestalt” or integration process that creates an entirely different flavor perception which gives a person the impression that it is happening in the mouth (Prescott, 1999, 2004, 2012; Chapters 45 and 46). Knowing this, we can expect the palette of the creative flavor chemist to be expanded beyond its present large size, particularly when odorants released by chewing become identified.

Surprisingly little is known about the structure or function of flavor molecules that dictates why they smell the way they do. This largely reflects the fact that many molecules participate in a given flavor sensation. The reader is encouraged to explore the cornucopia of chemistry described in Rowe (2005c) to appreciate just how many species of molecules contribute fragrance to the flavor of foods: alcohols, acids, esters, lactones, aldehydes, acetals, nitriles, ketones, carotenoids, hydrocarbons, and heterocycles. In addition there are the sulphur compounds, many of which have extremely low odor thresholds (such as  $10^{-7}$  for 4-methyl-4-mercaptopentan-2-one, a characteristic odor of the Sauvignon grape must; Jameson, 2005), and which include the thiols, thioesters, acyclic sulphides, polysulfides, and saturated heterocyclic sulphur compounds. There are many more molecular species and it

is typical for hundreds to make up a common odor such as the smell of brewed coffee (Rowe, 2005c).

The relationships between molecular structure and the perceived quality of fragrances have proven to be very complicated. Molecules with similar shapes can have distinctly different perceived qualities, while others with different shapes can have similar qualities (Youngentob 1999; Polak 2000; Turin and Yoshii, 2003). Some molecules inhibit or otherwise alter the activity of other molecules at the level of the olfactory receptors (i.e., in pharmacological terms are antagonists or agonists) or as a result of patterns of activity set up in higher brain regions, most notably the olfactory bulb. The discovery of the gene family that encodes olfactory membrane receptors by Buck and Axel (1991), and the demonstration of combinatorial receptor codes for the odorant reception mechanism (Malnic, et al., 1999), has encouraged the concept that knowledge of the odorant and odorant receptors may be of value in guiding the synthesis of new flavor molecules. However, this has proved to be difficult and progress has been slow. A case is made by Turin (2005) and Turin and Yoshii (2003) for the use of information on the vibrational characteristics of molecules (upon which Turin developed his spectroscopic theory of olfactory reception: Turin, 1996) to aid the discovery of useful molecules, such as an acid-stable lemon fragrance (Turin, 2005). Industry awaits further technological developments from discoveries of the mechanisms of receptor-ligand interactions. These are likely to include “designer molecules” for flavor and so-called “flavor modulators” that block the olfactory action of other molecules (Bell, 1996).

## 47.4 UNDERSTANDING WHAT THE CONSUMER EXPERIENCES

### 47.4.1 Cuisine versus the Global Product

The development of a global product that adheres to a single formula and can be made consistently at globally distributed plants is considered a desirable goal by many food and beverage companies. However, despite the spread of branded and identically packaged products, close examination of many “global products” reveals that a good deal of manipulation of the product takes place to meet the demands of local markets. Such factors as climate, familiarity with limited local cuisines, and even socioeconomic status, for example, can define the sweetness considered by the local consumers as “just right.” Based on sensory evaluations, many products have to be reformulated from the sensory core to the packaging, brand presentation, size of portion, and even recommendations as to when the product should be consumed. Publication of why products

fail in international markets is rare, despite the very useful practice of “flop analysis” which largely falls within the boundary of company know-how (Köster and Mojett, 2012).

However, attempts at such development can have unexpected consequences. For example, in many Asian countries relatively few food products were imported before the reduction of tariff barriers. When new and fresh products, such as fine butter was exported to Indonesia (as refrigeration became more widely available), consumers were puzzled that it didn’t have a rancid taste and a pineapple flavor which are the main sensory attributes of Indonesian canned butter: the only product that had been previously available (Easton et al., 1997). Consumer resistance to novelty and to branding or packaging which declares the product to be “foreign” was a frequent finding in the CSIRO’s Japan Project (Prescott et al., 1992, 1997; Laing et al., 1993, 1994; Prescott and Bell, 1995), a government supported project that included a review of the food culture of Japan (Bell et al., 1992), a public domain quarterly bulletin on food information and consumer behavior (*Food Japan* and *Food Japan and Asia*, 1991–1994), and confidential field work for sponsoring companies. When novelty and other identifiers of novelty were not made available to sensory panel members, resistance and cultural biases disappeared (Prescott and Bell, 1995).

#### 47.4.2 What is Flavor?

This question is fundamental to chemosensory science and is dealt with in detail in several other chapters of this volume. Flavor, in effect, is a unified “oral” perceptual composite of several sensory modalities: a “gestalt” determined entirely by higher order brain processes from a confluence of independent sensory inputs comprised of separate nerves, physical stimuli, receptors, and genes (Prescott, 1999). The visual analogy is binocular depth perception. With each eye tested separately the world looks quite flat, but with both eyes open it “leaps” into the familiar and unique experience of depth. Depth perception has a spectacular effect on a person’s experience and ability to perform visuo-motor tasks, as trying to reach for an item on a table with one eye closed will demonstrate. Similarly, combining smell, taste, and tactile sensations into the unified experience of flavor evokes an entirely different experience compared with each sensory component alone.

Valuable research on the chemical senses that relates to the food and beverage industries comes from consideration of the act of eating and its influences on flavor. Examples include studies of retronasal smelling (e.g., Burdach and Doty, 1987; Halpern, 2004, 2008), release of flavorants and odorants by the act of chewing (e.g., Taylor, 2005), the role of experience in perception of orthonasal and retronasal odor (e.g., Wilson and Stevenson, 2006), and

the oral perception of umami (e.g., Ninomiya, 2003), fat (e.g., Song, 2000, Gilbertson, 2003, Keast, 2012), texture (e.g., Brandt et al., 1963; Moskowitz, 1987; Szczesniak et al., 1975), astringency (e.g., Noble, 1999), “tingle” (e.g., Dewis, 2005), and the “burning” or “cooling” effects of oral trigeminal nerve stimulation (e.g., Alimohammadi and Silver, 2002; Green, 2004).

Surprisingly, an appreciation of the multiple sensory processes involved in flavor perception has been largely ignored by industrial scientists until relatively recently (Prescott, 1999, 2006, 2012). This reflects, in part, the delay in the development or application of sophisticated analytical tools that deal with such complexity, including conjoint analysis (Moskowitz, et al., 2001), data mining, and various forms of multivariate analysis (Lawless and Heymann, 2010).

### 47.5 ACADEMIC CHEMOSENSORY SCIENCE INFORMING INDUSTRY

Basic information from academia concerning the development and regression of chemosensory systems and their function has aided in the creation of products focused on both young and old segments of the population. Research on the influences of age on chemosensation has led food companies to the realization that they can safely abandon the “one size fits all” approach of the 1950s and 1960s and can profitably exploit niche markets or “strata” with targeted products (Moskowitz et al., 2011). Information derived from brain scans and, to a large degree, “artificial noses” has also made its way into the food and beverage industries from the public sector and other industries, providing novel means for assessing the physiological impact of products on the brain and for addressing basic issues of product quality control and differentiation.

#### 47.5.1 Age and Aging

The question of flavor perception is of vital importance when considering how best to formulate food for the very young and for the older person. Attempts at such stratified formulations have been challenging but remain a focus of research of many food and beverage companies.

**47.5.1.1 The Child.** Consideration of what should be fed to babies and young children has long been a food industry concern, with the focus being mainly on health and nutrition, rather than palatability. For generations diet supplements, such as cod liver oil, were served to children with scant regard to their tastes, which often were disgusting. In fact, the food preferences of children under the age of five are largely dictated by sweetness and familiarity

(Birch, 1979). Importantly, preferences established early in a child's life can last into later life (Mennella, et al., 2005). Relative to adults, children appear to prefer higher concentrations of sweet, salty, and sour tastants (Popper and Kroll, 2007), although the notion that children are more sensitive than adults to tastes and smells has received only scant support (Guinard, 2001).

"Fussy eating" by children is something most parents know well. Foods that the child will eat without complaint are often given acquiescence by busy and frustrated parents, and diets can become unbalanced, resulting in obesity and other unwanted health effects. Both the child and its parent become a market of interest to the food industry, since the parent is the shopper, while the child is the consumer. In a recent review, Mustonen and Tuorila (2009) examined the degree to which chemosensory factors and neophobia (avoidance of novelty) determine flavor preferences and eating habits in children ranging in age from 7 to 13 years. They concluded that neophobia is by far the stronger influence and that children can be educated to dispel their reluctance to try novel foods and thereby broaden and improve nutritional balance in their diets. Understanding the contributions of sensory and non-sensory factors in food selection by children is an area which has yet to be properly explored, and in which the food industry can work with sensory scientists to develop products and promotions to stimulate variety and nutritional balance in the child's diet.

**47.5.1.2 The Older Consumer.** People in developed countries who are over the age of 65 years have previously been of little interest to the food and beverage industries, owing mainly to their low economic power. This is no longer the case. They have emerged as a consumer force with significant disposable income, in retirement. Their resources, by which their choices can be felt in food sales and catering, has made the chemosensory determinants of their food choices commercially relevant.

The function of the primary sensory modalities that contribute to flavor perception begin to fail in many elderly (Doty et al., 1984; Doty and Kamath, 2014; Matsuda and Doty, 1995; Mojet et al., 2001, 2003). Over the age of 65 years, the perception of flavor becomes attenuated or radically altered, often with negative consequences for general safety as well as for good nutrition and health maintenance (DeVere, 2003; Reiter and Costanzo, 2003). The enjoyment and palatability of foods declines in many people after age 65, although only those with severe deficits report experiencing significant changes in food flavor (Kremer et al., in Mustonen and Tuorila, 2007). The onset of age-related chemosensory loss is gradual for some individuals, but rapid for others. Such loss can reflect the influences of cumulative lifetime damage from viral and

other xenobiotic insults to the olfactory epithelium (Deems et al., 1991), as well as neurological changes secondary to neurodegenerative diseases such as Alzheimer's disease, Parkinson's disease, cancer, medication usage, and multiple medical interventions, including treatments for hypertension, diabetes, and cancer (Doty, 2012; Schiffman, 2000; Schiffman and Zervakis, 2002; see also Chapters 18 and 38). Health consequences are not trivial. Chemosensory deficits can alter the motivation to eat and the kinds of food that are chosen. Such deficits can exacerbate medical conditions, impair nutritional status, and result in loss of weight and immunity to infections (Deems et al. 1991; DeVere, 2003).

A challenge for chemosensory researchers is to determine what can be done about improving foods for older consumers. Judicious use of flavor enhancement remains an option and has been shown to have measureable health benefits for some elderly (Schiffman, 2000, 2002). However, Mustonen and Tuorila (2007) have pointed out weaknesses in flavor enhancement strategies (reviewed by Bell and Strauss, 2007), including the heterogeneity of sensory deficits in the older population, their adaptation to deficits, and the failure to obtain positive health outcomes in experiments where foods were experimentally altered. That being said, commercially successful foods have emerged which have focused primarily on members of this age group.

### 47.5.2 Brain Scanning and Chemosensory Science

Scanning technology for recording human brain metabolism and cerebral blood-flow, such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), has been employed for decades in clinical settings. In recent years, chemosensory scientists working in or associated with hospitals exploited this technology and important studies on this topic began to emerge in the scientific literature in the late 1990s (Levy et al., 1997; Ohla et al., 2012b; Savic, 2002; Chapters 13 and 35).

Of immediate interest to scientists and the food industry were the findings of enhanced neural activity in identified brain areas when olfactory and taste stimuli were presented together, but not singly (Small et al, 1997, 2004). This finding suggested that specific brain regions could be identified that may be particularly important for understanding and quantifying flavor processing. In addition, the relatively early and landmark PET study by Small et al., (2001) revealed most compellingly the visualization of brain regions that were engaged during the enjoyment of chocolate: brain regions which diminished and gave way to other regions once satiety had been reached. More research is needed, however, to establish reliability, sensitivity and specificity of such measures. Other studies have found

brain areas that are relatively specific to food cravings (Pelchat et al., 2004), food texture and fat (Araujo and Rolls, 2004), taste enhancing effects of umami-related compounds (McCabe and Rolls, 2007), trigeminal nerve stimulation by pungent odorants (Billot et al., 2011; Hummel et al., 2005), visual food cues for pleasant tastes (Ohla et al., 2012 a), selective attention to chemosensory stimuli (Veldhuisen and Small, 2011), and enhancement of tastes by smells (Seo et al., 2011). Somewhat separate brain loci were reported for sweet and salty tasting stimuli (Spetter et al., 2010), for single and binary odor mixtures (Boyle et al., 2009), for pleasant and unpleasant odors (Henkin and Levy, 2001), and variations in odor-induced brain activity attributable to gender (Yousem et al., 1999a; Bengtsson et al., 2001) and age (Yousem et al., 1999b).

The question that has been asked by the food and beverage industries is how they can use such information from this new era of chemosensory science? Can the scanners be substituted for human sensory evaluation panels? The current cost of fMRI scanners and both the cost and need to supply medical isotopes necessary to use PET scanners, suggests that this equipment will most likely stay within medical and research institutions, where industry can, nonetheless, benefit from the funding of research employing such technology. However, the development of standardized protocols and instruments for routine brain scanning of any kind within the food industry is a long way off, both from the perspective of reducing costs for PET and fMRI, and in producing reliable and valid data.

Specific attempts have been made by the food industry to harness surface brain voltages measured through electrodes placed on the scalp (electroencephalography: EEG). Like functional imaging, such studies have the potential for providing useful information about attitudes and liking of people for food products and for minimizing the number of subjects required to obtain such information (Owen and Patterson, 2002; Owen et al., 2002). However, sensitivity and specificity issues are present and, despite fiscal support from the Australian food industry, the experimental results and technology have yet to be adopted by this industry.

### 47.5.3 Machine Sensing (Artificial Noses)

Another area of interest to industry, much of which has been developed in the public sector, is the invention of specialized detectors which can potentially replace human noses in quality control, product development, and other facets of food technology. Can machines replace people in food manufacturing? In some sectors of the industry the answer is yes. For example, at a number of large chocolate, candy, and cookie manufacturing facilities, visitors can be taken to a viewing point above a vast floor of machines and process lines. Finding the humans on the floor is quite

a task. A handful of floor operators will attend to hectares of production machinery. Engineering solutions govern oven temperatures, stress sensors control line speeds and roller pressures, and machine vision is now common in sorting products for optically discerned faults, dangerous inclusions, and so on. In each case a human has been replaced by a device with some form of reliable and valid decision-making ability.

In general, quality control of the final product still requires human intervention. Large costs are attached to every batch of product, and one of the most expensive events, dreaded by plant managers, is when a fault is discovered in the product after it reaches the consumer. An example of what can occur is that lines that add flavor during the process become temporarily blocked or otherwise fail, resulting in large and costly quantities of cookies arriving at the market that taste terrible.

Nevertheless, machine solutions are being sought to reduce the cost of running and training human judges. Chemical sensors and electronic noses have long been envisaged as playing a useful part in food production (Barnett, 1999; Hibbert, 1999; Levy and Naidoo, 1999; Mackay-Sim, 1999; Persaud, 2003). Although earlier and cumbersome devices were designed to detect a wide range of chemicals, the new trend is to tailor the device for the intended job, creating a sensor array with performance characteristics tuned for one or a few chemicals (Bell and Wu, 2006). The challenge for e-nose technology remains the achievement of useful and timely recognition of vapors in an operational context, in addition to the practicalities concerning sensor lifespan and reliability. An approach to data processing in real time using a Bayesian probability model may bring the technology closer to widespread use in the food and beverage industries (Hibbert and Bell, 2011).

## 47.6 HUMAN SENSORY EVALUATION

As noted in the introduction, the field of sensory evaluation or “sensory analysis” had its beginnings in the aftermath of WWII when the limitations of having one or a few persons make sensory decisions that could impact the future prosperity of a company became clear (Stone et al., 1974; Piggot, 1984; Jellinek, 1985). Eventually, the replacement of the individual expert taster of old with a group of tasters (members of a panel) which was not under any influence to deliver a replica of the manager’s opinion, became the standard. These panels replaced the heavily biased and haphazard managerial discussion groups notorious for influencing each other and delivering what the boss wanted, as delightfully illustrated in Jellinek (1985).

Today, a basic in-house panel or “group taster” is comprised of 10 to 15 healthy non-smoking employees

who volunteer for this task, often from a diverse set of departments. Their combined judgments are more objective (i.e., reliable and valid statistically) than that of a single individual. Consumer panels, which are hired from outside the company are usually comprised of larger groups. Such panels allow for better sampling the population in general. Today, new information technology is used to reach larger numbers of consumers in ways never possible previously, with interesting implications for how companies will develop and distribute products for newly identifiable consumer subgroups on a massive scale (Moskowitz et al., 2011). Nevertheless, the role of the “expert” has endured in many quarters, particularly in the wine industry where a single individual’s “expert” opinion, usually an established wine critic, carries enormous weight and influence.

### 47.6.1 Influence of Prior Experience on Liking and Choice

Each person brings their unique world of established knowledge and experience to the table when selecting and evaluating food products. Familiarity or expertise with a product, gained through learning, memory, and associated emotions, forms part of this established knowledge. Experientially-gained knowledge can be individual, hence leading to idiosyncratic responding by a person (Parr, 2003), but is often shared within a social or cultural group, as demonstrated by the culture-bound popularity of kimchi in Korea and Vegemite in Australia. In the latter case, the knowledge is often considered in terms of social representations (Dubois, 2000) which can be considered as “shared thoughts” within a group. Since food or beverage selection is a choice behavior, involving discrimination, the features of a product are subjected to scrutiny and recognition processes (Freeman et al., 1993). It is not surprising that familiarity or prior experience is an important determinant of food selection.

Scientific studies demonstrating such influences are widespread. Stevenson and Prescott (1994), for example, found that prior experience with chili, or long-term memory of chili, influenced intensity ratings of perceived burn by capsaicin solutions. Distel et al. (1999) showed that product familiarity determines the liking and perceived strength of an odorant. Ayabe-Kanamura et al. (1998), in a study of the responses of Japanese and German participants to odorants considered typical or untypical for each culture, also found that familiarity influenced participant responses. As noted by Dijksterhuis et al. (2006), prior experience with food or beverages “inarguably has an effect on current liking.”

Foods and beverages can be familiar in terms of their intrinsic (e.g., flavor characteristics) and extrinsic (e.g., packaging) characteristics. Labbe et al. (2006) reported a study of the influence of beverage familiarity

on the interaction between olfactory and taste perception. Cocoa-flavored beverages comprised the familiar item, and caffeinated milk comprised the non-familiar item. They found that familiarity or experience modulated taste perception even in participants trained in sensory panel work. Adding vanilla to the familiar cocoa beverage induced a significant sweet enhancement. However, addition of vanilla flavoring to the non-familiar beverage, the caffeinated milk, enhanced perceived sweetness as with the familiar cocoa beverage, but unexpectedly also enhanced perception of bitterness. In another study, van Herpen et al. (2012) found that familiarity with a product’s label influenced evaluation of the product (e.g., rating of trust in the label), but did not influence product choice based on perceived health benefits, emphasizing the fact that the influence of familiarity on product selection is a complex issue.

### 47.6.2 Expertise: Influence of Expert Opinion on Consumer Behavior with Examples from the Wine Industry

Assignment of grades, scores, or awards to foods and beverages to reflect quality is a long-established practice with its roots in industry rather than in science. Ratings of perceived wine quality go back at least as far as the mid nineteenth century with events such as the ranking of the Bordeaux chateaux (1855) and the first Australian wine show in 1845 (Walsh, 2002). Whereas the aim of grading or rating product quality was purportedly to improve products and grow the relevant industry (Walsh, 2002), more recently the award of medals or high grades to food and beverage products has been a major tool of marketing. For some wine companies, use of information about their medals and awards has served as the dominant factor in their marketing strategies, and it would appear that gold medals do sell wines (Murphy, 2002).

Today, there is a large number of forums for evaluation of food and beverage products such as formal shows where quality is judged by designated experts within a field (e.g., olive oil, cheese, or wine awards), and media for disseminating the results of such evaluations (e.g., specialist magazines such as *Wine Spectator* in the USA, and internet sites). It is not surprising that consumers take notice of expert opinion when selecting foods and beverages that they cannot taste at the point of purchase, especially for relatively complex and expensive products that can vary from product to product and carry a high level of perceived risk in a consumer’s mind (Hayes and Pickering, 2012). Researchers have shown expert opinion to influence a range of relevant product aspects including choice of wine by consumers (Murphy, 2002), liking of wine (Siegrist and Cousin, 2009), price of wine (Dubois

and Nauges, 2010; Hadj Ali, et al., 2008) and quantity of wine consumed (Hilger et al., 2011).

The wine industry recently has made attempts to formalize training and selection systems for their judges (O.I.V., 1994). This is aimed at remedying a situation where relative absence of guiding principles based on scientific knowledge leaves those deemed to have expertise within the food and beverage industries relying primarily on their own experiences and anecdotal evidence to achieve their tasks. Further research involving industry and science can only benefit all players, not least the consumer who it would appear from research to date is influenced by expert opinion when selecting, purchasing and consuming food and beverage products.

### 47.6.3 Genetic Factors

**47.6.3.1 Taste Genes.** By far the most active area of research into the genetics of human taste perception has been concerned with differences amongst people in perception of bitterness. Taste receptors of the TAS2R family detect bitter compounds (Newcomb et al., 2010). Ability to detect bitter compounds has been, from an evolutionary perspective, deemed an adaptive development that serves as a mechanism for avoidance of toxic compounds. Individual differences in human responsiveness to the bitter tastant known as PROP (*6-n*-propylthiouracil) have been studied extensively; see reviews by several authors in Prescott and Tepper (2004) and Reed et al. (2006).

That individual differences in sensitivity to a bitter compound can be linked scientifically with responsiveness to oral sensations such as astringency (Pickering et al., 2004) and with self-reported alcoholic beverage intake (Duffy et al., 2004) suggests a genetic basis, at least in part, for some food preferences. Nonetheless, whilst several studies do support a link between a person's PROP status and food choice (Tepper, 2008), the research area is plagued with methodological issues, not least the influence of a myriad of confounding variables that exemplify the difficulty in empirically separating out genetic influences from effects of environmental variables on a person's food preferences. Genetic heterogeneity for PROP sensitivity was demonstrated across a number of cultures (Bell and Song, 2004), demonstrating the degree to which the genes for this taste characteristic may influence behavior between populations of consumers in various countries.

Individual differences in perception of sweetness, sourness, saltiness, and of umami have been less frequently reported. An area where industry has for some years now had information linking genetic variation with differences in taste perception is that of bitterness perception. This has led to an understanding by companies that produce and market artificial sweeteners, that the bitter after-taste perceived by a proportion of the consuming population

(Roudnitzky et al., 2009) likely has a genetic basis. This knowledge allows a company to innovate by, say, choosing to produce an alternate product for that segment of the consuming population that is particularly sensitive to the source compound (e.g., a sweetener that cannot bind bitter taste receptors). The challenge remains for the industries to identify the appropriate subgroups and modify their products accordingly. We might expect the beer industry to take up this approach in future.

There is evidence for marked variation in human ability to detect sweetness (Reed et al., 2006), as well for variation in the sweet-related receptor genes TAS1R1 and TAS1R3. However, actual linkage of the genetic differences with behavioral differences related to perception of sweetness awaits further research (Newcomb et al., 2010). In the case of perception of umami, and the detection of sourness and saltiness, there are few data available that associate individual differences in perception with genetic differences. Nonetheless, as the state of knowledge concerning genetic differences in odor and taste perception improves, the food and beverage industries will have opportunity to consider the relevance of the data, and feasibility of application of results, to their particular products.

**47.6.3.2 Smell Genes.** As with taste, odor qualities contribute in large part to the desirability and selection of numerous foods and beverages. Perception of odor is arguably more complex to understand than that of taste given that genes for odorant receptors comprise one of the largest gene families in the human genome (Hasin-Brumshtain et al., 2009). What is clear is that marked individual differences occur amongst people in terms of both sensitivity and odor-quality perception (Ayabe-Kanamura et al., 1998). Twin studies have provided an important source of data that suggest that individual differences in olfactory perception have a heritable basis (Finkel et al., 2001), although the influences of heritability appear to be swamped by environmental factors in later life (Doty et al., 2011). Recently, Jaeger et al. (2010), using a genome-wide association approach, demonstrated differences in ability to detect the compound *cis*-3-hexen-1-ol, a compound that is considered an important source of flavor in fruit (e.g., green kiwifruit), vegetables (e.g., tomatoes), and in some white wines. Further research is underway (Jaeger et al., 2010) to determine whether genetic variation within the relevant area of the genome is able to be associated with behavioral data such as liking of specific foods and beverages containing *cis*-3-hexen-1-ol. This work has potential to serve as a model for other researchers interested in linking identified genetic variation with human behaviors, including those involved in the preference, selection, and purchasing of food and beverages.

Whether, and in what ways, the food and beverage industries will use the information from the emerging

science linking human genetic variation with behaviors associated with taste and odor perception remains to be seen. Newcomb et al. (2010) discuss what they perceive as opportunities for the food and beverage industries arising from the new knowledge about genetic variation, as well as some potential pitfalls. The idea that the marketplace could be segmented into groups of individuals more or less likely to prefer and purchase a particular product on the basis of their genetics, must be appealing and likely to be of increasing importance for the industries. They suggest that it will be in new flavor development that the biggest advantage to industry will probably be found. That is, costs of development of a new flavor may be reduced if the probability that it will appeal to a particular market can be accurately predicted on the basis of established genetic diversity in the consumer population. One obvious difficulty with such an approach is that the world is becoming “smaller”; many societies are ethnically multi-cultural, such that identifying individuals’ genetic makeup would rely on markers of genetic differences between individuals rather than on readily found criteria such as nominated nationality, visual appearance, and so forth. One way around this would be to genotype children at birth and aim to identify their likely flavor preferences. Clearly, not only would this be an expensive operation, but it raises major ethical issues in terms of to whom such information would be made available.

**47.6.3.3 Nutritional Genes.** A recent development is the research area of personalized nutrition, with its basis in molecular nutrition studies. It aims to identify the nutritional needs of individuals based on their genetic background (Williams et al., 2008). If it can be understood how nutrients influence humans with different genetic backgrounds, it may be possible to give dietary advice and develop food and beverage products that will improve quality and quantity of life, with such products tailored to meet the nutritional needs of particular groups in society (Newcomb et al., 2010). Clearly, the ethical issues associated with use of individuals’ genetic information to guide product development are enormous but will need to be addressed. We can expect the food and beverage industries to pay cautious attention to these genetic approaches.

## 47.7 SOCIETAL INFLUENCES AND FASHION

That the culture within which one exists markedly influences one’s food and beverage choices is not in question. Consumers from geographically different world regions have been shown to have different expectations and preferences regarding food and beverage products (e.g., Do et al.,

2009). Until recently, the majority of research addressing this topic involved comparisons of consumer preference and consumption behavior as a function of culture, where culture was defined in terms of geographic location. Over the last few decades, two new cultural influences on food and beverage choice have emerged: (i) the increased interest of consumers in perceived health benefits and risks pertaining to food and beverage products; and (ii) what can loosely be termed “green issues.”

### 47.7.1 Perceived Health Benefits

Consumers have become increasingly interested in the health benefits or perceived risks related to the food and beverage products that they consume. Informed choice in what one eats and drinks is now a common and accepted expectation for many of today’s consumers. Taking wine as an example, the notion that red wine confers a health benefit on the consumer, known as the “French paradox,” coincided with increased red wine consumption over white wine consumption, and more recently with an interest in red wines known to be high in compounds believed to be healthy, such as wines made from the grape varietal Tannat (Renaud and de Lorgeril, 1992; Lippi et al., 2010).

As well as favoring foods and beverages with agents perceived to offer health benefits, consumers have shown, over recent decades, an increased interest in avoiding what they perceive to be risky produce in terms of perceived healthiness, to the point of tolerating less palatable foods such as bitter vegetables. However, products that sacrifice pleasant flavor in the interest of being healthy seldom survive in the market; indeed, health benefits tend not to over-ride the sensory hedonic quality of foods, such as low fat or low salt products in determining choice, and is one reason why most diets fail (Prescott, 2012).

### 47.7.2 Green Choices: Organic and Biodynamic Food

Another influence that is usually short-lived in over-riding chemosensory determinants of food choice is so-called green issues, which are political or ideological in nature. These include individuals’ concerns for “ecologically sustainable agricultural practices” such as “organic” and “biodynamically-” grown produce. Consumer advocates for preferring such products stress absence of pesticides in production, absence of animal-unfriendly methods (free-ranged versus caged chickens), truth in labeling (to reveal inclusion of preservatives and flavor chemicals, including monosodium glutamate), and preferred sources of origin such as locally-made over imported products which have generated “more carbon” in their transport.

Marketing of organic and biodynamic foods and beverages includes notions such as “purity” and “fresh-

ness,” terms which imply a sensory quality, seldom confirmed by sensory measurement. Further, products produced by biodynamic agriculture typically command a higher price than more conventionally-produced products (Smith and Barquin, 2007; Kramer, 2006). However, research supporting superior sensory or nutritive value from organic or biodynamic produce is lacking. One of the few peer-reviewed studies comparing biodynamic and organic viticulture reported no consistent differences in any of the physical, chemical, and biological parameters measured (Reeve et al., 2005).

From these two social movements, we can deduce that the importance of sensory drivers of choice will act in opposition to the forces driving consumer interest in products with perceived health benefits, and “green value.” To survive in the market, such products will need to have a sufficient amount of sensory quality.

### 47.7.3 Cognitive Processes

Human experience includes imaging (i.e., remembering the sensory qualities such as odors, tastes, tactile sensations), judgment (making a decision), and language (Cowan, 1988; Parr, 2008). Food evaluations and choice involve many cognitive factors in the decision process. These factors can be idiosyncratic (Parr, 2003), not easily modifiable, and can include cognition, emotions, ideas, desires, motives, and context.

O’Mahony and colleagues have shown how cognitive judgment influences a person’s food and beverage choices (O’Mahony, 1992): perception of sensory differences will depend on a person’s propensity or bias toward saying that something is “different” when they are unsure (O’Mahony, 1991; 1992). Such “response bias” is a cognitive factor central to smell and taste judgment. When two products are easily distinguishable, response bias is not an issue: a consumer will detect the difference every time and select according to established preferences, but when subtle change in a product may exist, difference testing needs to take into account the response bias (O’Mahony, 1991; 1992).

**47.7.3.1 Expectations.** Expectations generated by both intrinsic (sensory) cues and extrinsic cues (non-sensory stimuli) can influence chemosensory perception leading to biased judgments (Deliza and MacFie, 1996). Coloring a white wine red influences the aromatic description of the wine (Pangborn et al., 1963; Morrot et al., 2001), in wine professionals, as well as in consumers (Parr et al., 2003). Similar effects have been demonstrated with extrinsic cues. Brochet and Morrot (1999) reported that information on a wine’s label influenced sensory evaluation of the wine. Siegrist and Cousin (2009) reported

that participants’ wine evaluations were influenced by whether negative or positive information (wine critic Parker’s ratings) was given to participants prior to their tasting of the wines. They found that favorable sensory expectations were generated by a high Parker score. Similarly, Piqueras-Fiszman and Spence (2012) weighed over 500 wine bottles in a wine retail store and demonstrated that the weight of a wine bottle correlated positively and significantly with wine price.

Several models for integrating the information a consumer receives during their sensory evaluations of a product are assessed by Deliza and MacFie (1996). Such models are based to some degree on Festinger’s (1957) notion of cognitive dissonance. In this context, cognitive dissonance refers to mental conflict between what we are currently experiencing in a food or beverage and what we expected to experience. Research shows that the information already in a consumer’s head, known as “top-down” or idea-based input (Reisberg, 1997; Dalton, 2000), can over-ride the sensorial input, biasing a person to “perceive” and report sensory experiences that are unrealistic given the nature of the product being experienced. Further, this can be accompanied by marked confidence that the erroneous judgment is in fact correct (Cain and Potts, 1996). This phenomenon renders the wine industry open to damaging fraud by false labeling, as reported in several countries (USA; New Zealand) in 2012.

Many factors influence the discrepancy between expected and experienced liking of food products. These include health and nutrition information (Tuorila et al., 1994) and information about product origin (Caporale and Monteleone, 2001). The rating of liking is influenced by factors such as food labeling, packaging, price, information, advertising, as well as intrinsic factors such as aroma, taste, and textural qualities. However, whether such factors modify the actual sensory experience or whether they merely create a cognitive status that modifies the overall judgment of the product, is not clear. In a study with wine, Siegrist and Cousin (2009) separated these two factors by providing either positive or negative information about a wine critic’s ratings of the wines at differing times, namely before the wine tasting or after the wine tasting but prior to the wine evaluation by participants. Results showed that information given prior to tasting the wines influenced participants’ ratings, but information given after tasting but before making their judgments did not influence participants’ ratings. This suggests that once a person has had an opportunity to taste a product unencumbered with prior information, their judgment thereafter is based on that sensory experience and not on intervening information, be it positive or negative.

In the food and beverage industries expectations of consumers are continually being manipulated by the marketplace: fancy and expensive packaging, label design,

price, and so forth. What is important in marketing is that the expectation is met. Un-met expectations can result in delayed reactions as a person tries to deal with the discrepancy, and difficulty in forming preferences for the object (Wilson et al., 1989).

**47.7.3.2 The Dynamic Nature of Liking.** There are many factors determining the hedonic quality of what we eat and drink, and this is the subject of a recent book (Prescott, 2012). Understanding why people like a particular food, is often a challenging and changing objective. Some factors involved are discussed here.

**REPEATED EXPOSURE** A consumer's perception and hedonic judgment of a product can change with repeated exposure to the product. Changes in liking as a function of repeated exposure can have positive health benefits and be commercially exploited. Increased liking can be achieved for food with reduced sodium chloride, sucrose or dietary fat, simply by sufficient repeated exposure to the "healthier" product (Sullivan and Birch, 1990). Understanding the parameters of food novelty, and therefore variables such as complexity, which are likely to interact with repeated exposure of food items to influence sensory perception and liking, is a current research area of interest (Köster and Mojet, 2007; Medel, 2011).

**COGNITION AND EMOTION** Influence of emotions and prior memories often occurs outside conscious awareness: a particular smell can influence a person's behavior (e.g., the kind of judgment they make), even though the person has no awareness of this, and may not even be conscious of the odor's presence (Herz, 1997). The influence of knowledge about food and beverage products that has been gained unintentionally (i.e., without explicit attention or learning) on memory for food items and on food preferences has been studied (Haller et al., 1999; Degel and Köster, 1999; Mojet and Köster, 2002). Use of emotive odor, such as freshly-brewed coffee or freshly-baked bread, is now commonplace in many commercial settings. Research on non-intentional learning and memory, involving odor, suggests that not only do such techniques have a reasonable probability of being successful, but that a consumer may well have no awareness of the ambient stimuli (e.g., pleasant odors) contributing to their decision making, thus raising ethical issues for consideration.

## 47.8 CONCLUSIONS

Chemosensory science of olfaction and taste and the knowledge it produces is essential to the modern food and beverage industries. Understanding the sensory and non-sensory

determinants of consumer behavior involving products is crucial to the economic success of companies within these industries.

Recent advances in food production and processing technology have expanded the choices for, and availability of, food and beverages to increasingly affluent consumer populations. As populous nations such as China, India, Indonesia, and Brazil increase in affluence, global economic growth is likely to continue, and with it chemosensory science. So long as consumers are free to choose what they buy, competitive companies will need to be informed about chemosensory science and apply it innovatively. Understanding why people select the products that they do, whether a function of age, gender, culture, contemporary fashion, genetic predisposition, political persuasion, or experience and familiarity, will require expertise and a constructive interaction between chemosensory scientists both within and outside of commercial food and beverage enterprises. They stand to learn from each other and to influence the direction, aims and methods of research activities, such as those examining the influence of aroma on the perception of sweetness intensity and how to develop low salt and low fat products with acceptable flavors. Understanding the fundamentals of chemoreception at the molecular level will provide flavor chemists with a rational basis for designing the next generation of economically and experientially compelling flavor molecules. Brain scanning by PET, fMRI and other methods offer another level of analysis by which insights into human chemosensory perception will, in future, yield useful knowledge for industrial applications. Developments in sensors, arrays, and algorithms for non-human judgments of product quality will find a greater place in production and quality control fields, and reduce costs of, and dependence on, human judges. Nevertheless, the consumer is the final judge of products in the all-important marketplace and it is their chemosensory systems that will remain an important meeting point for industrialists and chemosensory scientists.

## Olfaction and Gustation in the Flavor and Fragrance Industries

BENJAMIN MATTEI, ARNAUD MONTEL, and MATTHIAS H. TABERT

### 48.1 INTRODUCTION

In the preceding chapters different aspects of the olfactory and gustatory sensory systems have been discussed at length. In this chapter, we discuss how chemosensory perception is used in the flavor and fragrance industry to design flavors and fragrances. We first provide an overview of this industry, including its history. We then explore how this industry employs *chemosensory*, *affective*, and *conceptual* measurement in the development and assessment of products.

### 48.2 THE FLAVOR AND FRAGRANCE INDUSTRY AND ITS HISTORY

The primary mission of the modern flavor and fragrance industry is to create and blend raw materials into flavors and fragrances that meet market demands. While this industry started as an artisanal activity, it is now a multi-billion dollar chemical industry in which raw materials are either purchased, transformed from existing materials, synthesized *de novo*, or extracted from natural products. Flavorists and perfumers blend these ingredients into proprietary formulas which are then used in the development of the final fragrance or flavor.

The roots of creating flavors and fragrances date back over 5000 years ago to the early Egyptians. Herbs, spices, and flowers were used to flavor food and to make perfumes through distillation. While the more systematic use of distillations by pharmacies to make medicinal remedies

developed in the 16th and 17th centuries, the first aromatic chemicals were synthesized in the 19th century (see Chapter 1). Since then, thousands of aromatic compounds have been extracted or synthesized, and the production of flavors and fragrances has reached a global scale. As a result of such industrialization, the necessity arose to define and apply quality standards in manufacturing and distribution to ensure consistency in the chemosensory properties of the final products.

Although the original motivation behind flavor creation was to enhance the taste of food, other functions came into being as processed foods became popular. These included recreating the taste of original foods, masking off-notes in product formulations, and increasing shelf life. Similarly, the development of fragrances was initially focused on giving the human body, animals, objects, and living spaces a pleasant scent, as well as masking unwanted odors, such as sweat, smoke, dirt, and excrement. Subsequently fragrances were added to a wide range of products and some came to symbolize functions of such products. For example, lemon odor came symbolize cleanliness itself, reflecting the application of lemon scent to a wide range of cleaning agents.

As the industry matured and became more competitive, optimizing the quality of flavors and fragrances became a major priority. To achieve this end, considerable capital investment was made in research as to how to best create fragrances and flavors that meet the demands of increasingly sophisticated consumers from a variety of cultures. To capitalize on such advances, companies that market flavored or odorized products approach flavor and fragrance companies with “briefs” that specify the chemosensory

requirements needed in the end product and its desired effects on consumers. Each solicited company then develops a product to meet the specifications outlined in the brief with the goal of winning a contract. Briefs typically contain key performance indicators, such as a requirement to match and replace a current flavor or fragrance because of technical, regulatory, or economic reasons, or to create a new flavor or fragrance for introduction into the marketplace.

### 48.3 DESIGNING FLAVORS AND FRAGRANCES

Professional artisans, namely perfumers and flavorists, are essential in the creating of new flavors and fragrances. Such artisans employ chemical libraries that consist of successful final formulations, flavor or fragrance keys composed of molecules that illustrate a sensory direction, and single-molecule chemicals (Figure 48.1). The successful formulations are generally organized according to sensory profiles, regulatory information, price, and other factors. These often serve as a starting point to elaborate on and obtain the desired end-result in new creation. Flavor

and fragrance keys further facilitate and accelerate the creative process. For example, the use of a flavor key on a bland orange base could steer the overall flavor profile in a blood orange, ripe, peely, or candy direction. Typically, flavor key libraries are specific to a given artisan and define his or her olfactory personality or signature. One of the main tasks of a trainee perfumer or flavorist is to start building his or her own library of keys.

Nowadays, such artisans often work in conjunction with equipment that helps to identify or isolate volatile and non-volatile elements from natural products (e.g., the nectar of a flower). In the case of volatiles, separation is commonly performed using gas chromatography (GC), such that different volatiles appear at different times as they pass through a heated column within the device after the product is injected into it. In split-stream GC-analyses, the various “peaks” that occur over time represent different chemicals – chemicals which can be simultaneously sent to a nozzle where they can be smelled by the perfumer or flavorist. Further chemical identification of such peaks can be made using mass spectrometry (MS). This process makes it possible for perfumers and flavorists to discover combinations of molecules within natural products that guide them in better mimicking nature and inspiring the creative process. Importantly, the merging of sensory and analytical procedures makes it possible to understand and correct for seasonal and other variations in the chemical constituents of natural materials, such as flowers and herbs, thereby providing more consistent products.

### 48.4 MEASURING HUMAN SMELL AND TASTE PERCEPTION IN THE INDUSTRIAL CONTEXT

Aside from marketplace acceptance, consumer perception is the ultimate performance measure of a flavor or fragrance. In this context, perception is defined as the organization, identification, and interpretation of sensory information. At IFF, we focus on understanding consumer perceptions at three general levels: sensory, affective, and conceptual. The *sensory level* refers to the perceived sensory qualities of a product or its ingredients, such as the identification of its flavor or fragrance notes and their relative intensities. The *affective level* refers to the emotional or hedonic influences of a product on consumers. The *conceptual level* refers to more cognitive aspects of perception. For example, each time a person is exposed to and perceives an odor or taste, a *percept* or mental impression of the agent and its source is formed or reinforced. Different percepts contribute to the formation of *concepts*, or mental representations. For example, concepts like “authentic,” “natural,” “healthy,” or “feminine” may apply to a strawberry flavor in yoghurt or to the fragrance

**Figure 48.1** Image from an IFF perfumer evaluating a key in front of his fragrance library.

of shea butter in a skin care product. A major challenge of the flavor and fragrance industry is to decipher how such concepts are formed and their influence on the buying habits of consumers.

#### 48.4.1 Assessing Sensory Aspects of Flavors and Fragrances

**48.4.1.1 Sensory Panels.** Ultimately, the sensations induced by flavors and fragrances are evaluated by groups of people comprised of sensory panels. In an ideal world, such panels would consist of a large group of extra-sensitive people that are highly trained and able to describe the sensory elements of products with the utmost precision and reliability. In reality, sensory panels are usually composed of around ten to thirty people who are screened for their sensitivity (detection and saturation thresholds as well as their ability to discriminate between closely perceived intensities) and cognitive skills (ability to describe, identify, memorize and focus) (Stone and Sidel, 2004). The performance of sensory panelists are also carefully monitored over time to ensure repeatability, discrimination and consistency. However, less extensive variants are common. For example, in some elements of the fragrance industry, only one or a few extremely sensitive and highly trained panelists, termed evaluators, are used. This is risky, however, since it precludes averaging out possible mistakes or inconsistencies over a number of people.

Reflecting the need for less expensive, more flexible, and more holistic assessments of consumer perceptions, many sensory panels are now comprised of groups of largely untrained consumers (Varela and Areas, 2012). When the objective is to assess the similarity of sensations evoked by two different products, or preferences among different formulations, sensory panelists do not need to be specifically trained to detect flavor or fragrance notes. They just need to be sensitive and reliable enough to perceive the products and to detect possible sensory differences between them. To accommodate cost, resource, logistics, and experimental design considerations, different panels for different objectives are frequently employed. For example, separate panels may be used to assess the sensory proximity of two products, to generate an overview of the sensory space covered in a given marketplace, or to guide product development.

Although members of classic sensory panels are often screened for sensitivity using traditional procedures (see Chapters 11 and 34) and are thoroughly trained to learn and distinguish subtle differences between aromatic notes, this cannot make up for a lifetime of sensory experience in a cultural setting. Hence, the employment of panels within a culture where a product is to be marketed can sometimes be invaluable. This is exemplified by some people in India who are able to distinguish dozens of different curries, much like

the Inuit peoples of the Arctic North whose language distinguishes among dozens of different states of ice and snow. Importantly, repeated use of a product can also enhance sensitivity specifically for that product. For instance, some consumers who have been using a product several times a day for years are able to detect the slightest changes in its sensory profile. Moreover, people with an aversion to certain chemicals, which are often learned, may be more sensitive than others regarding the object of aversion. Finally, on a shorter timescale, scale, hunger tends to increase sensitivity and satiety tends to decrease sensitivity for at least some chemicals (Zverev, 2004).

##### 48.4.1.2 Sensory Panels vs Analytical Instruments.

While GCs and MS are extremely useful in detecting and identifying volatiles responsible for producing certain scents or flavors, sensory panels are preferred over such instruments in evaluating products. There are several reasons why this is the case. First, the human nose is more sensitive to some chemicals than such devices, including the more focused “electronic noses” and “electronic tongues.” Second, information from different sensory modalities (e.g., smell, taste, and texture) is integrated in the human brain through neural networks, using associative memory and other processes. Mimicking this integration with instruments and electronic neural networks, while theoretically possible, has not yet been achieved and will require much more future research and development. Third, target products often are influenced by the environment with which they interact in ways that are difficult for instruments to measure. This includes, for example, reactions of a perfume on the skin and the influences of a complex oral salivary and bacterial environment on chewed food. In order to reproduce the sensations that a person perceives while using or consuming such products, one would need to reproduce artificially the same processes with instruments, which is an enormous challenge. Finally, what instruments detect is not necessarily relevant for the consumer’s ultimate perception of the product.

##### 48.4.1.3 Sensory Profiling Methods Using a Common Sensory Language.

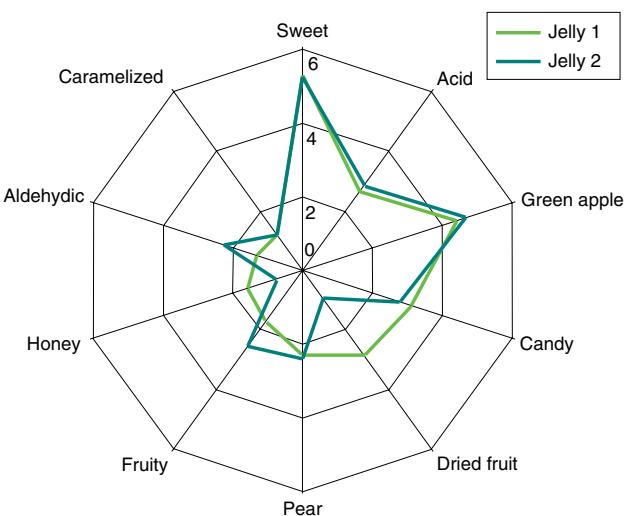

A primary goal of sensory profiling by panels is to identify the different flavor and fragrance notes that can be perceived in an evaluated product and to establish their relative intensities using scaling methods such as rating scales (Lawless and Heymann, 2010; Chapters 11 and 34). The language is said to be common because all the panelists share the same understanding and knowledge of each note. It is therefore easy to analyze the results with very simple statistical tests. The two most well-known methods are the Quantitative Descriptive Analysis (QDA®) (Stone and Sidel, 2004) and Spectrum Descriptive Analysis (Spectrum™) (Civille

and Lyon, 1996). However, these approaches are quite different and most sensory scientists actually use adapted or sometimes hybrid versions of them. Without going too much into detail, during the QDA® the panel will generate a common sensory language composed of descriptors that best represent the different sensations perceived from the products. This phase of language generation is supported by product tasting and/or smelling and discussion moderated by a panel leader who acts as a communication facilitator. The panelists then evaluate the perceived intensities of each of the descriptors and individually rate their perceptions on a scale. They are free to use the scale as they wish and, as a result, the differences in the intensities of the notes between different products will always be relative. The two main differences between QDA® and Spectrum™ is that with Spectrum™ the sensory language will be predefined and the panelists will be calibrated on the use of the intensity scale, both points supported by physical standards called references. Thus, Spectrum™ produces an absolute evaluation of perceived intensities. Both methods have their advantages and do not serve the exact same purpose. QDA® focuses on the sensory discrimination between products whereas Spectrum™ focuses on the absolute measure of perception of the products.

Another method worth mentioning is consensus profiling, a method formalized by the Arthur D. Little corporation in the late 1940s (Caul, 1957; Keane, 1992). It is one of the oldest methods of sensory profiling and is generally performed by a traditional sensory panel. Instead of evaluating the products individually, panelists discuss their perceptions in a group under the supervision of a panel leader until agreement is reached on a list of descriptors and on a score for the perceived intensity of each descriptor. Unfortunately, this archaic method introduces bias due to the panel discussion used to reach consensual intensity scores. Moreover, reliability of the results cannot be measured through statistical analyses. Due to the fact that it is very easy to implement and that it does not require much sensory expertise, this method is still in wide use today.

All of the aforementioned methods generate static sensory profiles that are generally represented as spider graphs (Figure 48.2). However, static sensory profiles do not account for the time component of the perceived sensations. When we first smell a perfume, for example, we do not perceive all the aromatic notes at the same time: first come the top notes generated by highly volatile molecules, then come the heart notes which appear from two minutes to one hour after application, and finally come the base notes, some of which can still be perceived after twenty-four hours.

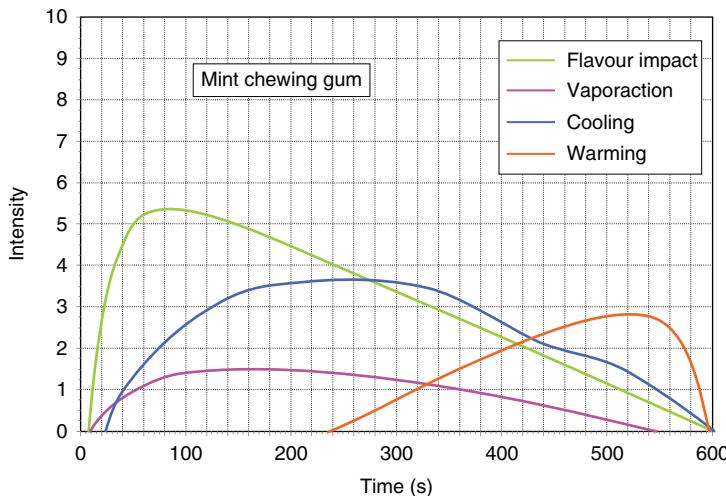

To address the dynamic nature of such time-related perceived sensations, we can, as a first approximation, assess static sensory profiles sequentially. For instance, while eating a potato chip, we can generate a static sensory

**Figure 48.2** Spider graph representing the sensory profiles of two jellies. Here for instance, both Jellies are showing a similar intensity for the descriptor Sweet whereas the Dried Fruit aromatic note is perceived as more intense for Jelly 1 compared to Jelly 2.

profile when the chip is being put on the tongue, followed by another static profile when it has been chewed for ten seconds, and a final one after it has been swallowed. The temporal definition of the description may be enough in most cases, but not always. Therefore, other methods have been created such as Time-Intensity Profiling (Figure 48.3). This dynamic sensory profiling method, which stemmed from early studies in which taste intensity was tracked longitudinally (e.g., Holway and Hurvich, 1937; Sjostrom, 1954; Jellinek, 1964), follows similar rules as the aforementioned static sensory profiling methods, except that the panelists continuously evaluate the intensity of each descriptor over a period of time, one after the other. Although it gives a much higher level of precision time-wise, it is impractical to perform Time-Intensity Profiling on the whole sensory profile of a complex product when dozens of descriptors may apply. For this reason, Time-Intensity Profiling usually employs a limited number of descriptors focused on the dynamic release of a few specific flavor or fragrance notes.

It is therefore critical to not only be able to measure the intensities of the different notes detected in the product but also to see how these intensities evolve with time in order to understand the dynamic aspect of product perception. Two very common examples can illustrate this point. First, it is possible to encapsulate flavors in order to better control their release over time. This is how chewing-gums can sometimes still have flavor even after having been chewed for thirty minutes. Second, the perceived intensity of sweetness generated by sugar varies over time according to a specific pattern and that the same pattern is not always reproduced by artificial sweeteners.

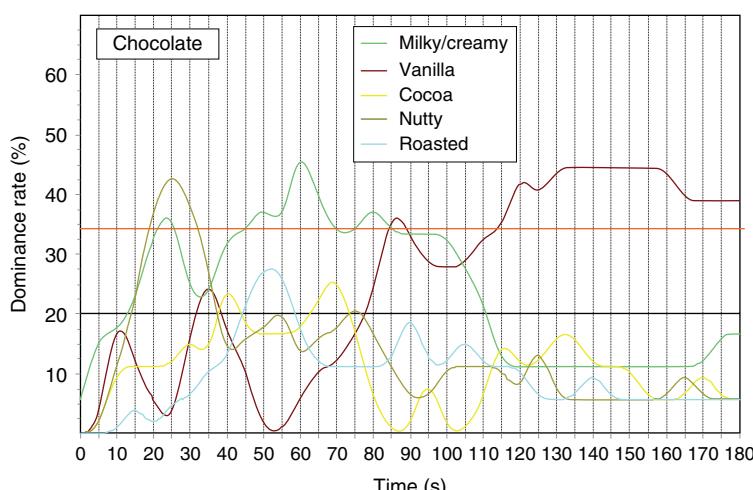

**Figure 48.3** Time-Intensity profile of a mint chewing-gum. Here for instance, the overall flavor has strong initial impact when the chewing-gum is put in the mouth whereas the warming effect is maximum after 500 sec of chewing. (*See plate section for color version.*)

Therefore, it is perfectly possible to have the same overall perceived intensity of sweetness in two products, but to see some differences of sweetness intensity over time between the two products. Hence, the sensory perception has to be measured not only qualitatively (notes) and quantitatively (perceived intensities), but also temporally. In short, taste perception is dynamic.

Another approach to dynamic sensory profiling is the Temporal Dominance of Sensations (TDS) method (Le Reverend et al., 2008). Instead of evaluating each descriptor separately, as in the time-intensity profiling method, the panelists consider all the different notes perceived in the product under evaluation and select the dominant one over time (Figure 48.4). This principle is very seductive since it keeps the same temporal definition as the time-intensity profiling but makes it possible to consider a greater variety of flavor or fragrance notes at the same time. One limitation of TDS is that it does not give a clear indication of the perceived intensities at all times and only focuses on the

most dominant notes. Another is that it does not provide an operational definition of dominance. A descriptor is traditionally said to be dominant when it represents the most striking perception at a given time. Under which circumstances is a given note perceived as the most dominant compared to the others at a certain time? Experience shows that this can happen in the following situations: when a note is the most intense and partly masks the others, when a new note appears over time while the other ones stay put or decrease in intensity, and when a note is perceived as incongruent with the others. Unfortunately, when the definition of dominant becomes ambiguous, panelists may change their use of definitions over time. This makes interpretation of the results difficult since what is being measured can be inconsistent and idiosyncratic among panelists. For instance, a panelist who is not familiar with cinnamon in chocolate might consider the cinnamon note as dominant whereas another panelist who is used to the association might focus on something else.

**Figure 48.4** TDS profile on a chocolate. The nutty and milky/creamy notes are co-dominant at the beginning. As the chocolate starts to melt down, the milky/creamy note becomes clearly dominant followed by the vanilla note that stays in the mouth even after swallowing. (*See plate section for color version.*)

Although an alternative approach would be to have consumers perform TDS to see what is most relevant for them, this would not be sensory profiling, per se, since it would include parameters such as familiarity, hedonic value, and so on. In order to make the results more objective, one can significantly increase the number of panelists beyond that employed in a typical sensory panel. In this way, the biases induced by individual panelists are averaged. Another way to overcome this problem is to restrain and fix the definition of dominance. A commonly accepted approach is to define as dominant the main changes in the sensory profile over time.

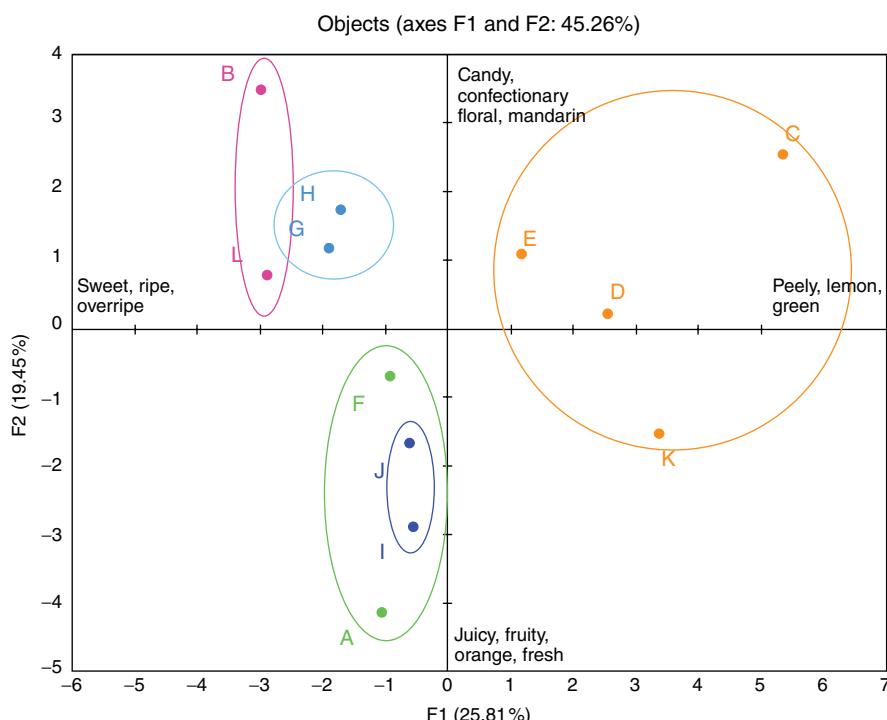

Whatever method is used, quality standards of the sensory language must be implemented to ensure the reliability of results. Each descriptor must be unique, independent from the other descriptors, consensual, understandable, discriminating, stable over time, and reproducible. Many of these requirements can be easily met if a physical standard (reference) is associated with each descriptor. These references can be essential oils, single molecules, mixes of few molecules or even finalized flavors or fragrances. In order to be as precise and specific as possible however, the references should be as unidimensional as possible, meaning that they should ideally evoke a sensation that is unitary. For example, if a reference induces several sensations, the target sensation induced by the reference may vary between panelists. This is why using finished products, where perception is generally very complex, is ill advised in such assessments.

#### 48.4.1.4 Other Sensory Profiling Methods.

The sensory profiling methods presented above require the sensory panelists to be trained thoroughly on a common language and are quite time consuming. This is one reason why many alternative methods have been developed in the past twenty years (for review, see Varela and Ares, 2012). The objective here is not to list and detail all of them, but rather to give the reader an idea of their general principles. Three families of methods that do not require language alignment and training of panelists are described in this section: verbal-based methods, similarity-based methods, and reference-based methods (Valentin et al., 2012).

Two verbal-based methods are Free Choice profiling (FCP) (Heymann, 1994) and Flash profiling (FP) (Dairou and Sieffermann, 2002). In both cases, the panelists evaluate the products individually with their own sensory language. In FCP, an intensity score is given to each descriptor whereas in FP, a ranking of products is performed for each descriptor. Therefore the main difference between the two is that FCP focuses on describing products and FP focuses on discriminating products. In both cases, though, the sensory language used to measure the perception of the products is not common to all panelists. While one can still position the products on a sensory map to gain insights into the nature of product differences (Figure 48.5), clear sensory profiles such as those represented with spider graphs cannot be obtained.

Free Sorting (FS) is a similarity-based method that is simple to implement (Faye et al., 2004). The principle

**Figure 48.5** Sensory map generated from Free Choice profiles of 12 orange drinks. Clusters of products have been identified here but we can see that the sensory description of the products is not very precise.

behind this method is to group products according to their similarities. Because variability exists in similarities among products as well as among panel members, it is possible to compute sensory distances among them. Let us consider a simple example with three products: a can of cola flavored soda, a can of apple juice, and an apple. Here there are two obvious groupings that will account for the similarities of the products. One way is to place the two cans in one group because they are both beverages and the other group will consist of the apple because it is a fruit. The second way is to place the can of apple juice and the apple in the same group because they are both apple flavored and the can of cola in the other group. Both are acceptable and if we were to perform this test with a panel, we would probably observe both ways of grouping the products. It is unlikely that panelists will place the can of cola flavored soda and the apple in the same group. When processing the answers statistically, we will therefore obtain a continuum in which the cola flavored soda is at one end and the apple at the other with the can of apple juice at the midpoint. From this example we can see that while FS allows us to measure sensory similarities and differences between products, it does not provide a reliable measure of the underlying factors that determine the sensory differences.

Finally, for reference-based methods, the recently developed Polarized Sensory Positioning (PSP) is worth mentioning (Teillet et al., 2010; Saldamando et al., 2013). Similar to FS, the basic idea behind the PSP is to measure the sensory distances (similarity or dissimilarity) between each product under evaluation with the addition of a few predefined benchmarks, or anchored products, that serve as references. One of the advantages of this method is that it can be performed with a small number of products, unlike the FS which generally requires many products to give relevant results. However, the choice of the reference products is critical and generally requires a good initial knowledge of the product space, meaning the main types of notes that will help to discriminate between products.

All these alternative methods are much faster and easier to execute than the traditional methods (Varela and Ares, 2012). However, there are some downsides as well. Indeed, appropriate data processing requires more advanced statistical analyses and the interpretation is not always as straightforward as with the traditional methods. Moreover, the information provided by these alternative methods is not precise and specific enough to efficiently guide the development of fragrances and flavors. They are therefore mainly used to get a quick overview of the structure of the sensory space covered by a group of products (market products or prototypes). For instance, performing a sorting on twenty orange beverages in Germany might allow us to identify three main clusters of products, and therefore three main flavor directions present in this market. It will not precisely identify the nature of the flavor

directions, but it will make it possible to select and run a traditional sensory profile on three products representing each of the three clusters. This is much more efficient than profiling the 20 orange beverages right from the start, an approach that may generate a level of detail not required at this initial stage of assessment.

#### **48.4.1.5 *Sensory Discrimination Methods.***

In the case of a replace/match scenario, we have seen that being able to describe in detail the sensory differences between different samples is not always required. Sometimes, we just need to quantify them in order to select the best match or to validate that a prototype is an acceptable match. This is the situation in which discrimination methods are mainly used in the flavor and fragrance industry.

There are dozens of discrimination methods to evaluate the sensory similarity or difference between products but only a few of them are commonly used. The most famous one is the triangle test (i.e., odd-man-out paradigm), which is widely employed and generally recognized as the standard for discrimination tests (Helm and Trolle, 1946; Peryam and Swartz, 1950). It has been used for many years, is easy to implement, and its results are easy to analyze. Its principle is simple: on each trial panelists evaluate three samples, two of which are the same (either the target or the match proposal) and the third is different. Panelists identify which product is different from the other two. This approach does not require prior knowledge about the products and keeps the total number of samples under evaluation reasonably low (three). The triangle test is not, however, the most sensitive discrimination method.

The two-alternative forced choice method (2-AFC) is another commonly used method. Here only two samples are presented: the target product and the match proposal. Panelists determine which of the two is perceived as stronger for a given descriptor. Although apparently less sensitive from a statistical point of view (the probability of choosing the right answer by chance is 1/2, compared to 1/3 for the Triangle test), the 2-AFC is actually much more powerful than the triangle test (Ennis and Jesionka, 2011). One reason for this is that the panelists focus on a single specific aspect of the product (i.e., intensity of a given descriptor) instead of having to deal with the overall perception of the product. Also, the panelists are evaluating two instead of three samples, limiting sensory fatigue when carry-over effects are present. However, the 2-AFC not only assumes that the experimenter has prior knowledge of the nature of the sensory difference between the target and the match proposal, but also that the panelists have a common understanding of the descriptor in order to evaluate the same sensation. Unfortunately this is often not the case, particularly in the testing of flavors and fragrances. However, a variant

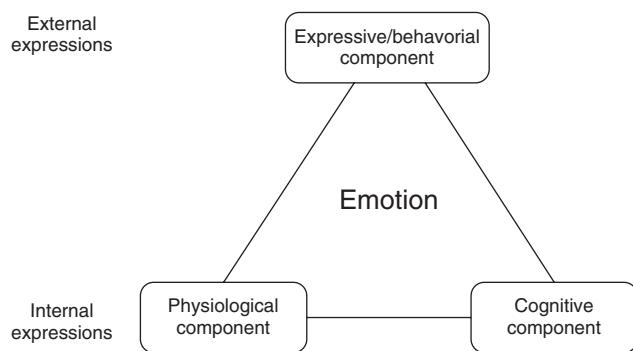

of the 2-AFC can be considered in which the two products (target and match proposal) are presented twice. The first time, panelists are asked to describe the main difference(s) between the two. The second time, each panelist is asked to find back these difference(s). For example, during the first product presentation, one panelist may find the target as sweeter whereas a second panelist may find it more intense. When presented with the products for the second time, the first panelist is then asked to identify the sample that is sweeter whereas the second panelist is asked to identify which sample has the stronger flavor intensity.

**48.4.1.6 Measures of Sensory Distances.** In a number of instances, the perceptual distances between chemosensory elements of a product are useful to obtain. As noted in Chapter 11, this can be done via signal detection approaches as well as via more elaborate procedures, such as multidimensional scaling. In the case of replace/match scenarios, sensory profiles often do not need to be described, but an evaluation of the sensory distance between a target product and a match proposal is needed. If this distance is small, differences between two products will most likely not be discriminated by consumers. On the other hand, if it is large, consumers will most likely note differences. The perceived sensory distance may be the result of different intensities of several notes and their evolution over time, or may be restricted to a specific note, depending upon the context and the purpose of the assessment.

#### 48.4.2 Assessing Affective Aspects of Flavors and Fragrances

Flavors and fragrances are universally recognized for their aesthetic value and, as such, hedonics continues to be the primary driver of product development (Montet, Warrengburg & Glazman, 2012). More than any other sensory system, olfaction drives perceptive and cognitive processes closely linked to human emotions. For this reason, and the fact that flavors and fragrances can trigger emotional responses, industry has sought to identify links between flavors, fragrances, and emotions. Products which elicit the strongest emotional responses, such as a stimulating flavor for an energy drink, a relaxing smell for a night cream, and a sensual fragrance for social occasions are more likely to have success in the marketplace.

Emotions give rise to internal effects (physiological and cognitive), as well as external ones (expressive or behavioral). Emotions are commonly measured according to three main components: physiological, expressive/behavioral (non-verbal), and cognitive/subjective (verbal) (Figure 48.6). The main advantage of physiological measures (e.g., skin conductance, blood pressure, and

**Figure 48.6** The three components of emotional measurement.

brain activity) is to avoid the subjective bias inherent in self-report. However, while they may differentiate two stimuli of opposed valence, they do not offer the required level of sensitivity needed to measure different emotions in finished products at the same level of liking. Moreover, the experimental setup required by this approach is not conducive for consumer testing and is far removed from consumption conditions. Expressive responses are preferable to behavioral responses, since flavors and fragrances do not typically modify behavior directly but trigger feelings. A popular means for such measurement is to assess basic spontaneous facial expressions in response to a flavor or fragrance. According to Darwin (1872), these innate expressions serve a highly adaptive communication function among social group members and include sadness, happiness, anger, fear, surprise, and disgust. Unfortunately, experience has shown that these basic expressions do not add much to the product evaluation beyond a standard liking measure.

Verbal self-report offers the most sensitive probe for assessing emotional responses to chemical stimuli. Using this approach, emotional effects can be computed accurately and reliably given an appropriate experimental design that includes pre- and post-exposure surveys and appropriate control conditions in which the target fragrance or flavor is lacking. A basic affective dimension that can be easily verbalized is that of liking. One can simply ask the consumer, "How much do you like this product," and have the consumer rate the degree of liking on a rating scale. In addition to comparing such ratings across products, relative preferences can be assessed using ranking procedures. For example, a consumer may be asked, "Rank these products from the one you like the most to the one you like the least." Such rankings can be subjected to statistical assessments and derivations of relative distances between products using scaling procedures such as that derived by Thurstone (1927).

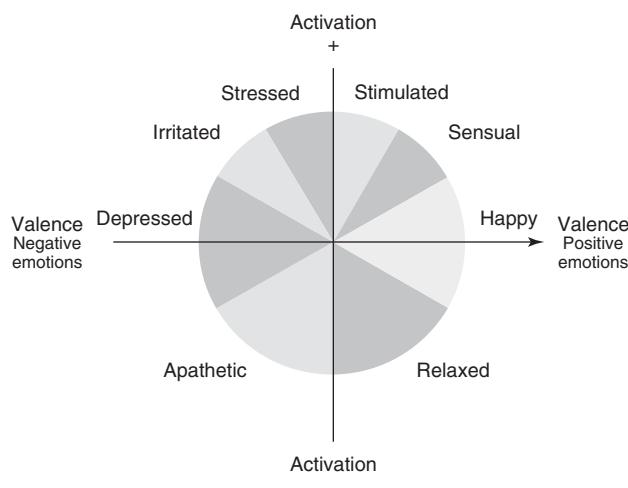

Theory largely drives research in this area, and two theoretical models of emotion have served as the basis for a number of tests. The first model is categorical and assumes

that such emotions as happiness, sadness, fear, disgust, and anger are innate, universal, and independent of one another (Ekman, 1992; Izard, 1977; Kemper, 1981; Plutchik, 1980). The second model is dimensional and assumes such emotions result from combinations of underlying psychological and psychophysiological dimensions such as valence (pleasant/unpleasant) and arousal (Russell, 1980).

Regardless of their theoretical basis, most measurements of emotion can be assessed using questionnaires and ratings scales. At IFF, raw ingredients have been evaluated on a selection of 44 attributes and over 2000 answers have been collected over the course of several decades (Warren and Warrenburg, 1993; Warrenburg, 2002). From the results of factorial mapping, a circular organization of emotions consistent with eight categories of moods has resulted from the combination of the valence and arousal dimensions (Figure 48.7).

#### 48.4.3 Assessing Cognitive and Conceptual Aspects of Flavors and Fragrances

As is evident throughout this chapter, consumers respond not only to the smell or taste of products, but to what the product means to them based on prior experience or social influences. Hundreds of non-chemosensory factors dictate, alone or in combination with chemosensory factors, the nature of a consumer's ultimate perception of a product. For example, the type of packaging and brand image directly influence perceived quality of a product and whether it is purchased by the end user. Such concepts as "authenticity," "naturalness," "uniqueness" or "newness" are increasingly being considered by the food industry as critical to the success of a product. When a consumer

**Figure 48.7** Structure of the emotional categories resulting from the organization of 44 emotional attributes.

expresses the desire to purchase a "natural" product, it does not necessarily only imply that the ingredients should be natural from a regulatory standpoint. Rather, it means that the expectation of the overall perception of the product be natural. In fact, "natural" changes over time. For example, during a recent test on vanilla ice-cream, consumers were exposed to a vanillin flavor (a molecule that is broadly used in the food industry to mimic vanilla taste, although its sensory profile is quite different from the actual vanilla) versus vanilla extract (which renders more faithfully the taste of the actual vanilla). Interestingly the consumers found the taste of the product with vanillin very authentic and natural whereas they found the taste of the product with the vanilla extract very artificial. This underscores the fact that the concept of naturalness and authenticity do not necessarily correspond to what we may think of as being truly natural or authentic.

#### 48.4.4 Dealing with Stimulus Complexity

It is important to note that an understanding of the perceived odor or taste of individual components of added flavors need not predict the ultimate chemosensory experience elicited by the product to which they are added. In fact, added flavors typically represent a very small percentage of the chemical ingredients of most food products (e.g., less than one percent). Thus, the ultimate flavor of a food product depends upon a combination of ingredients. In chicken soup, for instance, there are dozens of ingredients. The added flavors may enhance or complement aspects of the taste of the soup, but their perceived attributes, by themselves, may not represent the ultimate flavor of the soup.

There are numerous examples of how chemicals interact in complex ways producing the final percept (see Chapter 11). For example, anethole by itself smells like anise (licorice-like) and cis-3-hexenol by itself smells like freshly cut green grass. When you put the mixture of these two chemicals in water, you will smell a mix of anise and green grass, with a clear dominance of anise. However, if you put the same mixture in whole milk, it will smell mostly of green grass with a very slight hint of anise. This is because anethole, unlike cis-3-hexenol, is lipid soluble and will be partly taken up by fat globules contained in the milk, decreasing its release into the air in a milk medium.

Importantly, both the chemical and non-chemical sensory systems influence each other in dictating the flavor and ultimate enjoyment of flavors and fragrances and should not be considered in isolation. Hebb's classic theory of associative learning (Hebb, 1949) provides a theoretical framework of how sensory modalities can interact. The basic idea is that cells which fire together wire together. In other words, if two sensations are perceived

together repeatedly over time, they will tend to reinforce each other, to the point that when only one of these two sensations is generated by an external stimulus, the other sensation will still be perceived, albeit to a lesser degree (see Chapters 45 and 46). For instance, if someone is repeatedly consuming seaweeds, exposure will be made simultaneously to aromatic notes specific to seaweeds as well as to saltiness. Therefore the neurons responsible for the olfactory perception of seaweed aromatic notes will wire with the neurons responsible for the perception of saltiness and will reinforce each other. If the subject is subsequently exposed only to seaweed aromatic notes, it is likely that saltiness will be perceived even though no salt is actually present. This overall process, whose physiological correlates have been documented in the orbitofrontal cortex (see Chapters 35 and 46), is complex since multiple sensations and perceptions become interconnected as a result of experience.

Among such factors are those of context and interaction with non-chemosensory modalities. In regard to the latter, an orange drink that is colored orange or yellow will be perceived, respectively, as having a more orange or a more lemony taste. Also, the way the product is used or consumed plays a role. For instance, depending on the quantity of detergent that is put into a washing machine, the smell of the laundry will be more or less intense and certain fragrance notes may become masked by others. Therefore not only the intensity of the sensation but also the sensory profile will be impacted. Frequently a “magic moment” occurs when a fragrance is most salient and its benefit is most expected. For example, such a moment can occur when the detergent is poured, when the laundry is removed from the machine, when the laundry is hung, or when the clothes are worn. Such moments technically refer to different “life-stages” of the fragrance and correspond to different notes being released.

Idiosyncratic factors further complicate the matter. For example, skin type, diet, medications, pigmentation of the skin, and even mood can influence how a scent will react with body chemistry, thereby impacting its sensory performance. Such complexity is challenging for the chemosensory scientist and has led the flavor industry in particular to focus on sensations beyond the strictly olfactory or gustatory. The need for such a focus became clear when developing formulations that eliminated or greatly reduced the amount of sugar, salt, fat, and monosodium glutamate (MSG) in the final product. For example, removing sugar not only influences the perception of sweetness, but can modify the flavor profile, its overall intensity, and the mouth-feel perception. Sugar generates salivation and mouth-filling sensations that must be added back in a sugar-free product. Also, most non-sugar sweeteners can generate, at least in some people, “off-notes,” that is, undesired aromatic sensations, mouth feels, and distorted

taste sensations. Aspartame, for example, can generate bitterness, metallic taste, and a mouth-drying sensation.

## 48.5 MEETING MARKET ASSESSMENTS OF CONSUMER WANTS AND NEEDS

Before starting the development process for creating a new flavor or fragrance, it is often of great strategic value to characterize the current market landscape for a product category by describing how products are being used and perceived by consumers. Indeed, it helps to know what kind of scented or flavored products consumers are exposed to, most familiar with, and accept – factors that help to identify opportunities for new products rooted in chemosensory trends and directions. As a result of such insight, a consumer goods company may initiate a me-too strategy into an existing market or develop an entirely new product and new market.

Such “preliminary research” helps to understand critical benchmarks in the consumer’s mind, such as the collection of percepts that have been generated over time and that are associated to concepts. We know for instance that consumers from different cultural backgrounds and personal experiences will not expect the same type of flavor from a chicken bouillon. In some countries, for example, consumers expect and prefer a boiled chicken taste enriched with spices, whereas in others their expectation and focus is on a dominant roasted chicken taste with an overlay of herbs. This is due partly to culinary history and partly to the types of products present in their marketplace. Therefore, a possible way to approach the internal benchmark of consumers is to look not only at local market products but also at the products to which consumers are culturally and traditionally exposed. The same applies to fragranced products, given that smell is firmly anchored in culture. From an olfactory standpoint, childhood concepts are driven by baby care products with different culturally specific references and percepts. In the United States, these evocations are triggered by floral aldehydic powdery notes while in France they are triggered by musky orange blossom ones.

Clearly, an end product has to be aligned with consumer needs, especially in the affective dimension. Different flavors and fragrances will evoke different feelings and are therefore context and product specific. For instance, lavender notes, which have been shown to have a calming effect on people, should, *a priori*, not be dominant for a product that is positioned as being stimulating and exciting. Although some associations between affect and flavor or fragrance notes are known, most have yet to be discovered and are being explored proactively by industry. This second aspect of creation is definitely the main one that is given consideration when a perfume is being developed. Indeed, briefs provided to perfumers by cosmetic

companies are generally not defined in terms of sensory characteristics, but rather in affective and conceptual terms. For instance, a perfume brief may include requirements for “femininity and elegance, echoes with the fashion, food and life style from Northern Italy, and must appeal to modern and sparkling women”. This description is stated at the affective and conceptual levels to guide the types of notes that will be most likely to meet customer expectations. Finally, measuring the olfactory and taste perceptual elements of a finished product over time not only ensures that this product meets current consumer expectations, but also provides a perspective for how long the product will continue to be viable in the market.

In flavors more than in fragrances, consumers generally have sensory expectations linked to natural products or existing food benchmarks on the market. It is important for the industry to make sure that the consumers recognize the chemosensory character of the product that is marketed. In other words, the scent of a lavender air freshener should be recognized by the consumer as lavender. But here again the cultural background and the internal benchmarks have to be taken into account as olfactory references for lavender can vary from country to country. Before the industrial revolution, we can assume that the flavor and fragrance concepts were being formed through the exposure to natural and artisanal products. However, with the development of the flavor and fragrance industry, consumers are increasingly exposed to processed products that differ in aroma and flavor from the original products. Therefore, their exposure to such products alters their concepts of what a product should smell or taste like. For example, grenadine syrup, very famous in France, was originally made of pomegranate's pulp. However, with its industrialization, its flavor slowly drifted away from the original flavor and is now a mix of red fruits (often raspberry) and vanilla. Although it is still called grenadine syrup, its flavor is nothing like it was decades ago and today's consumers have an expectation of what an “original” grenadine syrup should taste like that is different from yesterday's consumers. Interestingly, the recent trend of consumers to cook at home, supported by the numerous television shows on cooking, may once again shift flavor concepts towards more natural products.

## 48.6 CONCLUSIONS

A major mission of flavor and fragrance houses is to design novel scents and tastes to satisfy consumer demands. It is therefore critical to understand consumer expectations and experiences. In this chapter we have shown how artisans create or duplicate flavors and fragrances, and have described a number of procedures by which product formulations and end-stage are compared and evaluated.

We have pointed out that there is much more to the art of understanding the influences of chemosensory creations on the behavior of customers than simply smells or tastes. Although traditionally hedonic factors dominated the focus of our industry, modern research is moving towards a more holistic perspective on product development. Thus, in addition to understanding hedonics, understanding emotional and conceptual processes of the consumer are now viewed as critical for the strategic positioning of products in the marketplace.

## The Smell and Taste of Public Drinking Water

GARY A. BURLINGAME and RICHARD L. DOTY

### 49.1 INTRODUCTION

The use of the human senses to distinguish good water from bad, such as by taste, smell, and appearance, is a basic means of self preservation. Aside from drinking water, natural water sources can also become aesthetically unpleasant, limiting their value in supporting recreation and development. Indeed, the whole water cycle is impacted by the sensory characteristics of the water.

Surprisingly, it was not until the late 1800s that serious scientific inquiry was made as to associations between human sensory observations and the safety of water (Corbin, 1986). While it is true that bad smelling and tasting water can be related to deadly germs or chemical contaminants, it should be pointed out that odorless and good tasting water can be teaming with pathogens or dangerous chemicals. Hence, the senses are not always a failsafe marker for the safety of water, as will be pointed out later in this chapter.

As chemical and biological tests of the constituents of water were being applied during this early period, human sensory techniques were also being developed to categorize the pollution found in rivers and waterways. Smells emanating from such sources of water were assessed and categorized under both hot and cold testing conditions (Whipple, Fair, and Whipple, 1948). Lists of odor descriptors were developed and included, among others, the following descriptors: aromatic, cucumber, chlorinous, earthy, fishy, grassy, geranium, medicinal, moldy, musty, nasturtium, oily, pigpen, sweetish, hydrogen sulfide, vegetable, and violet. It was during this early period that it was discovered that while some odors were found to be specifically produced by anaerobic conditions and waste

discharges, others came from natural organic matter and nuisance algal growth.

As the Germ Theory of Disease fought its way into acceptance in the late 1800s, the origins of waterborne diseases such as typhoid and cholera were being discovered and water treatment movements began in earnest. Filtration and chlorination became the standard means for treating water for potable use. Indeed, the use of chlorine was hailed as one of the greatest public health benefits of the 20th century (Friedman, 1998). Whereas filtration had a neutral or positive effect on the flavor of treated water, chlorination eliminated some odors, made others worse, such as in the formation of chlorophenols, and contributed to the formation of a distinct flavor of public drinking water with its chlorine smell.

In modern times, a safe water supply is provided through a multiple barrier concept – a series of strategies for treating and protecting the quality of the water from the source of origin (reservoir, river, spring, well), through treatment, and on to the consumer's point of use. The goal of treatment is to eliminate microbial pathogens, control nuisances, and produce biologically and chemically stable potable water. Most drinking water systems obtain their water supply from ground water which often needs little if any treatment. When water treatment is needed, such as for turning river or reservoir water into drinking water, several processes are typically used to achieve these ends. These include (a) pre-sedimentation or the settling out of sediment, (b) pre-oxidation for minimizing algae, iron, and manganese contaminants by the use, for example, of chlorine, chlorine dioxide, and potassium permanganate, (c) oxidation to produce chemically stable water, (d) disinfection to remove pathogens, (e) coagulation, flocculation,

and sedimentation to remove suspended matter using such additives as ferric chloride, alum, polymers, and lime, (f) fine particulate removal by filtration using such media as sand and anthracite, and (g) post-treatment or the addition of chemicals such as fluoride, corrosion-control phosphates, and ammonia to form a chloramine residual. Advances to oxidation and disinfection have included exposure to ozone and ultraviolet light with or without the addition of hydrogen peroxide. Sophisticated membrane technology is now available for the physical removal of microorganisms and other contaminants, and granular activated carbon filters are employed to remove organic chemical contaminants (Burlingame, 2011; Mackey, 2012).

The fallibility of relying solely on one's senses in accepting the safety of drinking water is illustrated by a well-studied waterborne disease outbreak in Walkerton, Ontario (Parr, 2005). During this outbreak in a groundwater system, seven people died from *E. coli* O157:H7 and half the town's population experienced varying levels of illness. The basis of this problem was contamination of the groundwater by surface runoff from a nearby farm. Although a number of factors contributed to this disaster, the flavor of the water was an important player. The town's people had resisted adding chlorine to their public water supply because they did not want to taste a chlorine residual. Since their groundwater looked and tasted good, it was erroneously assumed to be safe to drink. In North America, most public water systems are small in size and rely on groundwater sources. In the United States, as of 2009, these systems are now regulated under the Environmental Protection Agency's (EPA) Ground Water Rule to prevent microbial contamination of the drinking water.

The impact of post-treatment processes and materials to which water becomes exposed, such as pipes and linings, have been a concern (Khiari, 2002). Treated drinking water has a shelf life and its quality is affected by the materials to which it has been exposed (e.g., iron, copper, plastic, epoxy and bitumen) and by ongoing chemical reactions and biological activity as the water travels from the treatment plant to the consumer's faucet (Khiari et al., 2002; Malleret et al., 2002; Andreas and Gunten, 2009). A common customer complaint of public drinking water comes from iron release or rusty water from systems that use iron water mains, reflecting soluble iron that produces a metallic flavor (Mirlohi et al., 2011). Complaints also arise, although less commonly, from other types of pipes through which water travels including copper, which can occur in drinking water in a reduced or oxidized state in the form of cuprous or cupric ions. Much of the United States' indoor plumbing consists of copper tubing or pipe. Concern about the health effects of too much copper exposure led to a corrosion-based standard for copper by the EPA at 1.3 mg/L. The standard for preventing staining and off tastes was set slightly lower at 1 mg/L.

It is now apparent that copper can produce a copper-like odor or metallic flavor via chemical reactions in the mouth and nasal cavity. For example, the reduced form of copper ions in the presence of oxygen causes lipid oxidation reactions that produce such odorous compounds as carbonyls, resulting in metallic-like sensations (Dietrich et al., 2008). As a result, although individual sensitivities vary, retronasal detection of off flavors can occur for copper at levels below the USEPA standard of 1 mg/L.

In light of such issues, modern water utility customers have choices. They can avoid tap water altogether and use bottled water for drinking. However, the cost of bottled water over tap water is very significant. Customers can also install point-of-use and point-of-entry treatment systems to provide additional treatment to remove chemicals and bacteria, as well as to polish off the flavor of the water. Systems are certified and tested, so most consumers can become aware of their capabilities for filtering and improving the water's taste (see Consumer Reports, 2012). The attitudes that drive customers to make such choices have been investigated in numerous scientific studies, a number by public utilities that need to maintain the public's trust and support (Mackey et al., 2003). Included in such attitudes is the sensory experience of bathing in tap water, as off odors can also affect that experience (Omur-Ozbek et al., 2011).

Worldwide, the taste and smell of drinking water remains an important issue affecting the public's acceptance of water and the understanding of its safety. The World Health Organization's guideline states that an acceptable drinking water should be free of tastes and odors that would be objectionable to the majority of consumers who rely on its use (World Health Organization, 2008). As developing countries establish public water systems and safe water supplies, there will be increased demand for acceptable aesthetic water quality. This is a logical progression that has occurred throughout history, as exemplified by the Romans and other great civilizations.

## 49.2 DEVELOPING THE MEANS TO DESCRIBE THE TASTE AND ODOR OF WATER

In the 1980s, a resurgence of research brought better science to the assessment of drinking water flavor (Suffet et al., 1988; Desrochers, 2008). Flavor Profile Analysis (FPA) (American Public Health Association, 2007b), which was developed as the Flavor Profile Method in the 1940s by Arthur D. Little, Inc. for application in the commercial food industry, was adapted for assessing drinking water, as were other techniques from this industry (Meilgaard et al., 1987; Lawless and Heymann, 1998). Among tests already developed within the water industry were the

Threshold Odor Number and the Flavor Threshold Test (American Public Health Association, 2007b). During this exciting period, trained sensory panels with outstanding chemosensory capabilities (see Smith et al., 1993) were formed and reliably catalogued the flavors of water and the chemicals that give rise to off tastes and odors (Bartels et al., 1986). A fundamental understanding was made as to how flavor quality and its descriptors vary as odorant concentration is altered logarithmically according to the Weber-Fechner law (Suffet et al., 1995; Rashash et al., 1997). Attempts were made to develop the sniffing of gas chromatography effluents as a method for identifying the chemical compounds that give rise to odors in water (Khiari et al., 1992). By the year 2000, most or all possible tastes and smells in public drinking water had been identified by sensory and chemical means, and the causes explained (Burlingame, 2011). Flavor wheels for water (Suffet et al., 1999), as well as wastewater (Burlingame et al., 2004), were developed and refined, as has been the practice in the wine and beer industries. Such descriptors have made it possible to develop internationally useful taste and odor profiles. Importantly, sensory panels were developed within a number of companies to identify and classify olfactory and taste contaminants from sectors of water distribution systems. In some cases, trained panel members had been shown to outperform even blind persons on standardized taste and smell tests (Smith et al., 1993).

In the United States and many other countries, a measureable residual of chlorine or chloramine is required for the safety of the drinking water. EPA regulations require that the total chlorine levels range between 0.2 mg/L and 4 mg/L. As a result, public drinking water can have a “chlorinous” flavor or smell. The impact of the chlorine residual on public perceptions and attitudes has been the focus of a number of research studies (Mackey et al., 2004). In both the United States and in numerous countries in Europe, the flavor of public drinking water can now be described by common terms, including such descriptors as chlorinous, earthy, and musty with possible off flavors such as metallic, medicinal, plastic, decaying vegetation, sulfidic, grassy, fishy, cucumber, chemical, and solventy. The odor intensity of these descriptions can be quantified by standardized intensity scales. For most waters the ratings range from very weak to moderate in strength. Most recently, the influences of retronal smell on the flavor experiences of water consumers have become more apparent and undoubtedly will continue to receive continued scientific attention (Dietrich, 2009; Omur-Ozbek and Dietrich, 2011).

Historically, scientists within the water industry largely ignored actual tastes in water, being more focused on its mineral content, as measured by total dissolved solids (Bruvold and Daniels, 1990). This reflected, in part, the fact that people rarely complained about the sweetness, sourness, or bitterness of water. The exception was salty

taste, which often arose in geographical areas where salt had intruded into wells or where source water contained high levels of total dissolved solids. Nevertheless, a comprehensive review of the taste of water was published in 2007 (Burlingame et al., 2007).

### 49.3 THE GLOBAL IMPACT OF ALGAE

During the 1700s and 1800s in Europe, major urban rivers such as the Thames and the Seine smelled quite bad (Corbin, 1986). During the late 1800s and early 1900s, rivers in America followed suit. Water supplies for cities, such as Philadelphia, were selected in part based on how they smelled. Many people preferred their private wells because the wells produced clear and cool water even though the wells were often, especially in populated cities, contaminated by cesspools. The impact of source water characteristics on drinking water quality is still a major focus of research (Suffet et al., 1995; Taylor et al., 2006). Even today, many countries are struggling with the pollution of their surface and ground water supplies. In China, for example, source water pollution and surface runoff have created significant taste and odor problems for drinking water supplies (Yu et al., 2009). Earthy, musty, septic, swampy odors have been reported to make up the smell of the water due to such odorous chemicals as heptanal, benzaldehyde, dimethyl trisulfide, 1-octen-3-ol, benzene acetaldehyde, bis(2-chloroisopropyl) ether, 2-methylisoborneol, 1,10-dimethyl-9-decalol, and  $\beta$ -ionone.

The two most significant odorous chemicals in surface waters worldwide are metabolic byproducts of cyanobacteria, also known as blue-green algae: 2-methylisoborneol (MIB) and 4,8a-dimethyl-decahydronaphthalen-4a-ol, which is commonly known as geosmin (Jüttner and Watson, 2007). These two chemicals impart an earthy, musty smell to water that is difficult to remove. At the levels typically found in water supplies, these agents have no known adverse health effects. They can be detected by olfaction at levels as low as 2–5 ng/L. Moreover, their enantiomers can have different sensory properties. Geosmin, like MIB, can significantly impact a drinking water utility and its customers (Burlingame et al., 1986).

The same odorous chemicals produced by cyanobacteria can be produced by common inhabitants of the soil and aquatic environment known as actinomycetes (Zaitlin and Watson, 2006). The actinomycetes can be cultured and shown to be producers of the odors. They can be isolated from the water environment, but it has been difficult to correlate their detection by culture methods with the presence of earthy-musty odors.

Algal blooms are one cause of surface scum and offensive odors that negatively affect the recreational

uses of water. Aquaculture or the growing of fish for food in ponds can be greatly affected by algal products, including geosmin and MIB, which can taint the taste of fish. The potential for algae to contribute odorous chemicals to water is significant; algae can produce odorous compounds during their growth phase and during their death phase. Algal products can be emitted to the surrounding water or contained within the cells until the cells are lysed, as occurs during water treatment. The list of possible chemicals other than geosmin and MIB that algae can produce is enormous, and include dimethylsulfide, dimethyldisulfide, dimethyltrisulfide, hydrogen sulfide, heptanal, hexanal, pentanal, trans-2-nonenal, trans-hexenal, cis-3-hexen-1-ol, trans-2-cis-6-nonadienal, trimethylamine,  $\beta$ -ionone, 3-methyl butanal, limonene,  $\beta$ -cyclocitral, 3-methoxy-2-isopropylpyrazine and 2-isobutyl-3-methoxypyrazine (Watson, 2010). Reports of taste-and-odor episodes in public water systems have increased over the past 20 years. One possible cause is climate change and an increase in droughts. Even in the aftermath of wildfires, there have been taste-and-odor problems. However, there is no global system for tracking and reporting taste-and-odor episodes in public water supplies.

Water utility companies can no longer claim that algae-caused tastes and odors in drinking water have no associated health risks. In 2010, the United States Geological Survey (USGS), a scientific agency of the federal government, issued a statement indicating that “If Water Looks and Smells Bad, It May Be Toxic” (Graham et al., 2010). They went on to say, “Earthy or musty odors, along with visual evidence of blue-green algae, also known as cyanobacteria, may serve as a warning that harmful cyanotoxins are present in lakes or reservoirs.” Importantly, the same cyanobacteria that produce earthy and musty smelling compounds can produce non-odorous toxins. Thus, risk communication has become a rapidly growing field of study to help water utilities better communicate to the public the issue of drinking water safety. As a result, water systems have had to develop better public communication procedures in this age of social networking (Pollard et al., 2009). Information and mis-information gets out quite rapidly and extensively through blogs, twitter, text messaging and the internet. The means by which modern water utilities reach out to their customers include web sites, call centers, press releases, media interviews, newspaper notices, direct mailings, and consumer confidence reports.

#### 49.4 PUBLIC ACCEPTABILITY OF DRINKING WATER FLAVOR

Taste and odor problems in public water supplies are often short-lived and episodic in nature, such as from

an industrial spill or from a seasonal bloom of algae in a water supply reservoir. This occurrence characteristic, combined with a lack of regulatory standards, has allowed water utilities to defer applying long term solutions. As a result, customer complaints about the taste and smell of tap water have often been the main motivator for water utilities to take action to treat water to remove nuisance tastes and odors. Customers are sensitive to changes in the flavor of their tap water, but they are not reliable in their descriptions of those changes. Customers tend to make logical associations rather than relying on their sensory judgments, which can make it more difficult to track and respond to customer complaints. Since public perception and attitudes are not always accurately displayed through customer complaints, water companies have developed tools to better track and understand the attitudes of their customers (Burlingame and Mackey, 2007). This allows them to be certain that they are optimizing the selection and funding of taste and odor control strategies.

One approach to control the taste and smell of drinking water is through a quality control program that assesses the processes and controls at a water utility. Benchmarks are in place by which public water systems can evaluate their capabilities to control drinking water taste and odor (McGuire et al., 2004). Such quality programs have been gaining broader acceptance in the drinking water industry worldwide, as embodied in water safety plans (World Health Organization, 2008). Water safety plans utilize a comprehensive risk assessment and risk management approach that covers all the steps involved in providing a high quality drinking water supply.

Since taste- and-odor causing chemicals at the levels found in drinking water are not often directly linked to public health effects, there are no federal requirements for controlling taste and odor in public water systems. In the 1970s, Secondary Maximum Contaminant Levels (SMCLs) were established by the USEPA trans-2-cis-6-nonadienal, to assist public water systems in managing aesthetic water quality (USEPA, 1992). These guidelines cover the nuisance effects from taste, smell, color, and staining, as well as foaming and scale development. They also include guidelines for chloride, copper, corrosivity, foaming agents, iron, manganese, pH, sulfate, total dissolved solids and zinc. The smell of water is addressed by a Threshold Odor Number (TON) – a measure of the dilution needed to give water a just perceptible smell. However, the widely employed TON method is often misapplied at water utilities, such as by abbreviating the technique to make it simpler to perform (Dietrich et al., 2004). The SMCL guidelines that were developed during the 1970s are outdated and clearly in need of revision (Dietrich and Burlingame, 2015).

## 49.5 MTBE: A CASE STUDY OF ORGANOLEPTIC LIMITATIONS

Failed attempts to set national standards based on population-based odor thresholds are highlighted by the ongoing legal battle over methyl tertiary butyl ether (MTBE) contamination of groundwater. MTBE was added to gasoline in the United States beginning in the 1970s as a replacement for lead (Carter et al., 2006). Leaking underground gasoline storage tanks have since contaminated private and public ground water supplies with MTBE, an agent which leaches through soil and is not easily contained. MTBE is often said to have a sweet chemical turpentine-like odor, although a range of other odor qualities have been reported, including "chemical," "cleaning fluid," "ether," "gas," "gasoline," "paint," "paint thinner," "shellac," "stale garbage," "varnish" and, in the case of taste, "bitter" (e.g., Young et al., 1996). Attempts have been made to establish a population's odor threshold concentration as a standard for treatment and for legal cases (Stocking et al., 2001). Unfortunately, the odor threshold measurement methodology that has been generally employed, most notably ASTM E679 (ASTM, 1997, 2004), has significant limitations when used in attempts to set regulatory standards for MTBE.

As noted in Chapter 11, most psychophysical studies seek to determine individual odor threshold values. Clinically, such values are generally compared to normative data to establish whether a person's ability is normal or not. Based on a limited number of determinations of individual odor thresholds, some of which are methodologically flawed (e.g., failures to employ forced-choice procedures and epidemiological sampling procedures), the water industry has attempted to establish "group thresholds," i.e., concentrations of a contaminant that can be detected by some proportion of a target population of consumers that can be used for regulatory purposes. Unfortunately, practical and economic considerations often make it impossible to totally eliminate off flavors in water and some subset of the population can detect contaminants that are indiscernible to most people. The fly in the ointment is determining the contamination level that protects most members of the consuming public from perceiving off smells in water, yet does so at a cost that minimizes customer costs or, in some cases, taxpayer burden. There are advocates within the water industry for using a 50% group threshold, that is, a threshold value that can be detected by half of the population (e.g., Stocking et al., 2001). However, the acceptance of such a threshold would imply, by definition, that half of the consuming population would be able to discern the contaminant in their water at some level of intensity. It would seem prudent to set a more conservative standard in order to minimize objections of

consumers to the acceptability and safety of their drinking water.

In the largest study of its type to date, Stocking et al. (2001) sought to determine the 50% population olfactory threshold for MTBE in water for "consumers," i.e., untrained panel members. Individual thresholds were computed for 57 subjects using a concentration series that employed an odorant and two blanks on each trial. The task was to discern which of the samples was contaminated. Eight concentrations of MTBE were evaluated, beginning with the lowest concentration (ascending method of limits procedure; Chapter 11). This approach has been codified as the ASTM E679 procedure (ASTM, 1997, 2004) and was used by Stocking et al. to argue that an appropriate standard for regulating MTBE should be 15 µg/L (15 ppb).

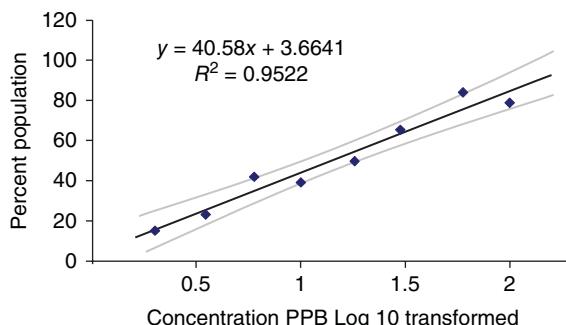

Analysis of the raw data of this study (Table 49.1) shows that nearly 20% of the subjects, that is, subject #'s 13, 14, 19, 21, 22, 24, 37, 41, 52 and 53, could detect the lowest MTBE concentration that was presented, that is, 2 µg/L. Hence, their actual individual odor thresholds fell below this low concentration. The ASTM E679 procedure requires that the stimuli to be presented fall below the lowest threshold of the subjects, so this procedure was not strictly followed in this study. On the other end of the scale, 14% of the subjects (#'s 12, 16, 20, 28, 31, 34, 35, and 47) could not detect the highest concentration that was presented, again resulting in inaccurate threshold estimates and violating the requirements of the ASTM E679 procedure.

Aside from these study-specific issues is the fact that thresholds based upon single ascending series trials are highly unreliable, throwing into question the accuracy of the ASTM E679 threshold determinations in the first place (Chapter 11). In the three-choice paradigm, correct responses can occur by chance a third of the time on a given trial. Two successive correct responses, which were used as a primary criterion for determining the detection thresholds of the Stocking et al. (2001) study, would be expected to occur by chance 1/9th of the time (i.e., 1/3 x 1/3).

A preferred approach for assessing group sensitivity from data such as that collected by Stocking et al. would be one that takes into account all of the data. For example, the percent of the group that reports detecting the stimulus can be calculated at each concentration, rather than relying on the unreliable single point estimates of each participant's threshold. A correction for guessing can also be applied, such as the application of Abbott's formula:  $P_{adjusted} = (P_{observed} - P_{chance})/1 - P_{chance}$ . When this approach is taken, ~15% of the panelists of the Stocking et al. study were able to detect the 2 µg/L (2 ppb) and ~25% the 3.5 µg/L concentration of MTBE. The 6 µg/L and the 10 µg/L MTBE concentrations were discernable by about 40% of the study group.

**Table 49.1** Raw data presented as Table 2 in Stocking et al. (2001). Shaded areas represent the transition points from detecting (x) and not detecting (o) the vapor phase of the MTBE laden aqueous solution. The trials began at the lowest concentration (2 µg/L) and increased in concentration to the highest concentration (100 µg/L). Gray boxes indicate data used by Stocking et al. to calculate threshold values.

Since the relationship between the ability to detect chemical stimuli and their concentration is often well described by a log linear function, the second author of this chapter and a colleague modeled the Stocking et al. data of Table 49.1 using linear regression. A plot of  $\log_{10}$  concentration vs. the percent of subjects detecting MTBE (chance corrected by Abbott's formula) of these data is shown in Figure 49.1 (similar findings were found when the MTBE concentration is expressed in natural logs or when logistic regression is employed). Note the strong linear association between these measures, as indicated by the high  $R^2$  value, an index of the amount of variance that is accounted for in the measurements. The antilog of the concentration values provides the concentration in  $\mu\text{g/L}$  (ppb). In these analyses, 10% of the study population is estimated to be able to detect MTBE at levels ranging from 1–2  $\mu\text{g/L}$ ; 15% at 2–3  $\mu\text{g/L}$ ; and 50% at 13–14  $\mu\text{g/L}$ .

This approach results in a different conclusion than arrived at by Stocking et al. who found 15  $\mu\text{g/L}$  to be a reasonable value for "establishing the federal SMCL for MTBE and other organic chemicals in drinking water" (p. 95). However, is it acceptable that 50% of a population can still detect a contaminant in their tap water when they are told that the water is safe to drink? Some might argue that while an individual can detect the presence of

something in the water by smell, they cannot determine whether the sensation is unpleasant or alarming. From this perspective, the detection threshold may be overly conservative as an index of consumer acceptability. Such questions have not received adequate study.

A subsequent study that followed the same procedures as the Stocking et al. study was performed in England in an effort to replicate the 15  $\mu\text{g/L}$  threshold value in a different group of consumers (Campden, 2003). With minor exceptions, the same general conditions applied; that is, a similar number of men and women, three general age groups, and the testing of consumers rather than trained panel members. If one accepts the proposition that the Stocking et al. (2001) and the Campden et al. (2003) studies are two samples of the same general population, then their data can be combined into a single sample of 112 subjects. A summary of the combined data is shown in Table 49.2. As apparent from this table, the same conclusions are apparent when the sample size is essentially doubled. Thus, ~13% of the combined study group detected 2  $\mu\text{g/L}$  of MTBE. When linear regression was applied to the chance corrected and combined data (Figure 49.2), 10% of the study population detected MTBE in the 1–2  $\mu\text{g/L}$  range.

The aforementioned studies represent the largest and most technically sophisticated studies to examine MTBE

**Figure 49.2** Least squares regression analysis of percent of population detecting MTBE across concentrations presented in the combined data of Stocking et al. (2001) and Campden et al. (2003). Note goodness-of-fit  $R^2$  value of 0.93.

thresholds in the general population. Despite this fact, however, methodological considerations limit the degree to which these can be relied upon in establishing solid regulatory standards. Importantly, while Stocking et al. have concluded that 15 µg/L is an appropriate value for establishing a regulatory threshold for MTBE, the fact that their own data suggest that 10–15% of their subjects were able to detect MTBE by smell at 2 µg/L or less make this conclusion debatable. This is especially true when the odor quality of MTBE (e.g., paint thinner) would denote to the consumer that the water is unsafe and contains chemical contamination.

It is unfortunate that measuring taste and odor thresholds in the general population are expensive and time consuming. Importantly, the impact of the background matrix on the odor threshold has not been adequately explored. For example, the odor threshold can be influenced by the presence or absence of free chlorine residual in the water as well as the water's temperature. Considering the difficulty with setting a standard for MTBE, as well as other chemicals that can impact the acceptability of drinking water, the search continues for standards for the taste and odor quality of water (AWWA Water Quality Division Taste and Odor Committee, 2002). To date, no standard test has been developed by which to regulate whether drinking water has an acceptable taste or odor quality or meets public acceptance. Public investment in well-performed chemosensory studies employing larger groups of subjects who are representative of the population at large would avert much debate and cost in the litigation arena, serving the general public at large.

## 49.6 CONCLUSIONS

The human senses of taste and smell have been successfully used to improve the quality of drinking water. The first author has used his own sense of smell to track an algae-produced cucumber-like odor over 200 miles upriver

to its source in a reservoir (Burlingame et al., 1992), to track an off flavor to an illegal, waste cutting oil dump site, to determine that a pipe joint lubricant was causing customer complaints (Burlingame et al., 1994), to determine that the leaching of metals in household plumbing was causing one particular customer to persistently complain about her tap water, and to find the cause of a canned-corn-like malodor at a wastewater treatment plant that could not be determined by chemical testing (Burlingame, 2009a; Cheng et al., 2009). This would not have been possible without a good understanding of the instrument of detection (the human sensory system) and the data it produces. This understanding comes from the many diverse fields of study on the human senses and their application such as provided in this book. For example, the University of Pennsylvania Smell Identification Test (UPSiT; see Chapter 11), which is used for medical diagnoses and research, has been used to identify panelists who have a reduced smell ability. Such persons may explain anomalies in research data during the testing of water samples and some human failures in detecting off flavors that require treatment.

Unlike foods and non-water beverages, drinking water should not have any noticeable taste or smell (Burlingame, 2009b). It should produce a refreshing and pure sensation. However, good tasting water is not chemically pure water, but water that contains a careful blend of minerals at a neutral pH and cool temperature. Nonetheless, in many places where a public drinking water is provided, the consumers become accustomed to a chlorinous flavor in the water because the safety of the water supply is maintained by the addition of chlorine.

Off flavors can have a significant political and economic impact on the public's acceptability of public drinking water. While most of the chemical and biological causes of off flavors in drinking water have been identified, and while sensory and analytical tests are being used to monitor the flavor quality of drinking water, there remains a need for national and international standards for chemicals that cause off flavors in water or for the proper

management of the aesthetic quality of drinking water. This was recently highlighted by the January 2014 spill of crude methylcyclohexanemethanol (MCHM) into the Elk River just upstream of a drinking water treatment plant in West Virginia. This spill resulted in a do-not-use order for about 300,000 water customers, a state-of-emergency, and the President declaring the area a federal disaster (Rosen et al., 2014). When analytical testing of the drinking water produced test results that allowed the do-not-use order to be lifted, the customers could still detect the sharp licorice smell of MCHM in their tap water. Sensory testing revealed that the odor threshold was below the analytical detection limit and the limit of health concern (McGuire et al., 2014). The contaminant's odor became the leading factor for guaranteeing the water's safety. How could the public trust the pronouncements that the water was safe when they still could detect the MCHM telltale licorice smell in their homes? As a result, public and private utilities that supply drinking water need to effectively communicate with their customers about the taste and odor quality of the tap water. Customers are the most effective, though not highly accurate, detectors of changes in tap water taste and smell. Customers provide a valuable service to a water utility company in not only ensuring that water system problems are quickly responded to when they inevitably arise, but in helping to develop strategies to be proactive in preventing problems before they occur (Welton et al., 2007).

## Trigeminal Chemesthesia

J. ENRIQUE COMETTO-MUÑIZ and CHRISTOPHER SIMONS

### 50.1 INTRODUCTION

In addition to the classical modalities of smell (olfaction) and taste (gustation), all body mucosae can respond directly to chemicals in our environment. This broadly distributed mucosal chemosensitivity was originally labeled the “common chemical sense” (Parker, 1912). In fact, such chemical sensitivity is also present in the skin, under the epidermis (Keele, 1962). The name remained until not long ago (Cain, 1981; Silver, 1987) and it is still occasionally used. More recently, this chemosensory modality is referred to as “chemesthesia” or “chemesthesia,” in analogy to “somesthesia,” since one can think of it as “chemically-induced somesthesia” (Green and Lawless, 1991; Green et al., 1990b). More simply, chemesthesia conveys the concept of chemical “feel” for sensations that are neither odors nor tastes (Bryant and Silver, 2000; Green et al., 1990a). Mucosal chemesthetic sensations are usually sharp and/or pungent. They include: prickling, piquancy, stinging, irritation, tingling, freshness, coolness, burning, and the like.

Although, as mentioned, all body mucosae possess chemosensitivity, those most exposed to environmental chemicals are the face mucosae: nasal, ocular, and oral. Early studies already had established that the trigeminal nerve (cranial nerve V, CN V), which provides chemical sensitivity to these three mucosae, is responsible for a variety of physiological responses to chemical irritants (Allen, 1928; 1929a; b; Dawson, 1962; Stone et al., 1966; Stone and Rebert, 1970; Stone et al., 1968; Ulrich et al., 1972). Thus, it is quite appropriate that this chemosensory system is now often referred to as “trigeminal chemoreception” (Cometto-Muñiz et al., 2010; Doty and Cometto-Muñiz, 2003; Doty et al., 2004; Silver and Finger, 2009; Sliver and

Finger, 1991). Previous reviews have described in detail the anatomy and physiology of the trigeminal chemosensory system (Doty and Cometto-Muñiz, 2003; Doty et al., 2004). Briefly, the three branches of the trigeminal nerve – the ophthalmic, the maxillary, and the mandibular – provide the bulk of chemesthetic sensitivity to the ocular, nasal, and oral mucosae. The glossopharyngeal (CN IX) and vagus (CN X) nerves also contribute to chemesthesia in the mouth (posterior tongue) and the nasopharyngeal and pharyngeal (throat) areas. Studies in mice and rats have shown that nasal solitary chemoreceptor cells (SCCs) can contribute to nasal chemesthesia (Finger et al., 2003; Silver and Finger, 2009; Tizzano et al., 2010), although their development and survival does not seem to be dependent on intact trigeminal innervation (Gulbransen et al., 2008a). SCCs express receptor proteins involved in gustatory chemoreception (T1Rs, T2Rs) and, thus, are also related to the sense of taste (Gulbransen et al., 2008b; Ohmoto et al., 2008; Sbarbati et al., 2004; Tizzano et al., 2011). However, expression of these receptors is thought to enable identification of potentially noxious irritants or pathogenic secretions (Tizzano et al., 2010). SCCs, which have also been described in several organs from the digestive and respiratory systems, have been proposed to be part of a diffuse chemosensory system (Osculati et al., 2007; Sbarbati et al., 2010).

In the present chapter we will summarize some important functional properties of the human trigeminal chemosensory system in the nasal, ocular, and oral mucosae. Among others, we will address issues related to candidate molecular receptors for trigeminal chemesthesia, chemesthetic sensitivity (i.e., detection thresholds), structure-activity relationships, detection of chemical mixtures, and temporal properties of trigeminal chemesthetic sensations.

## 50.2 MOLECULAR RECEPTORS FOR TRIGEMINAL CHEMESTHESIS

Chemesthetic sensitivity in the mucosae of the human face (nasal, ocular, and oral) is mediated by C and A<sub>delta</sub> fibers primarily from the trigeminal nerve, although in the case of oral chemesthesia, the glossopharyngeal and vagus nerves also contribute (see reviews in Doty and Cometto-Muñiz, 2003; Doty et al., 2004; Rentmeister-Bryant and Green, 1997). The ion-channels and receptors involved are expressed by a class of peripheral neurons called polymodal nociceptors since they can respond to chemical, thermal, and mechanical stimuli (Belmonte et al., 2004). Some of the channels and receptors found in trigeminal and other sensory neurons are particularly sensitive to one or another prototypical irritant. This is the case, for example, for nicotine (Alimohammadi and Silver, 2000; Thuerauf et al., 2006), capsaicin (Tominaga and Tominaga, 2005), and menthol (Xing et al., 2006). Nevertheless, the ion-channels responding to the last two chemicals are also thermoreceptors that respond to warm/hot and cool/cold temperatures, respectively. In fact, the capsaicin channel not only responds to chemically-related vanilloids (Szallasi and Blumberg, 1999), but also to unrelated VOCs (Silver et al., 2006; Trevisani et al., 2002), to other pungent compounds (Macpherson et al., 2005; McNamara et al., 2005) and even to inorganic volatiles (Trevisani et al., 2005). It has also been shown that menthol (Macpherson et al., 2006) and other pungent substances (Bautista et al., 2005; Jordt et al., 2004) interact with more than one type of channel. Even the nicotinic receptor is modulated by VOCs such as homologous alcohols (Godden et al., 2001). In turn, VOCs can stimulate trigeminal neurons that are insensitive to cooling and capsaicin, suggesting that they can activate other mechanism(s) and receptors (Inoue and Bryant, 2005). VOCs that are reactive towards tissue can produce nociception indirectly by damaging cells and producing the release of intracellular mediators like K<sup>+</sup>, H<sup>+</sup>, ATP, and glutamate, among others, which, in turn, would activate nociceptors (Garle and Fry, 2003; Lee et al., 2005; Moalem et al., 2005; Vaughan et al., 2006; Wood and Docherty, 1997).

Among the large family of transient receptor potential (TRP) ion-channels that includes the capsaicin (TRPV1) and menthol (TRPM8) receptors (Appendino et al., 2008; Inoue, 2005; Kim and Baraniuk, 2007; Woodard et al., 2007), the TRPA1 nociceptor has been implicated in the chemesthetic response to environmental irritants (Bautista et al., 2006; Macpherson et al., 2007b; McNamara et al., 2007) and even to CO<sub>2</sub> (Wang et al., 2010), as well as to weak organic acids (Wang et al., 2011). The TRPM5 channel has also been implicated in responses to irritants (Lin et al., 2008). At least two mechanisms have been suggested for the activation of TRPA1 by ligands (Peterlin

et al., 2007). Under one mechanism, compounds such as eugenol, carvacrol, and methyl salicylate would act via a classical binding pocket (Xu et al., 2006). Under a second mechanism, electrophilic ligands such as acrolein, trans-2-pentanal, and trans-cinnamaldehyde would act by a covalent modification of thiol (cysteine) and, less likely (LoPachin et al., 2008), amine groups in the ion-channel protein (Hinman et al., 2006; Macpherson et al., 2007a). A recent review has described the molecular mechanisms of such reactions (LoPachin et al., 2008). In fact, the TRPV1 nociceptor has also been found to be activated by covalent modification of cysteine residues (Salazar et al., 2008). These studies explored the molecular/cellular and animal behavioral aspects of chemesthesia. The general picture emerging from them reflects a complex interplay of many factors and variables (acidity, temperature, release of endogenous mediators) modulating the response of any single TRP channel. Added to this is the generally broad chemical spectrum of ligands and modulators acting on any given receptor. As the chemesthetic neural message travels towards higher levels of the nervous system, convergence of input from different TRP channels (Zanotto et al., 2007) and other modulatory influences (Omote et al., 1998; Waters and Lumb, 2008) are likely to occur. In view of such complex array of factors, structure-activity approaches to trigeminal chemesthesia that rely on selective physicochemical properties of irritants governing their transport from the gas phase to a receptor biophase (or area) constitute very useful tools to describe, model, and predict human irritation potency from VOCs as measured psychophysically (Abraham et al., 2010b; Abraham et al., 2010c).

## 50.3 NASAL AND OCULAR CHEMESTHESIS

### 50.3.1 Separation of Nasal Trigeminal Chemosensitivity from Olfactory Sensitivity

The great majority of airborne chemicals that we detect with our noses are able to produce both an olfactory and a trigeminal response (Cain, 1974; 1976). That is, they can elicit both an odor and a chemesthetic (i.e., pungent or irritative) sensation (Doty et al., 1978). As a rule, virtually all these volatiles are initially detected by smell and, if their vapor concentration keeps increasing, there is a level where they also begin to evoke nasal chemesthesia (Doty, 1975). This presents a challenge if one wishes to measure nasal pungency thresholds devoid of olfactory biases, for example by using force-choice procedures against blanks. In other words, for most chemicals, a force-choice response between a stimulus (irritant) and a blank (plain

air) will be biased since the participant will easily detect the stimulus by its odor, and will do so at concentrations well below those necessary to barely elicit any trigeminal chemesthetic sensation (i.e., to reach the vapor's pungency threshold). To address this situation, investigators have employed two main strategies. The first is to measure nasal pungency (i.e., chemesthetic) thresholds in subjects lacking a sense of smell (called anosmics) but otherwise healthy, thus avoiding odor biases (Cometto-Muñiz and Cain, 1990). The second is to measure nasal localization (or lateralization) thresholds, rather than detection thresholds, where subjects seek to localize which nostril (left or right) received a puff of irritant vapor when the other nostril simultaneously receives a puff of plain air (Cometto-Muñiz and Cain, 1998; Wysocki et al., 1997). Findings obtained using these two strategies are discussed in the next section.

### 50.3.2 Nasal Trigeminal Chemosensitivity as Reflected by Nasal Pungency Thresholds in Anosmics

Since anosmic subjects lack functional olfaction, any vapor that they can detect when presented to the nose has to be detected by means of the trigeminal system. Thus, one possibility to measure nasal pungency thresholds unbiased by odors is to measure them in anosmic participants. Early studies suggested that simple physicochemical properties might predict the chemesthetic potency of vapors (Doty, 1975; Doty et al., 1978). A number of physicochemical properties change orderly and systematically along homologous chemical series. These observations prompted a series of investigations that, using carbon chain length as a practical unit of chemical change, measured nasal pungency thresholds in anosmics and odor detection thresholds in normosmics (i.e., subjects with normal olfaction) towards selected members of homologous alcohols (Cometto-Muñiz and Cain, 1990), acetate esters (Cometto-Muñiz and Cain, 1991), 2-ketones and secondary and tertiary alcohols and acetates (Cometto-Muñiz and Cain, 1993), n-alkylbenzenes (Cometto-Muñiz and Cain, 1994), aliphatic aldehydes and carboxylic acids (Cometto-Muñiz et al., 1998a), and terpenes (Cometto-Muñiz et al., 1998b). They all employed a uniform methodology that included delivery of vapors via squeeze bottles, a two-alternative forced-choice procedure against blanks (mineral oil), an ascending concentration approach, a fixed-criterion of five correct choices in a row, and measurement of headspace vapor concentration in the bottles via gas chromatography (Cometto-Muñiz and Cain, 1990).

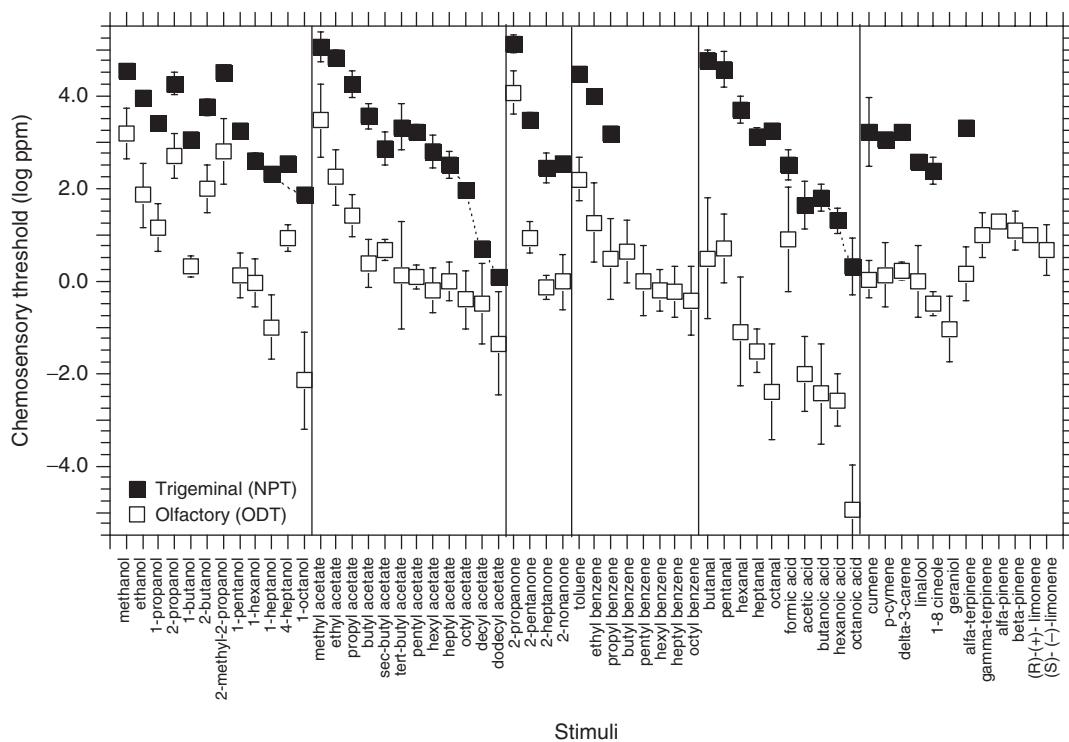

The outcome from these studies revealed the following (Figure 50.1): (1) In all cases, nasal pungency

thresholds (NPTs) were higher than odor detection thresholds (ODTs) by a factor ranging from 1 to 5 orders of magnitude, depending on the chemical. In other words, trigeminal chemesthetic sensitivity was always lower than olfactory sensitivity by the factor mentioned. (2) NPTs and ODTs tend to decrease with carbon chain length within homologous series; that is, trigeminal and olfactory chemosensitivity increase with carbon chain length within the series. (3) Trigeminal chemosensitivity experiences a "cut-off" effect along homologous series, meaning that a certain homolog is reached that fails to elicit an NPT even at saturated vapor concentration for room temperature (see section "50.3.7 Cut-off effect..." further below). Once this cut-off homolog is reached, all larger homologs fail to evoke pungency as well.

### 50.3.3 Nasal Trigeminal Chemosensitivity and Anosmia

The measurement of NPTs in anosmics as a method to assess trigeminal chemesthetic thresholds in normosmics, assumes that the absence of smell does not interfere in a significant way with nasal trigeminal chemosensitivity. The outcome of psychophysical and electrophysiological studies addressing this assumption have been mixed, as described below, but they lead to the conclusion that nasal trigeminal chemosensitivity is not largely different in normosmics and anosmics.

As noted earlier, psychophysical studies of nasal trigeminal chemesthetic sensitivity in normosmics need to control for odor biases since the great majority of chemicals evoke both odor and irritation but olfactory sensitivity is higher than nasal trigeminal sensitivity (i.e., odor thresholds are lower than chemesthetic thresholds for any given chemical). Unfortunately, effective control for odor biases in normosmics cannot be established in suprathreshold intensity procedures (e.g., (Kendal-Reed et al., 1998), and is sometimes not included even in detection threshold measurement procedures, (e.g. (Gudziol et al., 2001)). This could explain the apparent outcome in such studies of higher chemesthetic sensitivity in normosmics compared to anosmics. Nasal detection thresholds for the strong irritant chloroacetyl phenone were not significantly different between congenital anosmics and age- and gender-matched normosmics (Cui and Evans, 1997). The virtually odorless irritant carbon dioxide ( $\text{CO}_2$ ), see (Cain and Murphy, 1980; Cometto-Muñiz and Cain, 1982; Dunn et al., 1982; García Medina and Cain, 1982), elicited lower intensity ratings in congenital anosmics than in normosmics (Frasnelli et al., 2007b) but, in contrast, it elicited intensity ratings no different in anosmics after upper respiratory tract infection or after head trauma than in normosmics (Frasnelli et al., 2007a). In terms of  $\text{CO}_2$  detection thresholds, anosmics after upper respiratory tract infection and those after head

**Figure 50.1** Showing trends in trigeminal (chemesthetic) and olfactory thresholds along lineal members of homologous series (plus some branched homologs), including alcohols, acetate esters, 2-ketones, alkylbenzenes, aliphatic aldehydes, and carboxylic acids. Also shown are both type of thresholds for cumene and selected terpenes. Trigeminal data are nasal pungency thresholds (NPTs) measured in anosmic subjects, and olfactory data are odor detection thresholds (ODTs) measured in normosmic subjects. A cut-off effect in chemesthesia detection (i.e., the saturated chemical vapor fails to elicit irritation) begins to develop for compounds whose NPTs are joined by a dashed line and fully develops for compounds whose NPTs are not plotted (see text). Bars indicate standard deviation.

trauma, but not hyposmics, had higher thresholds than normsmics (Frasnelli et al., 2006). A follow-up study found a similar outcome but also included congenital anosmics (Frasnelli et al., 2010). Unfortunately, CO<sub>2</sub> thresholds in these studies were obtained under a “yes-no” response approach without blanks, a method quite susceptible to criterion-based biases, rather than obtained under a more robust forced-choice procedure against blanks.

Electrophysiological studies on human nasal chemesthesia have explored peripheral responses, for example, the negative mucosal potential (NMP) (Kobal, 1985; Thürauf et al., 1993), and central responses generated in the cortex, e.g., trigeminal event-related potentials (tERP) (Kobal and Hummel, 1988; Kobal and Hummel, 1998). Peripheral responses to CO<sub>2</sub> stimulation in congenital anosmics and in anosmics from acquired etiologies showed a larger activation than in normsmics (Frasnelli et al., 2007a; b). In contrast, central responses to CO<sub>2</sub> stimulation in congenital anosmics showed no significant differences with those in normsmics (Frasnelli et al., 2007b), whereas anosmics from acquired etiologies (and hyposmics) showed a significantly smaller activation than normsmics (Frasnelli

et al., 2007a; Hummel et al., 1996a). The specific origin for this smaller central activation in certain anosmics remains unclear: in some cases the smaller activation was observed for the peak-to-peak amplitude of the early P1N1 wave (Hummel et al., 1996a) but in other cases it was observed for the base-to-peak amplitude P2 and peak-to-peak amplitude N1P2 (Frasnelli et al., 2007a).

The conflicting results discussed above led us to conclude that any advantage in nasal trigeminal chemosensitivity that normsmics might have over anosmics, if indeed real, appears to be relatively small.

### 50.3.4 Nasal Trigeminal Chemosensitivity as Reflected by Nasal Localization (i.e., Lateralization) Thresholds in Normsmics and Anosmics

A pioneer investigation concluded that nasal localization (i.e., lateralization) of chemical vapors entering the nose through the right or the left nostril cannot be achieved via olfactory stimulation (odor) but can only be achieved when the vapors additionally activate the nasal trigeminal nerve

(chemesthesia) (von Skramlik, 1925). A later paper argued in favor of nasal localization via olfaction (von Békesy, 1964), but it is likely that the odorants presented were at concentrations that activated trigeminal chemesthesia. Further studies concluded that for short chemical vapor presentations, and with the head in a fixed position, nasal localization only occurs via trigeminal chemesthesia, not via smell (Kobal et al., 1989; Schneider and Schmidt, 1967). This finding provided the opportunity to: (1) assess nasal trigeminal chemesthetic sensitivity directly in normosmics via nasal localization thresholds (NLTs), without olfactory interference, and under a robust forced-choice procedure, and (2) use NLTs to directly compare nasal trigeminal chemesthetic sensitivity in normosmics and anosmics, using a common method.

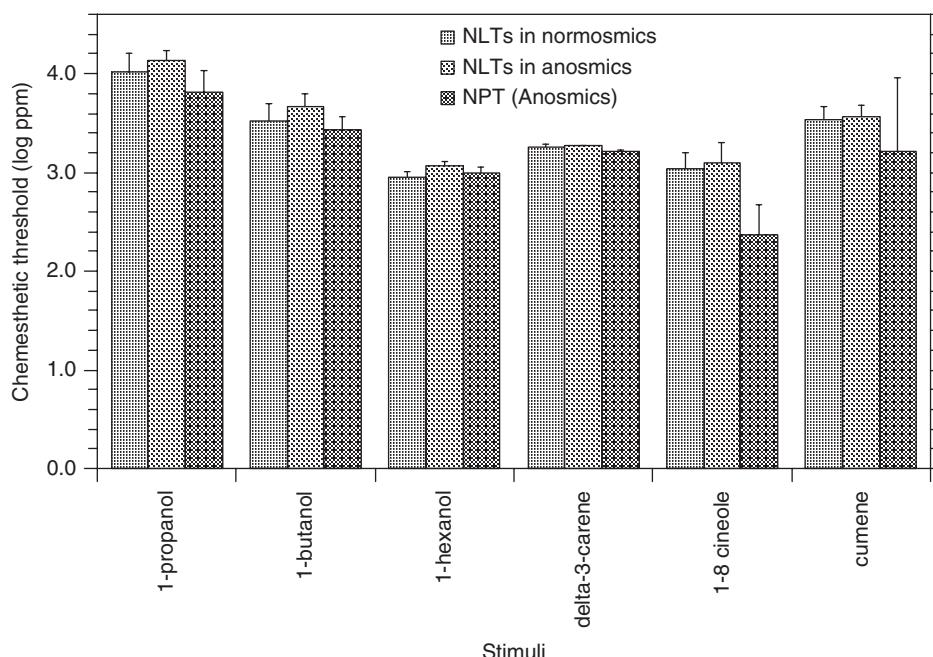

Some studies have measured nasal localization thresholds in normosmics and in anosmics for selected homologous n-alcohols, terpenes and cumene, employing a “squeeze-bottle” delivery system, an ascending concentration approach, and quantification of vapor concentrations using gas chromatography (Cometto-Muñiz and Cain, 1998; Cometto-Muñiz et al., 1998b). Their outcome suggested slightly lower NLTs for normosmics but the difference failed to achieve statistical significance. In fact, the three estimates of trigeminal chemesthetic sensitivity: NLTs in normosmics, NLTs in anosmics, and NPTs (as defined, always in anosmics) produced quite similar results (Figure 50.2). In two studies using a single concentration (neat vapor) of eucalyptol, with no chemical-analytical quantification, congenital anosmics (Frasnelli et al., 2007b) and anosmics from acquired etiologies (Frasnelli et al., 2007a) did not differ significantly from normosmics in

their ability to lateralize that vapor. In contrast, a previous study had found the lateralization scores of normosmics to be significantly higher than those of subjects with olfactory dysfunction (both anosmics and hyposmics) when using the neat vapors from eucalyptol and from benzaldehyde, with no analytical quantification of either vapor (Hummel et al., 2003). Another investigation found that a high stimulus volume (21 ml) enhances the ability of subjects to localize neat vapors, compared to a low volume (11 ml) (Frasnelli et al., 2011b).

In conclusion, now in terms of nasal localization, the comparison of nasal trigeminal chemesthetic sensitivity between normosmics and anosmics has produced mixed results, again indicating that any sensitivity advantage for normosmics, if indeed real, seems relatively small.

### 50.3.5 Ocular Trigeminal Chemosensitivity as Reflected by Eye Irritation Thresholds in Normosmics and Anosmics

As noted, the trigeminal nerve also innervates the eyes, so vapors reaching the ocular mucosa can give rise to eye irritation, a key symptom invariably mentioned in studies of indoor air pollution (Korpi et al., 2009; Wolkoff et al., 2006; Wolkoff et al., 2003). Eye irritation thresholds (EITs) were measured in normosmics for homologous n-alcohols, acetate esters, 2-ketones, n-alkylbenzenes, for various terpenes, and for cumene, using a methodology analogous to that described above for NPTs, including vapor quantification via gas chromatography (Cometto-Muñiz and Cain, 1991, 1995, 1998; Cometto-Muñiz et al., 1998b).

**Figure 50.2** Illustrating the similarity between nasal localization thresholds (NLTs) in normosmics and in anosmics for selected homologous n-alcohols, terpenes, and cumene (Cometto-Muñiz and Cain, 1998; Cometto-Muñiz et al., 1998b). Also shown, for comparison, are the nasal pungency thresholds (NPTs) (by definition, always obtained in anosmics) for the same chemicals. Bars indicate standard deviation.

The overall outcome showed the following (Figure 50.3): (1) Both EITs and NPTs tend to decline with carbon chain length along homologous series. (2) In general, EITs are very close to NPTs for any given vapor, although in particular instances the EIT can be higher (e.g., ethanol) or lower (e.g., butyl acetate) than the NPT. (3) In some cases, the saturated vapor of a chemical fails to reach an NPT but does reach an EIT (e.g., 1-octanol, octyl acetate, and geraniol).

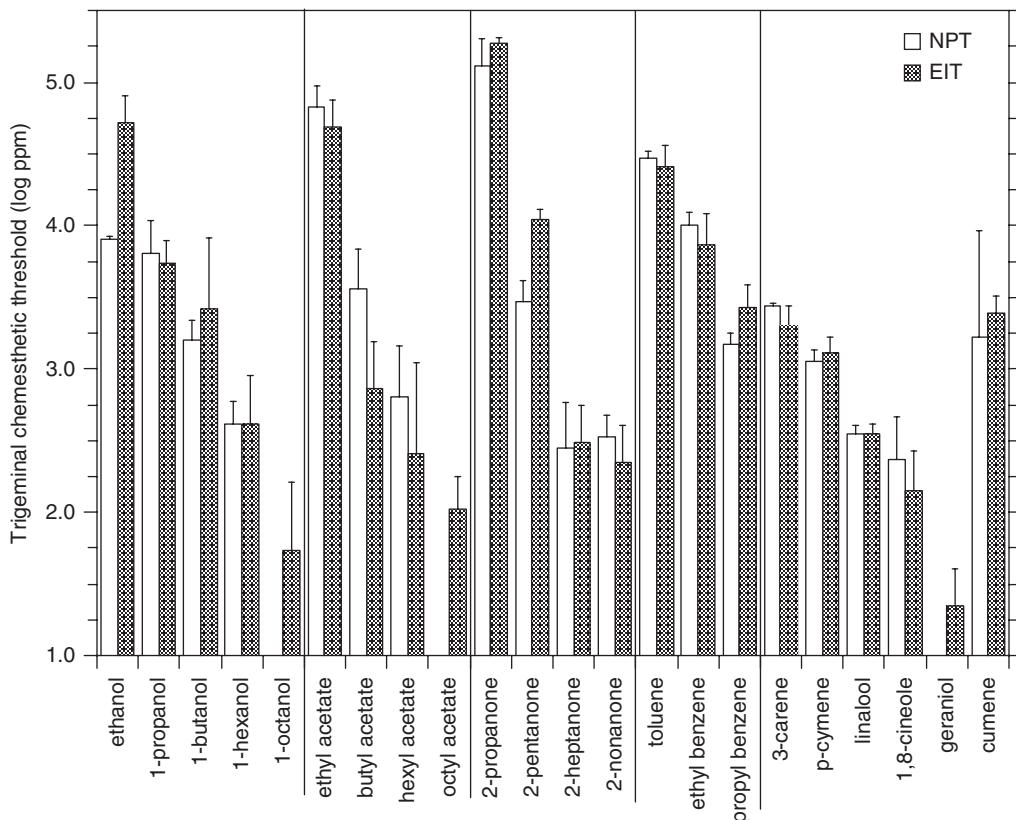

Measurement of EITs provided another opportunity to compare the trigeminal chemosensitivity of normosmics and anosmics. The outcome for 10 vapors tested revealed similar EITs across the two groups of subjects (Figure 50.4), again indicating quite comparable trigeminal chemesthetic sensitivity between normosmics and anosmics, now in the ocular mucosa (Cometto-Muñiz and Cain, 1998; Cometto-Muñiz et al., 1998b).

### 50.3.6 Structure-Activity Relationships in Nasal and Ocular Trigeminal Chemesthesia

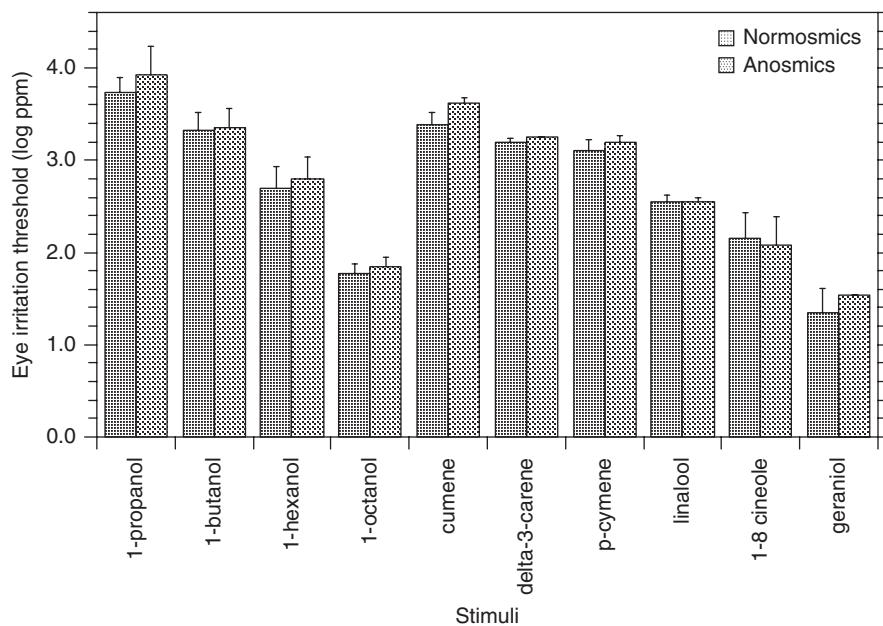

A key element for understanding how a chemosensory system functions is to establish the relationship between

the structural and physicochemical properties of the stimulating chemicals and the elicited chemosensory responses, including sensitivity, intensity, and quality. In this section we discuss such relationships in terms of the initial step of a sensory response, namely, stimulus detection, that is, thresholds, as an indicator of stimulus potency.

The wide chemical and structural variety of pungent (i.e., irritating) vapors suggests that, in many but not all cases, these irritants exert their effect via “selective” rather than “specific” processes. *Selective* processes rest on the physicochemical transfer of the irritant from the air into the nasal mucus or tear film, and its further transfer through successive biophases (i.e., biological compartments or environments) until reaching the receptor sites responsible for chemesthetic activity. In turn, *specific* effects are those where activity is mostly dependent on a narrowly defined key characteristic or property of the irritant stimulus that allows it to interact effectively with the receptor site. For example, to be active the chemical might need to be a strong electrophile, or to possess a restricted molecular configuration (e.g., only one of two enantiomers is active), a certain molecular size (e.g., molecules above that size are

**Figure 50.3** Comparability between nasal pungency thresholds (NPTs) and eye irritation thresholds (EITs, in normosmics) for 22 VOCs from four homologous series, selected terpenes, and cumene (Cometto-Muñiz and Cain, 1991, 1995, 1998, Cometto-Muñiz et al., 1998b). Bars indicate standard deviation.

**Figure 50.4** Depicting the similarity between eye irritation thresholds (EITs) measured in normosmics and in anosmics across 10 VOCs (Cometto-Muñiz and Cain, 1998; Cometto-Muñiz et al., 1998b). Bars indicate standard deviation.

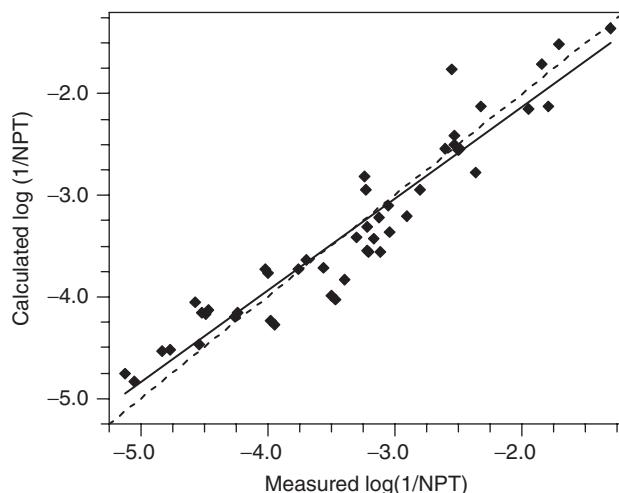

inactive), or a particular chemical functional group (e.g., only thiols are active).

A number of studies have attempted to correlate trigeminal chemesthetic potency with a variety of structural and physicochemical properties, including: molecular weight, water solubility, molecular geometry, saturated vapor pressure, boiling point, adjusted boiling point, Ostwald solubility coefficient, other partition coefficients, and combinations of these and other parameters, experimental and/or calculated, (Doty, 1975; Doty et al., 1978; Hau et al., 1999; Muller and Greff, 1984; Nielsen et al., 1990, 1992; Roberts, 1986). As pointed out by (Abraham et al., 2010c), many of these attempts lacked a general mechanistic or chemical interpretation of the basis for the chemesthetic potency of pungent vapors. In contrast, a quantitative structure-activity relationship (QSAR) based on a solvation equation (Abraham, 1993a; b) has the advantage of including a mechanistic and chemical interpretation of the properties (or “descriptors”) selected to model and predict human trigeminal chemesthetic sensitivity towards airborne compounds (Abraham et al., 2010c). This solvation-based QSAR takes the following general form:

$$SP = c + e.E + s.S + a.A + b.B + l.L \quad (50.1)$$

In the context of chemesthesia, SP (the dependent variable) is a sensory property reflecting chemesthetic potency of a series of irritants (i.e., solutes) towards humans, when the irritants reach, penetrate, diffuse, and trigger stimulation of the target mucosa (nasal or ocular). For example, SP is the logarithm of the reciprocal of nasal pungency thresholds,  $\log(1/NPTs)$ , or of eye irritation thresholds,  $\log$

(1/EITs). (We used reciprocals so that the more potent is the irritant, the larger numerically is 1/NPT or 1/EIT.) On the other side of the equation, E, S, A, B, and L are physicochemical properties or descriptors (independent variables) of the series of irritants. These descriptors are defined as follows: E is the excess molar refraction of the irritant that can be determined from the refractive index of the compound; it represents the tendency of the irritant to interact with a receptor phase through  $\pi$ - or n-electron pairs. S is the dipolarity/polarizability of the irritant. A is the overall or effective hydrogen bond acidity of the irritant. B is the overall or effective hydrogen bond basicity of the irritant. L represents  $\log L^{16}$  where  $L^{16}$  is the gas-hexadecane partition coefficient of the irritant at 298 °K, and it is a measure of the lipophilicity (i.e., lipid solubility) of the irritant. The constant c, and the coefficients e, s, a, b, and l are obtained by multiple linear regression analysis, but these are not merely fitted coefficients because they define the complementary physicochemical properties that characterize the receptor biophase with which the irritants interact. That is, they provide a physicochemical characterization of the environment or phase associated with the chemesthetic receptors. They do so in the following way: “e” gives the propensity of the receptor phase to interact with the irritant’s  $\pi$ - and n-electron pairs; “s” quantifies the receptor phase dipolarity/polarizability because a dipolar irritant will interact with a dipolar phase and a polarizable irritant will interact with a polarizable phase; “a” reflects the receptor phase basicity since an irritant that is a hydrogen-bond acid will interact with a basic phase; “b” reflects the receptor phase acidity since an irritant that is a hydrogen-bond

**Figure 50.5** Relationship between observed (i.e., experimentally measured) and calculated (from equation (2)) nasal pungency thresholds (NPTs). Both types of thresholds are plotted as  $\log(1/\text{NPT})$ , with NPTs expressed in units of parts per million (ppm) by volume. The dashed line represents the line of identity.

base will interact with an acidic phase; and, finally, “I” measures the lipophilicity of the receptor phase area.

The solvation equation (50.1) has been applied to describe and model experimentally-measured human NPTs from up to 48 volatile organic compounds (VOCs), including alcohols, acetate esters, ketones, alkylbenzenes, aldehydes, carboxylic acids, terpenes and other chemicals (Abraham et al., 1996; Abraham et al., 2001; Abraham et al., 2000; Abraham et al., 1998b; Abraham et al., 1998d; Abraham et al., 2007; Abraham et al., 2010b; Cometto-Muñiz et al., 1998a; 2005a). The solvation equation was found to account for 90 to 95% of the variability in measured NPTs. There is a strong correlation between the measured and the calculated NPTs (Figure 50.5). The latest version of the equation, as applied to NPTs, reads as follows (Abraham et al., 2010c):

$$\begin{aligned} \log(1/\text{NPT}) = & -7.770 + 1.543 \mathbf{S} + 3.296 \mathbf{A} \\ & + 0.876 \mathbf{B} + 0.816 \mathbf{L} \end{aligned} \quad (50.2)$$

$N = 47$ ,  $R^2 = 0.901$ ,  $SD = 0.312$ ,  $F = 95$ ,  $Q^2 = 0.874$ ,  
 $\text{PRESS} = 5.1901$ ,  $\text{PSD} = 0.351$

where **S**, **A**, **B**, and **L** (descriptor **E** was not significant) are as defined after equation (50.1);  $N$  is the number of data points (i.e., VOCs),  $R$  is the correlation coefficient,  $SD$  is the standard deviation,  $F$  is the F-statistic,  $Q$  and  $\text{PRESS}$  are the leave-one-out statistics, and  $\text{PSD}$  is the predictive standard deviation.

The same solvation equation (50.1) has also been successfully applied to describe and model experimentally-measured human EITs and, quite interestingly, also Draize

eye scores in rabbits (Abraham et al., 1998a, c, 2000, 2001, 2003, 2009, 2010b). In fact, it was shown that the two data sets assessing ocular chemesthesia: the one on human EITs and the one on Draize scores in rabbits can be made compatible and actually be combined into one single QSAR including up to 91 compounds (Abraham et al., 1998c, 2003). The equation combining the two types of measurement reads as follows (Abraham et al., 2003):

$$\begin{aligned} \text{SP} = & -7.892 - 0.379 \mathbf{E} + 1.872 \mathbf{S} + 3.776 \mathbf{A} + \\ & 1.169 \mathbf{B} + 0.785 \mathbf{L} + 0.568 \mathbf{I} \end{aligned} \quad (50.3)$$

$$N = 91, R^2 = 0.936, SD = 0.433, F = 204.5$$

where  $\text{SP} = \log(1/\text{EIT})$  or  $\text{SP} = \log(\text{MMAS}/\text{P}^\circ)$ , i.e., a modified rabbit Draize score as previously defined (Abraham et al., 2003), and **I** is an indicator variable taking the value  $I = 0$  for human data and  $I = 1$  for Draize rabbit data. All other symbols are exactly as defined for equations (50.1) and (50.2).

The success of the solvation model to describe NPTs and EITs indicates that the VOCs included exert their chemesthetic effect mainly via selective, rather than specific, processes as defined at the beginning of this section. Instead, vapors that act mainly via specific processes might depart from the values predicted by the solvation equation. Typically, this departure is in the direction of being more potent than predicted, that is, having a lower NPT or EIT than predicted. We can say that the solvation equation calculates the general chemesthetic potency of any vapor with certain physicochemical properties, but, if in addition, the vapor activates one or more receptors in a strongly specific manner, its potency will be greater than that calculated by the equation, and, in consequence, its NPT or EIT will be lower than calculated. Examples of pungent compounds acting specifically on certain receptors are capsaicin (Tomina and Tomina, 2005), nicotine (Alimohammadi and Silver, 2000) and acrolein (Bautista et al., 2006). However, some of them, for example, capsaicin, have very little volatility. There are also compounds for which the solvation model predicts some level of chemesthetic potency but, when tested, fail to elicit chemesthesia. These cases were discovered when studying chemesthetic potency within homologous chemical series. The phenomenon, called the “cut-off” effect, is discussed in the next section.

### 50.3.7 Cut-Off Effect for Eliciting Trigeminal Chemesthesia along Vapors from Homologous Chemical Series

As illustrated in Figures 50.1, 50.2, 50.3, and 50.4, trigeminal chemesthetic thresholds tend to decrease with carbon

chain length along homologous series (Cometto-Muñiz, 2001). Nevertheless, this trend often ends abruptly when a certain homolog is reached for which no threshold can be measured since even the saturated vapor of the compound at room temperature ( $\approx 23^\circ\text{C}$ ) fails to elicit chemesthetic detection reliably (Cometto-Muñiz and Cain, 1991, 1994, 1998; Cometto-Muñiz et al., 1998a). We labeled this phenomenon a “cut-off” effect for the detection of trigeminal chemesthesia, in analogy with a similar effect described for anesthesia (Franks and Lieb, 1985; 1990; Horishita and Harris, 2008). In turn, we labeled the smallest homolog failing to elicit chemesthetic detection the “cut-off homolog.”

At least two possible mechanisms could explain the occurrence of the cut-off effect: (1) the saturated vapor concentration, at room temperature ( $23^\circ\text{C}$ ), of the cut-off homolog (and all ensuing homologs) falls below the necessary threshold, and (2) the cut-off homolog (and all ensuing homologs) lacks a key feature to trigger chemesthesia. We looked into these two possibilities by following three approaches: (1) calculating a predicted chemesthetic threshold via the solvation QSAR model described just above and comparing it with the saturated vapor concentration (at  $23^\circ\text{C}$ ) of the cut-off homolog; (2) increasing the saturated vapor concentration of the cut-off homolog by heating it to  $37^\circ\text{C}$  and testing if this would precipitate detection; and (3) measuring complete concentration-detection functions (rather than just a threshold point) for the cut-off compound and for its immediate homologous neighbors (Cometto-Muñiz and Abraham, 2008; Cometto-Muñiz et al., 1998a, 2005a, b, 2006, 2007a; b). The combined outcome from these approaches indicated that the cut-off effect often results from a restriction other than an insufficient vapor concentration; for example, it could result from reaching a large enough homolog that exceeds a critical molecular dimension to be able to elicit chemesthesia (Cometto-Muñiz et al., 2010). If so, this molecular size restriction would constitute a specific effect (as defined at the beginning of the previous section) and, in consequence, it would not be predicted by the solvation model represented by equation (50.1).

### 50.3.8 Chemical Mixtures and Chemesthesia

An interesting functional aspect of trigeminal chemesthesia relates to the stimulation with chemical mixtures, both at threshold (i.e., detection) and suprathreshold (i.e., perceived intensity or magnitude) levels. When probing the rules by which trigeminal chemesthesia detects chemical mixtures, as compared to the detection of the individual constituents, it is important to rule out physicochemical interactions and associations among components that

might occur before the mixture even reaches the receptor sites. This consideration is usually not addressed in mixture studies. A recent investigation concluded that, at concentrations near chemesthetic detection thresholds, the association between non-reactive VOCs in mixtures upon reaching their biological site of action would only amount to less than 5% of their total concentration (Abraham et al., 2010a).

In terms of threshold chemesthetic detection of chemical mixtures, an intensive study of nine individual VOCs from a number of homologous series and five of their mixtures including 3, 6, and 9-components, found various degrees of agonism (i.e., additive effects) among the constituents (Cometto-Muñiz et al., 1997). The investigation included two chemesthetic endpoints: NPTs and EITs, and an olfactory endpoint: ODTs. Chemosesthetic thresholds showed a larger degree of agonism than olfactory ones, with eye irritation having stronger agonism than nasal pungency. The extent of chemosensory agonism became larger as the number and the lipophilicity (i.e., lipid solubility) of the mixture components increased. Later studies followed a more detailed approach by focusing in binary mixtures and by measuring full concentration-detection (i.e., psychometric or detectability) functions, (see (Cometto-Muñiz et al., 2002), rather than just threshold values. As before, components of the mixtures were chosen from homologous series, allowing us to address the role of structure-activity relationships in the chemesthetic detection of binary mixtures (Cometto-Muñiz et al., 1999, 2001, 2004a). The results were analyzed in terms of response-addition (i.e., sum of detectabilities) and of dose-addition (sum of doses within a selected psychometric function). The outcome pointed towards relative agreement between these two ways of quantifying addition, and indicated a larger degree of addition at low than at high levels of detectability (Cometto-Muñiz et al., 2004b). In these latter studies, which are based on concentration-detection functions, nasal pungency showed a larger degree of addition than eye irritation for mixtures presented at moderate and high detectability levels.

In terms of perceived intensity of chemical mixtures (i.e., suprathreshold range), a study of mixtures of the pungent odorants ammonia and formaldehyde revealed that, as the mixtures increased in concentration, the total nasal perceived intensity switched from being significantly lower to being significantly higher than the sum of the perceived intensities of its components (Cometto-Muñiz et al., 1989). A follow-up investigation confirmed that this effect was due to a gain in the relative contribution of nasal chemesthesia over olfaction as the concentration of the mixtures increased (Cometto-Muñiz and Hernández, 1990). In another study, the ocular mucosa seemed more responsive than the nasal mucosa regarding the

chemesthetic intensity elicited by the complex mixture environmental tobacco smoke (Cain et al., 1987). Under a dose–response approach, the eye irritation intensity produced by a mixture of eight VOCs and two mixtures of four VOCs indicated that the components acted in a simple additive way to produce ocular irritation (Hempel-Jorgensen et al., 1999). A recent paper employed nasal lateralization scores and intensity ratings to compare three single chemicals (menthol, eucalyptol, and allyl isothiocyanate) and two mixtures (menthol/eucalyptol and menthol/allyl isothiocyanate) (Frasnelli et al., 2011a). Intensity ratings probably included odor plus chemesthesia (i.e., total nasal intensity), although it is not specifically stated. Individual stimuli were presented at a single liquid dilution (found to be iso-intense by a different group of experienced subjects) and the mixtures were presented at 50%, probably volume/volume (v/v), but no analytical quantification of the vapor concentrations from either single or mixed stimuli was presented. The results suggested suppression within the mixture activating a common receptor (i.e., menthol/eucalyptol) given that this mixture produced lower intensity ratings than the other mixture, and slightly lower lateralization scores than the other mixture (albeit only under a one-sided t-test since the main effect “stimulus” failed to reach significance for lateralization scores). This outcome should be taken with the caveat that many chemesthetic stimuli that are mainly known to activate a certain receptor type can also activate or inhibit other types (Macpherson et al., 2006) with more or less potency and/or efficacy (Lambert, 2004).

Real world chemical exposures often involve mixtures of at least dozens or hundreds of components (Feron et al., 2002). A number of investigations have looked into complex mixtures of VOCs to establish their ability to elicit nasal and/or ocular trigeminal chemesthesia in humans, at threshold and suprathreshold levels, among other diverse effects. Examples of such complex stimuli include: environmental tobacco smoke (Cain et al., 1987), fragranced products (Millqvist et al., 1999; Opiekun et al., 2003), indoor air (Hudnell et al., 1992; Laumbach et al., 2005; Meininghaus et al., 2003; Otto et al., 1990), and outdoor air surrounding composting facilities (Müller et al., 2004), animal production facilities (Schiffman et al., 2000; Schiffman and Williams, 2005), and other industries (Dahlgren et al., 2003). In such studies, the typical goal was to assess the effect of the mixture (diluted or neat) on different groups of subjects (e.g., unexposed controls, exposed subjects, asthmatics, etc.). Since, in most cases, these very complex mixtures were not fully defined from a chemical standpoint, no attempts were made to relate the chemesthetic impact of the mixtures to that of the individual constituents.

### 50.3.9 Temporal Properties of Nasal and Ocular Chemesthesia

Since nasal and ocular trigeminal chemesthetic responses often act as a warning signal against the continued exposure to potentially deleterious airborne compounds, these sensations tend to increase with time of exposure before reaching a plateau or declining thereafter (Shusterman et al., 2006; Wise et al., 2009b). At near-threshold levels, an increase in stimulation time produces lower detection thresholds, at least within the first few seconds ( $\approx$ 4–6 sec) of stimulation. This temporal integration of threshold nasal chemesthesia, whether measured with a trigeminally-induced reflex apnea (Dunn et al., 1982) or with the nasal localization approach, has been observed for a variety of irritants including ammonia (Cometto-Muñiz and Cain, 1984; Wise et al., 2005), CO<sub>2</sub> (Wise et al., 2004), ethanol (Wise et al., 2006), homologous alcohols (Wise et al., 2007), and homologous propionates (Wise et al., 2009a). Within short stimulation times (up to 6 sec), the relationship between exposure-time and concentration falls close but often is short of a perfect trade off; that is, to achieve the chemesthetic threshold, it takes somewhat more than doubling the stimulus duration to compensate for a twofold decrease in concentration.

At supra-threshold levels, the perceived intensity of nasal chemesthesia increases with stimulation time for at least the first 4 sec, as shown with ammonia (Cometto-Muñiz and Cain, 1984; Wise et al., 2005) and CO<sub>2</sub> (Wise et al., 2003). Under a protocol testing homologous alcohols with alternative cycles of 3 sec of chemical stimulation and 3 sec of clean air for a 1 min trial, the intensity of nasal chemesthesia showed adaptation, that is, it decreased for recurrent pulses of the alcohol vapor (Wise et al., 2010). Using fixed suprathreshold levels of CO<sub>2</sub> as the nasal chemesthetic stimulus, a series of studies have looked into the effect of repetitive stimulation with CO<sub>2</sub> at different inter-stimulus intervals (ranging from 2 to 90 sec) in subsequent ratings of pain intensity. They concluded that, for intervals ranging from 10 to 90 sec, pain ratings for repetitive CO<sub>2</sub> presentations were lowest after a 10-sec interval and largest after a 90-sec interval (Hummel and Kobal, 1999). For very short intervals (2 to 8 sec), pain ratings increased after 2-sec intervals but decreased after 6- and 8-sec intervals (Hummel et al., 1994; Hummel et al., 1996b). In contrast, the decrease in amplitude to repetitive CO<sub>2</sub> stimulations of both the peripheral negative mucosal potential (NMP) and the central chemo-somatosensory event-related potential (CSERP) were more pronounced with the shortest inter-stimulus interval, that is, 2 sec. (Hummel et al., 1994; Hummel et al., 1996b). Nevertheless, a more recent report found that the amplitude of chemosensory event-related potentials to repetitive CO<sub>2</sub> nasal stimulations increased when the inter-stimulus interval was shortened from 30 to 10 sec, concluding

that the effect is due to trigeminal sensitization during repeated stimulation (Kassab et al., 2009). In another study, a linear relationship emerged between the stimulus duration of a steady CO<sub>2</sub> pulse increasing from 100 to 300 msec and the amplitude of the P3 component of the trigeminal event-related potential, suggesting that the later components of this potential encode not only for stimulus concentration but also for stimulus duration (Frasnelli et al., 2003).

Other studies on the effect of exposure time on nasal chemesthesia explored much longer durations, in the range of minutes to hours, and under whole body exposures. Chamber studies testing formaldehyde at various fixed concentrations revealed that perceived irritation (nasal and ocular) increased with time during a 30-min exposure (Cain et al., 1986). In realistic daily home or occupational exposures to a chemical vapor that might be causing mild irritation, the nasal chemesthetic threshold for that chemical increases, revealing desensitization, but the effect does not appear to generalize to other irritants (Dalton et al., 2006; Smeets and Dalton, 2002; Wysocki et al., 1997). Exposures of two to three hours to mixtures of VOCs (Hudnell et al., 1992) and to the complex stimulus environmental tobacco smoke (Cain et al., 1987) revealed that the perceived intensity of chemesthesia clearly increases with time.

## 50.4 ORAL CHEMESTHESIA

### 50.4.1 Separation of Oral Trigeminal Chemosensitivity from Gustatory Sensitivity

Typically, the detection of water soluble chemicals occurs in the oral cavity and is critical to the survival of organisms. In the case of gustation, chemosensitivity provides a mechanism by which foods can be instantaneously evaluated prior to ingestion. This ability has a profound impact on an organism's survival because, in the case of sweet sensitivity, it allows for the identification of potentially nutritious food sources, whereas for bitter and sour sensitivity, provides the ability to detect and avoid poisonous or spoiled foods (for review, see Brody et al., 2012). Although there are similarities, gustation is differentiated from oral chemesthesia in a number of important ways. Prototypical chemesthetic stimuli include many plant-based molecules such as (a) capsaicinoids (capsaicin from chili peppers} (Szolcsányi and Jancsó-Gábor, 1975; Stevens and Lawless, 1987; Green, 1989; Caterina et al., 1997; piperine from black pepper (Stevens and Lawless, 1987; Green, 1996; Dessirier et al., 1999)), (b) isothiocyanates (allyl isothiocyanate from mustard oil) (Simons et al., 2003; Jordt et al., 2004; Bandell et al., 2004) and allicin from

garlic (Bautista et al., 2005) and (c) the alkaloid nicotine (Jansco et al., 1961; Dessirier et al., 1997; 1998), found in the nightshade family (Solanaceae) of plants. Ingestion of these compounds at low levels elicits a predominantly pungent or burning sensation from the oral mucosa (Keele, 1962; Lawless and Stevens, 1988; Rentmeister-Bryant and Green, 1997) and vermillion border of the lips (Lawless, 1984; Lawless and Stevens, 1988), but have minor or no discernible taste qualities on their own (except for nicotine which has been described as bitter) (Pfaffman, 1959). Recently, oleocanthal from olive oil has been identified which elicits an irritant sensation sensed primarily from the pharynx (Beauchamp et al., 2005; Peyrot des Gachons et al., 2011). Other chemesthetic sensations include (a) pungency from ethanol (Green, 1988; Prescott and Swain-Campbell, 2000), cinnamic aldehyde (Prescott and Swain-Campbell, 2000; Klein et al., 2011) and zingerone (Prescott and Stevenson, 1996a; 1996b), (b) cooling from menthol (Eccles, 1994; Cliff and Green, 1994; 1996) and other compounds including icillin (Wei and Seid, 1983), WS-12 (Sherkheli et al., 2010), WS-23 (Sherkheli et al., 2010) and a recently identified high-potency synthetic compound that elicits a strong cooling sensation of long duration (Furrer et al., 2008), (c) warming from camphor (Green, 1990; Moqrich, 2005) and (d) tingling from alpha-hydroxy-sanshool (Bryant and Mezine, 1999; Albin and Simons, 2010) or spilanthol (Ley et al., 2006), unique compounds derived from the sechuan peppercorn and jambu fruit, respectively. These compounds are in contrast to gustatory stimuli that are usually detected at much higher levels (mM) and evoke specific taste sensations including sweet, sour, salty, bitter, umami and possibly fat (for review on fat taste, see Mattes, 2011). Importantly, it should be noted that salts and acids, which evoke sensations of saltiness and sourness, respectively, can elicit pungent sensations from the oral cavity (Simons et al., 1999; Dessirier et al., 2000b; 2001) when used at high concentrations. Thus, unlike many chemesthetic stimuli, acids and salts have both gustatory and irritant properties.

Chemesthetic and gustatory sensitivity are underpinned by different receptor families and different neuronal pathways (for detailed discussion see Section 50.1) and, in some cases, evoke different behaviors. Oral chemesthetic stimuli typically interact with one of three main families of receptors including members of the Transient Receptor Potential (TRP) family (for review, see Clapham, 2003 and Talavera et al., 2008), nicotinic cholinergic receptors (nAChRs; Dessirier et al., 1998; Simons et al., 2003b; Thuerauf et al., 2006), and outward-rectifying 2-pore potassium channels including KCNK3, KCNK9 and KCNK18 (Bautista et al., 2008). Most irritants interact with one of several ionotropic TRP channels including TRPA1, TRPM8, TRPV1, and TRPV2. Nicotine and sanshool, a compound that induces tingling sensations,

activate the nAChRs, TRPA1 (see Talavera et al., 2009), and 2-pore potassium channels (Bautista et al., 2008). These receptors are expressed by polymodal nociceptors or, in the case of the 2-pore potassium channels, a mechanosensitive subpopulation of sensory neurons (Bautista et al., 2008; Lennertz et al., 2010; Patapoutian et al., 2009). Ligand-receptor interaction evokes direct excitation of the neuron whose signal is conveyed centrally to the trigeminal nucleus (Sessle, 1989; Carstens et al., 1998). From there, neural projections to the thalamus and, subsequently, primary somatosensory cortex, allow for higher processing of the nociceptive information (Sessle, 1989). When ingested, chemesthetic stimuli evoke reflex pathways and aversive behaviors intended to minimize intake. Salivation (Ley and Simchen, 2007) dilutes the irritant and behavioral responses reduce additional exposure. However, one central feature specific to oral chemesthesia is its contribution to flavor. The sensations associated with chili peppers, wasabi, mustard, and carbonation, while pungent, are often sought after, and contribute to the flavor profile of many cuisines. Not surprisingly, therefore, chemesthetic compounds have a long history in culinary use. Several hypotheses have been forwarded to explain the use of these aversive compounds by humans ranging from thrill-seeking (Rozin and Schiller, 1980) to proposed health benefits. Interestingly, research has identified a range of health-related benefits of various chemesthetic stimuli including antibacterial activity (Ozçelik et al., 2011), cardiovascular protection (Peng and Li, 2010), and anti-obesity effects (Hursel and Westerterp-Plantenga, 2010).

These findings are in contrast to those ascribed to gustation. Identified in the early 2000s, gustatory receptors include the 7-transmembrane, g-protein coupled T1R (Nelson et al., 2001; 2002) and T2R (Adler et al., 2000; Chandrashekhar et al., 2000) subfamilies, which are involved in the transduction of sweet and umami and bitter tastes, respectively (see Chapter 31). Although still unidentified in humans, it is believed that ionotropic channels transduce salty (Yarmolinsky et al., 2009) and sour (Yarmolinsky et al., 2009) sensations. Recently, in addition to texture and olfaction, fat has been proposed to have a gustatory component (Chalé-Rush et al., 2007) that involves activation of CD36 (Laugerette et al., 2005), the g-protein coupled receptors GPR40 (Matsumura et al., 2007; Cartoni et al., 2010) and GPR120 (Matsumura et al., 2007; Cartoni et al., 2010), and/or the inactivation of outward rectifying K<sup>+</sup> channels (Gilbertson et al., 1997). These receptors are expressed in taste receptor cells which are derived from local epithelium (Stone et al., 1995) and innervated by primary neurons of the chorda tympani, glossopharyngeal, and vagus nerves (for review, see Whitehead, 1988). The central projection of these neurons is to specific gustatory centers in the brainstem, thalamus and

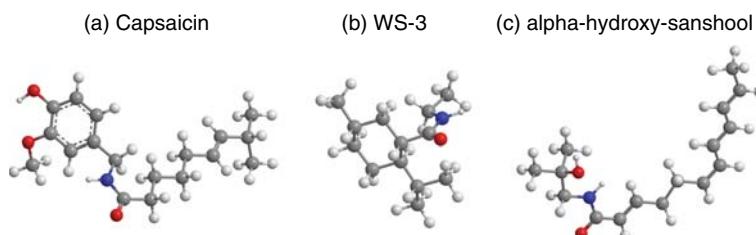

insular cortex (Whitehead, 1988). When ingested, tastant stimuli largely evoke innate stereotyped behaviors that can often be modified through learning. Sweet, umami, and salt (low concentrations) stimuli elicit appetitive behaviors whereas sour and bitter tastants evoke aversive behaviors which limit intake (for review, see Brody et al., 2012).

### 50.4.2 Structure-Activity Relationships in Oral Trigeminal Chemesthesia

To date, the vast majority of psychophysical investigation linking oral irritancy to chemical structure-activity relationships (SAR) has been related to capsaicinoids. Several capsaicinoid compounds have been utilized to probe the human irritant response and identify the key structural attributes responsible for the pungency of this class of molecules. Capsaicin, the prototypical chemesthetic irritant, consists of an alkyl chain joined to a vanillyl moiety through an acyl amide (Figure 50.6a). This compound has been studied extensively and has been shown to elicit an irritant sensation in humans at levels as low as 0.2 ppm (Szolcsányi, 1990). Three critical structural features of capsaicin have been identified that impact the perceived pungency of this molecule. The vanillyl moiety is important and contributes greatly to the perceived pungency (Szolcsányi and Jancso-Gabor, 1975). However, if the ring is opened, as in the case of undecenoyl-3-amino-propanol, pungency can still be elicited albeit at a significantly reduced potency (Szolcsányi and Jancso-Gabor, 1975). The length of the alkyl chain also impacts pungency with perceived irritation peaking when carbon chain length reaches approximately ten carbons (Szolcsányi and Jancso-Gabor, 1975). Finally, the presence of an acyl amide group contributes to perceived irritancy. Conversion of the acyl amide into an acyl ester significantly reduces pungency (Szolcsányi and Jancso-Gabor, 1975).

Structure-activity relationships for other irritants have not been as extensively studied although a key structural feature of many irritants activating TRPA1 is their ability to covalently modify specific cysteine residues within the N-terminal domain of the channel (Hinman et al., 2006).

A substantial body of knowledge generated from the flavor and fragrance industry has provided important insight into the central features of cooling compounds. Using a pharmacophore hypothesis, key structural elements were identified for menthane carboxamides (Figure 50.6b), the most widely used and investigated family of cooling compounds (Furrer et al., 2008). The primary binding interaction between this class of compounds and TRPM8, its cognate receptor, is believed to be hydrophobic in nature and mediated via the menthane core (Furrer et al., 2008). Additionally, the affinity of menthane carboxamides can

**Figure 50.6** Chemical structures of three chemesthetic stimuli. (a) The TRPV1 agonist capsaicin. (b) The TRPM8 agonist WS-3, a simple methane carboxamide. (c) The KCNK, two-pore potassium channel blocker, alpha-hydroxy-sanshool. (See plate section for color version.)

be modulated by the amidic moiety. Finally, the importance of two hydrogen bond acceptors in proximity to the compact methane core was found to improve potency of these molecules (Watson et al., 1978; Furrer et al., 2008). However, it should be noted that other chemical cores have the capacity to evoke cooling (see, for example, Furrer et al., 2008). For instance, icillin, a compound having little structural similarity to menthol, is a potent activator of TRPM8 (McKemy et al., 2002; Chuang et al., 2004; Dhaka et al., 2007).

Finally, recent structure-activity relationships have been investigated for compounds that elicit a tingle sensation via blockade of 2-pore potassium channels. Sanshools (Figure 50.6c) are long-chained polyenamides and the prototypical stimulus to elicit the tingle sensation. Four key structural elements associated with sanshools have been identified which are necessary for the perceived sensation (Galopin et al., 2002). In particular, a N-isobutylcarboxamide motif is required as well as the presence of a cis-double bond in the fatty chain. Furthermore, the efficacy of these compounds can be enhanced by the presence of a long fatty chain, saturation of the alpha-, beta-, gamma- and delta- carbons, and a hydroxyl on the N-alkyl group (Galopin et al., 2002).

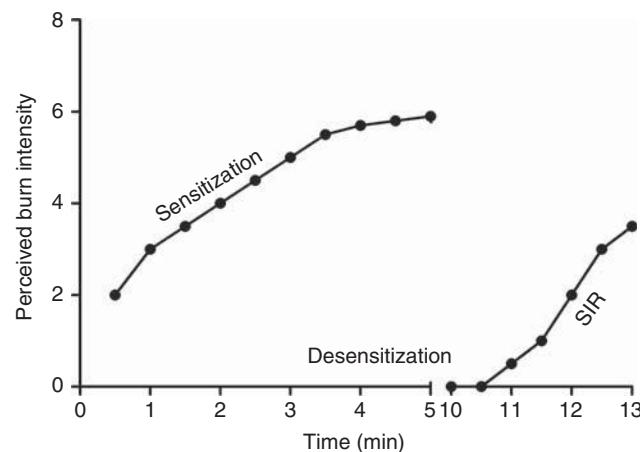

#### 50.4.3 Temporal Properties of Oral Chemesthesia

A unique property of most oral chemesthetic irritants is their ability to elicit temporally dynamic patterns of irritation with repeated application. Psychophysical methods have been described that allow investigators to track oral irritation intensity across time (Lawless and Stevens, 1988; Stevens and Lawless, 1987; Green, 1988; 1989; Dessirier et al., 1999, 2001; Prescott, 1999; Prescott and Stevenson, 1996a; 1996b). Using these techniques, several distinctive patterns (see Figure 50.7) have been identified including sensitization, desensitization, cross-desensitization, and stimulus-induced recovery (SIR). Interestingly, these same patterns of response have been observed electrophysiologically in single-unit recordings of trigeminal cells in Vc (Dessirier et al., 2000c; Sudo et al., 2002). Sensitization is described as the increase in perceived intensity of a given sensation upon repeated exposure. In the oral cavity, the occurrence of sensitization is dependent upon the

inter-stimulus intervals with which chemesthetic agents are applied (Green, 1989; Green and Rentmeister-Bryant, 1998; Prescott, 1999). With short inter-stimulus intervals, typically on the order of three minutes or less, the perceived irritation grows until it reaches a plateau (Green, 1991). Many, but not all, chemesthetic compounds elicit this pattern of irritation including the capsaicinoids capsaicin (Lawless, 1984; Stevens and Lawless, 1987; Green, 1989; Prescott, 1999) and piperine (Stevens and Lawless, 1987; Green, 1996; Rentmeister-Bryant and Green, 1997), high concentrations of acids (Green, 1996; Dessirier et al., 2000b) and salts (Dessirier et al., 2001), and menthol (Cliff and Green, 1994, 1996). Interestingly, mustard oil (allyl isothiocyanate) was found to elicit a sensitizing pattern of irritation when delivered to the nasal cavity (Brand and Jacquot 2002) but not when delivered to the oral cavity (Simons et al., 2003a). Other irritants, including zingerone (Prescott and Stevenson, 1996a, 1996b) and nicotine (Dessirier et al., 1997) do not evoke sensitization.

Several mechanisms underlying this phenomenon have been proposed (see Carstens et al., 2002) including the peripheral and central sensitization of nociceptive pathways that typically accompany inflammation (Willis, 2009). Spatial recruitment has also been proposed as a mechanism underpinning sensitization (Carstens et al., 2002). In this model, irritant chemicals applied to the lingual surface activate chemosensitive neurons. With repeated application, the irritant compounds diffuse into the lingual epithelium where they encounter and excite previously unactivated neurons. The increasing number of activated nociceptors results in a progressive increase in the perceived intensity of the irritation sensation. Eventually, the rate of diffusion through the epithelium is equaled by the clearance rate of the compound. At this point, spatial recruitment cannot continue and the intensity of the perceived irritant sensation plateaus (see Figure 50.7).

When the repeated application of irritant chemicals occurs after a hiatus or at longer inter-stimulus intervals, typically greater than 5 min, self- or cross-desensitization occurs (Green, 1991; Prescott and Stevenson, 1996b; see Figure 50.7). Self-desensitization, like adaptation, is described as a decrease in perceived sensation intensity with repeated or continued application of a given chemesthetic compound. Cross-desensitization is the term given wherein application of one chemoirritant causes reduced

**Figure 50.7** Temporal patterns of oral chemesthesia. Repeated application of a chemesthetic irritant at short interstimulus intervals (e.g. 30 sec), elicits a sensitizing pattern of irritation in which the perceived sensation grows more intense until it reaches a plateau. When the repeated application of irritant chemicals occurs after a hiatus or at longer inter-stimulus intervals (greater than 5 min) desensitization occurs. However, desensitization can be overcome by recurrent stimulation at short inter-stimulus intervals. With continued stimulation, stimulus induced recovery (SIR) occurs and the perceived irritant sensation grows more intense.

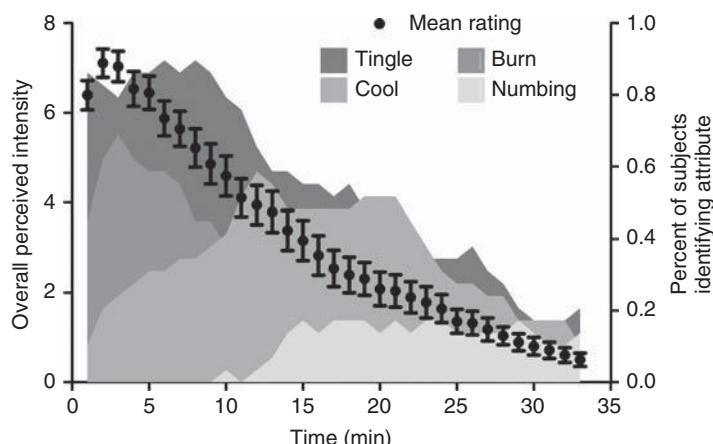

sensitivity to subsequent applications of a second irritant. Cross-desensitization is often used as evidence supporting the view that two compounds share the same receptor and/or neural mechanisms (e.g., Cliff and Green, 1996; Dessirier et al., 2000a; Green, 1996). To date, many of the chemorirritants tested in psychophysical protocols evoke desensitizing patterns of oral irritation including capsaicin (e.g., Green, 1989, 1991; Szolcsányi, 1990; Prescott, 1999), piperine (Green, 1996; Dessirier et al., 1999), ethanol (Prescott and Swain-Campbell, 2000), acids (Dessirier et al., 2000b), salts (Dessirier et al., 2001), nicotine (Dessirier et al., 1997), allyl isothiocyanate (Simons et al., 2003a), cinnamic aldehyde (Prescott and Swain-Campbell, 2000), zingerone (Prescott and Stevenson, 1996a, 1996b), and menthol (Cliff and Green, 1994; 1996).

Desensitization is likely due to peripheral mechanisms occurring at the receptor or neuronal level. In whole-cell patch-clamp experiments of trigeminal and dorsal root ganglion neurons, repeated application of capsaicin resulted in successively smaller inward currents (Liu and Simon, 1996, 1998; Su et al., 1999; Yao and Qin, 2009). This reduction could be mitigated by the removal of extra-cellular  $\text{Ca}^{+2}$ , suggesting the importance of this ion in regulating the process (Liu and Simon, 1998). Interestingly, other capsaicinoids, including zingerone and olvanil, elicit cellular desensitization however, the mechanism appears to be  $\text{Ca}^{+2}$ -independent (Liu and Simon, 1998). An additional

mechanism contributing to desensitization could be the result of some irritants ability to inhibit voltage-sensitive  $\text{Na}^+$  channels as is the case for capsaicin (Su et al., 1999 and Liu et al., 2001). Clearly, this could also serve as the root cause of cross-desensitization.

An interesting aspect of lingual desensitization is that it can be overcome with subsequent, recurrent stimulation (Green, 1996). This phenomenon, termed Stimulus-Induced Recovery (SIR; Figure 50.7), is both concentration- and inter-stimulus interval-dependent. Initiating and driving SIR to completion requires stimulus concentrations equal to or greater than the concentrations used to elicit the desensitized state. For instance, in studies using capsaicin, a 33  $\mu\text{M}$  solution could elicit SIR only when the desensitizing capsaicin concentration was 33  $\mu\text{M}$  or lower, but not when a 99  $\mu\text{M}$  or 330  $\mu\text{M}$  solution was used (Green and Rentmeister-Bryant, 1998). Additionally, like sensitization, initiation of SIR requires recurrent stimulus applications with short inter-stimulus intervals – the shorter the inter-stimulus interval, the greater the incidence and magnitude of SIR (Green and Rentmeister-Bryant, 1998). Studies investigating the temporal dependence of SIR showed that an inter-stimulus interval greater than 60-sec was inefficient at reversing capsaicin desensitization (Green and Rentmeister-Bryant, 1998). Although still speculative, the mechanism underlying SIR is thought to be the same as that underlying sensitization – namely, peripheral and/or central sensitization, and spatial recruitment.

Many chemesthetic compounds activate multiple receptor sub-types. Additionally, the kinetics of sensitization, desensitization, and adaptation for each of the sub-qualities can differ (Lawless and Stevens, 1990). As a consequence, many chemesthetic compounds evoke unique and complex sensory profiles that are temporally dynamic. An excellent example of this occurs with lingual application of alkylamide compounds such as alpha-hydroxy sanshool (Figure 50.8). Sanshool has been shown to activate 2-pore potassium channels (Bautista et al., 2008), TRPV1 (Sugai et al., 2005; Koo et al., 2007; Menozzi-Smarrito et al., 2009; Riera et al., 2009), and TRPA1 (Koo et al., 2007; Menozzi-Smarrito et al., 2009; Riera et al., 2009). Additionally, lingual nerve recordings in rat have shown that sanshool activates low and high threshold cold-sensitive fibers as well as low threshold mechanosensitive fibers (Bryant and Mezine, 1999). As expected from the diverse receptor and neuronal types that are activated by these compounds, the psychophysical results are equally complex. Lingual application of a synthetic alkylamide elicits a sensation that is described as initially tingling and pungent but after approximately 15 minutes as cooling and numbing (Figure 50.8).

**Figure 50.8** Temporal profile and attribute identification following lingual application of a synthetic alkylamide. The figure shows the mean overall intensity perceived over time and the proportion of panelists selecting tingle, burning, cooling or numbing at each time point. Error bars indicate SEM. Figure adapted from Albin and Simons, 2010.

#### 50.4.4 Threshold for Oral Chemesthesia

Testing oral chemesthetic thresholds is difficult due to the presence of sensitization, desensitization and SIR. Typical bias-free methods used to establish threshold sensitivity, such as forced-choice, ascending and descending staircase approaches, cannot be used because they require repeated stimulation. As discussed above, a short inter-stimulus interval can result in sensitization leading to confounded threshold determinations. Conversely, with a longer inter-stimulus interval, desensitization can result leading to detection thresholds that are artificially high. Allowing time for recovery from desensitization is potentially possible, however, in some cases this phenomenon has been shown to last for days (Carstens et al., 2007; Green, 1996; Karrer and Bartoshuk, 1991). Moreover, long inter-stimulus intervals require subjects to remember preceding stimulus intensities and memory effects have been shown to worsen performance on discrimination tasks (Avancini de Almeida, 1999; Cubero et al., 1995).

The limitations associated with investigating chemesthetic compounds restrict the options available for sound psychophysical testing. One potential solution that has been developed is the use of “half-tongue” methodologies (e.g., Dessirier et al., 1997; Simons et al., 1999) in which forced-choice, discrimination tasks are accomplished by placing a compound of interest on one side of a subject’s tongue and the control solution on the other. Subjects can compare the sensation on both sides of the tongue simultaneously to identify any intensity differences. Previous investigations have indicated no differences in sensitivity across both sides of the tongue as long as the same dorsal lingual surface is being stimulated bilaterally (Lawless and Stevens, 1988; 1990). Over several days, multiple stimulus concentrations can be compared to identify threshold sensitivity and, as the stimuli being compared are delivered simultaneously, memory effects are obviated.

# Chapter 51

---

## The Vomeronasal Organ

LISA STOWERS and MARC SPEHR

### 51.1 INTRODUCTION

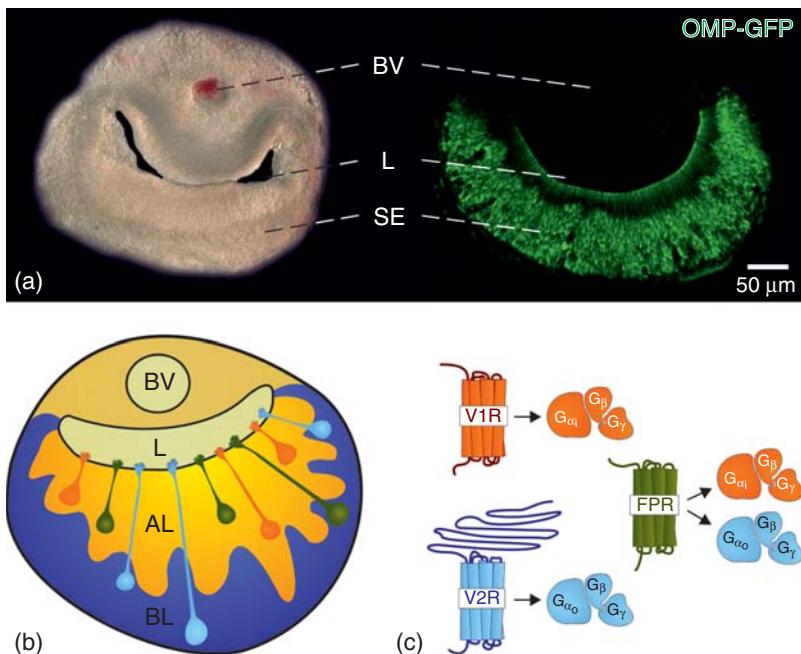

In 1813, the Danish anatomist Ludvig L. Jacobson (1783–1843) described a richly innervated mammalian organ that “is located in the foremost part of the nasal cavity, in close contact with the nasal cartilage (septum), on palatal elongations of the intermaxillary bone” (Jacobson et al., 1998). From his comparative investigations in different domesticated and wild mammalian species, Jacobson concluded that “the organ exists in all mammals” and likely functions as a secretory and / or “sensory organ which may be of assistance to the sense of smell” (Jacobson et al., 1998). Eighty-two years after its discovery, the “organ of Jacobson” was (re)named “organon vomeronasale (Jacobsoni)” or vomeronasal organ.

While most mammals have a vomeronasal organ (VNO) as the peripheral sensory structure of an accessory olfactory system (AOS), its enormous morphological diversity complicates extrapolation of findings between species (Salazar and Sánchez-Quinteiro, 2009; Salazar et al., 2007). In the following, we therefore focus on the rodent AOS with particular emphasis on mouse models. Mice have emerged as the best-studied mammalian VNO model system and their genetic amenability allows integrated investigations that span the molecular, cellular and systems level (Chamero et al., 2012).

The VNO is a paired cylindrical, bilaterally symmetrical tubular structure that is located at the base of the anterior nasal septum just above the palate (Halpern and Martinez-Marcos, 2003; Meredith, 1991). The entire blind-ended organ is enclosed in a bony capsule and, depending on the species, opens anteriorly into either the nasal or the oral cavity via the vomeronasal or nasopalatine duct, respectively. Viscous secretions of lateral glands fill the VNO lumen with approximately

0.5 mm<sup>3</sup> mucus (Leinders-Zufall et al., 2009). On its medial side, a crescent-shaped pseudo-stratified neuroepithelium is mainly composed of three cell types – basal cells, sustentacular cells, and mature vomeronasal sensory neurons (VSNs) (Figure 51.1A). Each small bipolar VSN extends a single unbranched apical dendrite that terminates in a microvillous knob-like structure at the epithelial surface. While the dendritic VSN endings float in the lumen’s mucus, single long unbranched axons gather into vomeronasal nerve bundles that project dorsally under the septal epithelium through openings of the cribriform plate along the medial side of the olfactory bulb to the glomerular layer of the AOB (Meredith, 1991). In total, the mouse VNO harbors a few hundred thousand VSNs (Rodriguez, 2004) that gain structural and metabolic support from a band of microvillous supporting cells in the most superficial epithelial layer. Remarkably, VSNs are short-lived neurons that are continuously replaced from a local stem cell reservoir even in aged individuals (Brann and Firestein, 2010). This robust regenerative capacity is ensured by a population of adult pluripotent cells – basal cells – that are located both along the basal epithelial membrane and in the marginal zone (Halpern and Martinez-Marcos, 2003).

On the lateral side of the VNO, highly vascularized cavernous tissue harbors a large blood vessel that is extensively innervated by sympathetic nerves from the superior cervical ganglion that enter the posterior VNO along nasopalatine fibers (Figure 51.1a) (Ben-Shaul et al., 2010; Meredith and O’Connell, 1979). Sympathetic activity triggers adrenergic release and, consequently, vasoconstriction of the vascular tissue that results in negative intraluminal pressure. This peristaltic vascular pumping mechanism causes massive fluid entry into the VNO in situations of stress and / or novelty-induced arousal. This way, the VNO can take up relatively non-volatile stimuli such as peptides

**Figure 51.1** The mouse VNO – structure, epithelial dichotomy, and chemosensory GPCRs. (a) Coronal sections reveal the typical VNO anatomy. In both acute vibratome sections (left) and fixed tissue cryosections (right), the crescent shaped sensory epithelium (SE), the lumen (L) and the large lateral blood vessel (BV), that drives the vascular pump, become apparent. (b) schematic diagram illustrating the molecularly distinct apical (AL; yellow) and basal (BL, blue) layers of the sensory neuroepithelium. Color code of individual VSNs indicates chemoreceptor expression as in C. (c) Three classes of vomeronasal chemosensory GPCRs. (See plate section for color version.)

or proteins that dissolve in the ventral nasal mucus following direct contact with urine deposits, vaginal secretions, facial gland secretions or saliva (Luo et al., 2003; Wysocki et al., 1980).

Confirmation of Ludvig Jacobson's original hypothesis that the VNO serves a sensory / olfactory function emerged in the late 1960s and early 1970s (Raisman, 1972; Winans and Scalia, 1970) when the neuroanatomical description of segregated parallel projections of the main and accessory olfactory systems to different telencephalic and diencephalic nuclei founded the dual olfactory hypothesis (Scalia and Winans, 1975). Accordingly, the main and accessory systems have traditionally been viewed as both anatomically and functionally separate pathways that detect distinct sets of olfactory cues and trigger different behavioral responses. Today, it has become evident that a clear-cut distinction – the AOS detecting nonvolatile pheromones, while the main system functions as a nonselective molecular analyzer of volatile odorants – is far from true (Spehr et al., 2006b).

AOS ontogeny and postnatal development are best described in the rat and mouse. The rat vomeronasal neuroepithelium is embryologically derived from an evagination of the olfactory placode that can be observed between E12 and E13 (Cuschieri and Bannister, 1975). Based on expression of the olfactory marker protein (OMP), mouse neurons are first identified by E14 (Tarozzo et al., 1998). At E18, the lateral vascular pattern is complete (Szabó and Mendoza, 1988) and the vomeronasal nerve appears fully developed. Thus, all structural VNO components are present at birth and the organ reaches adult size

shortly before puberty (Giacobini et al., 2000). Whether the VNO is functional in neonates is less clear. Contrary to previous observations (Coppola and O'Connell, 1989), Hovis and coworkers (Hovis et al., 2012) report that the vomeronasal duct is open and thus allows stimulus access to the sensory neuroepithelium at birth. During the first postnatal week, VSNs form complete microvilli (Mucignat-Caretta, 2010) and release glutamate from their axon terminals (Hovis et al., 2012). It is therefore still subject to debate if the rodent AOS functions in juveniles (Mucignat-Caretta, 2010).

Regulation of VSN development is still poorly understood. Currently, two transcription factors – Mash1 and Bcl11b/Ctip2 – have been attributed critical functions in VSN differentiation (Enomoto et al., 2011; Murray et al., 2003). Genetic ablation of *Mash1* in vomeronasal progenitor cells results in a profound reduction of VSN proliferation in late embryonic and postnatal stages, whereas loss of *Bcl11b/Ctip2* function seems to primarily affect postmitotic VSNs. In such newly differentiated neurons, *Bcl11b/Ctip2* apparently regulates the fate choice between molecularly distinct VSN types (Enomoto et al., 2011).

## 51.2 SIGNALING MECHANISMS IN VOMERONASAL NEURONS

### 51.2.1 Vomeronasal Chemoreceptors

In many, though not all, mammalian species the VNO displays a structural and functional dichotomy (Dulac and

Torello, 2003; Halpern, 1987; Mucignat-Caretta, 2010). Two topographically segregated VSN subpopulations express distinct repertoires of receptors and other putative signaling molecules. VSNs located in the apical layer of the sensory neuroepithelium, closest to the lumen, express the G protein  $\alpha$ -subunit  $G_{\alpha i2}$  in concert with one member of a multigene family that encodes ~150 intact G protein-coupled receptors (GPCRs) – the V1Rs (Figure 51.1b-c) (Dulac and Axel, 1995; Rodriguez et al., 2002).

While initial attempts to identify putative vomeronasal chemoreceptor genes based on odorant receptor homology were not successful, Dulac and Axel differentially screened cDNA libraries from single rat VSNs. They uncovered a large multigene family of class-A (i.e., rhodopsin-like) GPCRs that are exclusively expressed in vomeronasal tissue (Dulac and Axel, 1995). In mice, this *V1r* family of genes contains more than 150 potentially functional members as well as an approximately equal number of likely pseudogenes (Rodriguez et al., 2002; Roppolo et al., 2007). Antisense probe labeling revealed a punctate, non-overlapping transcription pattern in VSNs restricted to the apical  $G_{\alpha i2}$ -/PDE4A-positive layer of the sensory epithelium (Berghard and Buck, 1996; Dulac and Axel, 1995; Halpern et al., 1995). *V1r* genes are unusually divergent and polymorphic across alleles. They share intron-free coding regions and are generally clustered on most chromosomes (Capello et al., 2009; Roppolo et al., 2007). Classified into 12 relatively isolated families that each contain between one and 30 members (Rodriguez et al., 2002; Zhang et al., 2004), *V1r* gene choice in a given VSN is tightly controlled. Monogenic, indeed monoallelic, expression ensures that individual VSNs display a single V1R chemodetector “morph” (Rodriguez et al., 1999) and, thus, obtain a distinct functional identity. Deletion of a single 600 kb *V1r* gene cluster on mouse chromosome 6, containing all (but one) *V1ra* and *V1rb* family members, has clearly shown the essential requirement for some V1Rs in mediating VSN chemoresponsivity (Chamero et al., 2012; Del Punta et al., 2002a). In the fifteen years since the discovery of the *V1r* genes the majority of vertebrate V1Rs still remain orphan receptors, so it is technically remarkable that the Dulac group recently succeeded in determining the specificity of 56 individual V1Rs to a range of ethologically relevant cues (Isogai et al., 2011). Using a high-throughput molecular readout of VNO activity mapping, Isogai and coworkers concluded that individual receptor subfamilies have evolved towards the recognition of specific groups of animals or behaviorally relevant chemical structures.

While strict monogenic / monoallelic gene choice is a well-documented hallmark of *V1r* expression (Belluscio et al., 1999; Rodriguez et al., 1999; Roppolo et al., 2007), the underlying molecular mechanisms that ensure only

one receptor is expressed by each sensory neuron are far less clear. *V1r* clusters are typically not interrupted by other genes, an arrangement that allows regulatory mechanisms to function at the cluster level. Thus, cluster organization may not just reflect the result of multiple gene-duplication events, but rather play an additional role in expression regulation (Roppolo et al., 2007). Similar to monoallelic and mutually exclusive odorant receptor (OR) gene choice (Lewcock and Reed, 2004; Serizawa et al., 2003), transcription of a nonfunctional *V1r* mutant allele mediates coexpression of a second, functional *V1r* gene. In turn, transcription of this functional *V1r* gene then drives an unknown negative feedback mechanism that maintains monogenic expression. Remarkably, mutant gene transcription silences the *V1r* gene cluster in *cis* relative to the nonfunctional allele, yet allows alternative choice of a functional receptor gene located on the homologous cluster in *trans* (Roppolo et al., 2007). These findings contradict a concept of a molecular “tag” that marks either parental chromosomes / cluster for gene expression. Notably, the negative feedback signal that ensures gene exclusion is also maintained by exogenous expression of an OR gene from a *V1r* locus (Capello et al., 2009), strongly suggesting a common mechanistic basis of monogenic / monoallelic transcription in chemosensory neurons.

Between the apical layer and the basement membrane is a molecularly distinct zone of neurons which form the basal layer. Basal neurons are  $G_{\alpha o}$ -positive and express members of an unrelated GPCR family – the V2Rs (Figure 51.1b-c) (Herrada and Dulac, 1997; Matsunami and Buck, 1997; Ryba and Tirindelli, 1997). In the mouse genome, about 120 *V2r* genes have apparently intact coding regions, whereas an additional ~160 seem to be pseudogenes (Munger et al., 2009; Young and Trask, 2007). As typical class-C GPCRs, members of the V2R family share a large hydrophobic amino (N)-terminal extracellular domain that is believed to form the primary site of ligand binding (Mombaerts, 2004b; Spehr and Munger, 2009). The *V2r* genes share no significant sequence homology with the *V1r* family, but are distantly related to metabotropic glutamate receptors,  $\text{Ca}^{2+}$ -sensing receptors, and sweet/umami-sensing *T1r* taste receptors (Dulac and Torello, 2003; Mombaerts, 2004b). Similar to *V1r* genes, *V2rs* are usually found in clusters on most chromosomes and, according to sequence homology, are grouped into four distinct families: family-A, -B, -D, and -C (also known as *V2r2*) (Silvotti et al., 2007; Silvotti et al., 2011; Young and Trask, 2007). While family-A genes comprise the vast majority of *V2rs* with more than 100 members, only 4 genes constitute family-D. Like *V1r* genes, but with the notable exception of family-C receptors, *V2r* genes are also characterized by mutually exclusive monoallelic transcription that leads to a punctate expression pattern restricted to the more basal  $G_{\alpha o}$ -positive

layer of the VNO sensory epithelium. While family-A, B and D receptors, thus, “obey” the one neuron – one receptor rule for chemosensory cells (Mombaerts, 2004a; Munger et al., 2009), those seven highly homologous (>80 %) family-C receptors are found in most, if not all,  $G_{\alpha o}$ -positive VSNs (Martini et al., 2001), effectively allowing for combinatorial V2R coexpression patterns in basal VSNs. The unusual expression of family-C *V2r* genes is somewhat reminiscent of the atypical insect olfactory coreceptor Orco (Vosshall and Hansson, 2011) which appears functionally orthologous across species and serves as a chaperoning dimerization partner for the odor-specific subunits of the insect olfactory receptor gene family (Larsson et al., 2004; Nakagawa and Vosshall, 2009). Whether family-C V2Rs serve an analogous function in vomeronasal chemoreception remains to be determined (Spehr and Munger, 2009).

In 2003, two groups discovered that V2R-positive basal VSNs also express members of a family of nine non-classical class Ib major histocompatibility complex (MHC) genes, known as *H2-Mv* or M10 (Ishii et al., 2003; Loconto et al., 2003). *H2-Mv* proteins were initially proposed to associate with V2Rs and, in complex with  $\beta 2$ -microglobulin, serve a critical chaperone function for proper V2R trafficking and surface expression (Dulac and Torello, 2003; Loconto et al., 2003). Later, Ishii and Mombaerts reported that a substantial fraction of V2R-positive VSNs does not express any of the nine *H2-Mv* genes while other neurons express multiple *H2-Mv* family members in a combinatorial manner (Ishii and Mombaerts, 2008), questioning the general requirement of *H2-Mv* proteins as V2R escort molecules. Moreover, while the *H2-Mv* gene family is exclusively found in rodents, other mammalian species such as the opossum express putatively functional *V2r* genes without intact *H2-Mv* open reading frames (Shi and Zhang, 2007; Young and Trask, 2007).

Direct proof that at least some V2Rs mediate VSN chemoresponsivity has been obtained from gene deletion studies. Mice deficient for *Vmn2r26* (*V2rlb*) or *Vmn2r116* (*V2rp5*) exhibit dramatically reduced sensitivity to genotype-specific MHC class I peptides (Leinders-Zufall et al., 2009) or male-specific exocrine gland-secreting peptide 1 (ESP1 (Haga et al., 2010)), respectively. In wildtype mice, however, these macromolecules elicit robust and highly sensitive responses with VSN activation thresholds in the picomolar range (Leinders-Zufall et al., 2009).

Contrary to current concepts of isolated *V1r* gene expression in apical VSNs (see above), combinatorial coexpression of three multigene families in non-random combinations – family-A/B/D V2rs (115 genes), family-C V2rs (7 genes), and *H2-Mvs* (9 genes) – appears to bestow a functional identity on a given basal VSNs (Chamero et al., 2012). So far, efforts to deorphanize V2Rs (as well as V1Rs) in recombinant protein expression systems have

largely failed because of a general lack in understanding the regulatory mechanisms that control V1R/V2R cell-surface expression. However, some recent promising advances in heterologous V2R plasma membrane targeting (Dey and Matsunami, 2011) raise expectations that more detailed knowledge on vomeronasal receptor function could soon become available.

A third family of putative vomeronasal chemoreceptors has recently been identified by two groups (Liberles et al., 2009; Rivière et al., 2009). Parallel large scale screening for yet unidentified sensory cell populations and corresponding chemosensory GPCRs identified five candidate non-*V1/2r* chemoreceptor genes that share many of the structural and functional hallmarks of previously identified olfactory GPCRs. All five genes (*Fpr-rs1*, *rs3*, *rs4*, *rs6* and *rs7*) are members of the formyl peptide receptor (FPR)-like gene family, show a putative seven-transmembrane topology, display a selective and punctate transcription pattern in the VNO neuroepithelium, and are monogenically expressed with respect to both their own and other chemoreceptor gene families (Liberles et al., 2009; Rivière et al., 2009). Immunocytochemical localization studies of one particular family member, FPR-rs3, revealed protein translocation to the microvillous dendritic endings of VSNs (Rivière et al., 2009, Ackels et al., 2014). With the exception of *Fpr-rs1* which is coexpressed with  $G_{\alpha o}$ , the remaining vomeronasal *Fpr-rs* genes all coexpress with  $G_{\alpha i2}$  in the apical epithelial layer (Figure 51.1b–c).

Immune cells such as neutrophils and monocytes express FPR1, the founding family member, as well as the related receptor FPR-rs2 (Le et al., 2002). Both receptors play important roles in host defense against pathogens (Soehnlein and Lindblom, 2010). Immune system FPRs recognize a broad range of chemoattractants such as the prototypical formylated bacterial peptide N-formylmethionine-leucine-phenylalanine (fMLF), mitochondrially encoded peptides or various antimicrobial / inflammatory modulators (Kolaczkowska and Kubes, 2013). These ligand spectra are therefore defined by immunological function than by structural properties. Upon activation, this unusually broad FPR tuning profile enables granulocytes and macrophages to use both pathogen- and host-derived compounds as chemotactic guideposts towards sites of infection or tissue damage. However, neither of the “classical” immune system FPRs is transcribed in VSNs (Liberles et al., 2009; Rivière et al., 2009).

Neither immune system nor vomeronasal *Fprs* share significant sequence similarity with other chemosensory GPCRs such as V1/2Rs, ORs or trace amine-associated receptors (TAARs; Liberles and Buck, 2006). Moreover, phylogenetic analysis suggests that vomeronasal *Fprs*, which form a single gene cluster directly adjacent to a stretch of 39 *V1/2r* genes, selectively evolved from several

recent gene duplications and positive Darwinian selection in the rodent lineage (Liberles et al., 2009), thus, arguing for neofunctionalization of VNO *Fprs* (Bufo et al., 2012). Yet, vomeronasal neurons are activated *in situ* by fMLF as well as the mitochondria-derived formylated peptides ND1-6T or ND1-6I (Chamero et al., 2011) and heterologously expressed FPR-rs1-7 proteins retain agonist spectra similar to immune system FPRs (Rivière et al., 2009). Thus, the exact biological function of vomeronasal FPRs remains to be determined.

### 51.2.2 Signaling Cascade(s) and General VSN Physiology

The signal transduction mechanisms following detection of ligands by V1R, V2R, or FPR-rs receptors are only partly understood and many important aspects of general VNO physiology still remain elusive. It is clear, however, that VSNs display membrane depolarization, an increased action potential firing rate and, consequently, a transient increase in cytosolic  $\text{Ca}^{2+}$  levels upon exposure to natural stimuli (Chamero et al., 2007; 2011; Del Punta et al., 2002a; Haga et al., 2010; Inamura and Kashiyayanagi, 2000; Inamura et al., 1997; 1999; Kim et al., 2011; Kimoto et al., 2007; Leinders-Zufall et al., 2000; 2004; Lucas et al., 2003; Nodari et al., 2008; Papes et al., 2010; Spehr et al., 2002). Given their extraordinarily high input resistance (typically several gigaohms (Hagendorf et al., 2009; Liman and Corey, 1996; Shimazaki et al., 2006; Ukhanov et al., 2007)), VSNs are exquisitely sensitive to electrical stimulation. Thus, at resting membrane potentials of between  $-60$  and  $-75$  mV (Liman and Corey, 1996; Ukhanov et al., 2007), depolarizing current injections of only a few picoamperes produce repetitive firing (Munger et al., 2009).

In addition to “standard” Hodgkin-Huxley type voltage-gated conductances such as those of TTX-sensitive sodium and delayed rectifier potassium currents (Bean, 2007), VSNs express several additional ion channels that shape their specific electrophysiological input–output relationship. L-type and T-type  $\text{Ca}_v^{2+}$  currents (Liman and Corey, 1996) generate low-threshold  $\text{Ca}^{2+}$  spikes that partly drive action potential discharge (Ukhanov et al., 2007). These  $\text{Ca}_v^{2+}$  currents are functionally coupled to large-conductance  $\text{Ca}^{2+}$ -sensitive  $\text{K}^+$  (BK) channels in the VSN soma that were proposed to either maintain persistent rhythmic firing (Ukhanov et al., 2007) or, quite contrary, to mediate sensory adaptation via arachidonic acid-dependent BK channel recruitment during stimulation (Zhang et al., 2008). A homeostatic function is served by layer-specific and activity-dependent expression of ether-à-go-go-related (ERG)  $\text{K}^+$  channels that control sensory output of basal V2R-positive VSNs. ERG channel expression extends the dynamic range of the VSN stimulus–response function

and is thus ideally suited to adjust VNO neurons to a target output range in a use-dependent manner (Hagendorf et al., 2009). Likely mediated by HCN2 and/or HCN4 channel subunits, hyperpolarization-dependent  $I_h$  currents represent another voltage-gated conductance that directly controls VSN excitability (Dibattista et al., 2008).

Layer-specific coexpression of the G-protein  $\alpha$ -subunits  $G_{\alpha i2}$  and  $G_{\alpha o}$  in microvilli and dendritic tips of V1R- and V2R-expressing VSNs, respectively (Berghard and Buck, 1996; Halpern et al., 1995; Matsuoka et al., 2001), had early on raised speculation about a functional role of  $G_{\alpha i2}$  and  $G_{\alpha o}$  in apical and basal signaling pathways. Conclusive proof of this attractive model, however, came only recently from conditional olfactory neuron-specific gene deletion studies that demonstrated an essential requirement of  $G_{\alpha o}$  in VSN responses to MHC I antigens, MUPs, as well as ESP1 (Chamero et al., 2011). Moreover,  $G_{\alpha o}$  was found to be critical for sensing mitochondrially encoded FPR-rs1 ligands (Chamero et al., 2011), whereas neuronal responses to fMLF, a stimulus shown to activate at least some of the four  $G_{\alpha i2}$ -coupled FPRs (Rivière et al., 2009), were not significantly altered in  $G_{\alpha o}^{-/-}$  mice (Chamero et al., 2011). With respect to  $G_{\alpha i2}$ , functional evidence supporting a role of this subunit in V1R-mediated signaling is still lacking. Global deletion of  $G_{\alpha i2}$  did not result in an unambiguously VNO-dependent phenotype (Norlin et al., 2003) and functional recordings from defined neurons in those  $G_{\alpha i2}$  null mice were not performed. As also true for a previous global  $G_{\alpha o}$  deletion model (Tanaka et al., 1999), unconditional knockout of abundantly expressed and highly promiscuous signaling proteins such as  $G_{\alpha i2}$  and  $G_{\alpha o}$  is rather expected to induce a wide variety of defects (Chamero et al., 2011).

There is more consensus on a critical role of the  $\beta 2$  isoform of phospholipase C (PLC $\beta 2$ ) in VSN signal transduction (Spehr et al., 2006b), although corresponding genetic deletion studies are also lacking. Activation of this enzyme by non-GTP-binding  $G_{\beta/\gamma}$  complexes promotes cleavage of phosphatidylinositol-4,5-bisphosphate into the soluble messenger molecule inositol-1,4,5-trisphosphate (IP<sub>3</sub>) and the membrane-bound lipid diacylglycerol (DAG). IP<sub>3</sub> is usually coupled to massive  $\text{Ca}^{2+}$  release from intracellular storage organelles, whereas DAG exerts direct signaling functions at target membrane proteins or is metabolized to polyunsaturated fatty acids. Different models for the actions of either or all products of PLC-dependent lipid turnover have been proposed (Dibattista et al., 2012; Kim et al., 2011; Lucas et al., 2003; Spehr et al., 2002; Yang and Delay, 2010). The common denominator of basically all models is a central role of  $\text{Ca}^{2+}$  and an important, though maybe not indispensable function of the VNO-specific transient receptor potential (TRP) channel TRPC2 (Liman et al., 1999). The TRPC2 protein is highly localized to VNO sensory microvilli and *Trpc2*<sup>-/-</sup> mice show severe defects in a variety of

social and sexual behaviors (Leypold et al., 2002; Stowers et al., 2002). Yet, there are some different phenotypes induced by *TrpC2* deletion versus surgical VNO ablation (Kelliher et al., 2006; Pankevich et al., 2004) and recent reports of (residual) urine-evoked vomeronasal sensory activity in *TrpC2*<sup>-/-</sup> VSNs (Kelliher et al., 2006; Kim et al., 2011; Yang and Delay, 2010) have added another layer of complexity to our current understanding of vomeronasal transduction.

Elevated cytosolic Ca<sup>2+</sup> – from TRPC2-dependent influx (Lucas et al., 2003) and maybe also IP<sub>3</sub>-mediated store depletion (Kim et al., 2011; Yang and Delay, 2010) – appears to affect a variety of downstream cascade proteins. Increased Ca<sup>2+</sup> was shown to exert both negative and positive feedback regulation in VSNs (Chamero et al., 2012). Down-regulation of TRPC2 by Ca<sup>2+</sup>/calmodulin functions in vomeronasal sensory adaptation and gain control (Spehr et al., 2009). By contrast, a significant portion of urine-evoked VSN activity appears to be carried by a Ca<sup>2+</sup>-activated chloride current ( $I_{Cl}$ ) (Dibattista et al., 2012; Kim et al., 2011; Yang and Delay, 2010) that, similar to transduction mechanisms in OSNs (Pifferi et al., 2009; Stephan et al., 2009), appears to be mediated by members of the recently identified anoctamin family of Ca<sup>2+</sup>-activated chloride channels (Caputo et al., 2008; Schroeder et al., 2008; Yang et al., 2012). Different groups have shown that both anoctamin1 and anoctamin2 are present in VSNs and largely colocalize with TRPC2 (Billig et al., 2011; Dauner et al., 2012; Dibattista et al., 2012; Rasche et al., 2010). However, whether  $I_{Cl}$  contributes to depolarization (analogous to olfactory neurons) or leads to membrane hyperpolarization is directly and only dependent on the *in vivo* chloride equilibrium potential at the VSN microvillar membrane – a physiological parameter that is currently unknown. A third ion channel target of elevated Ca<sup>2+</sup> conducts a Ca<sup>2+</sup>-activated nonselective cation current ( $I_{CAN}$ ) found in both hamster (Liman, 2003) and mouse VSNs (Spehr et al., 2009).  $I_{CAN}$ , however, requires much higher Ca<sup>2+</sup> concentration levels than  $I_{Cl}$  for activation (Tirindelli et al., 2009).

### 51.3 VOMERONASAL CHEMOSENSORY CUES

VNO neurons are responsive to ethologically relevant odors emitted from other animals including so-called pheromones and kairomones, as well as a subset of odors of unknown biological function that are not emitted by other animals (Chamero et al., 2012; Sam et al., 2001; Trinh and Storm, 2003). Pheromones (pherin = to transfer and hormone = to excite) have been commonly assumed to be chemosensory ligands that elicit a specialized behavior or neuroendocrine response upon detection by members of

the same species (Karlson and Luscher, 1959; see Doty, 2010). Kairomones are ligands emitted by other species that upon detection lead to a behavioral advantage in the receiver and disadvantage the signaler. Current knowledge of VNO stimuli has been obtained through the study of the effects of native odor sources such as urine, saliva, and soiled bedding on conspecifics (Ben-Shaul et al., 2010; He et al., 2008; Isogai et al., 2011). Electrophysiology and behavioral observations have guided the isolation and identification of VNO ligands based on three major assumptions. First, it is presumed that relevant VNO ligands are secreted or excreted from an individual into the environment and their emission and detection is likely to be species-specific. Larger molecules that are not a common byproduct of general metabolism are more likely to meet this requirement (although not so complex that synthesis becomes costly) (Wilson, 1963). Second, if the ligand promotes a sexually dimorphic behavior, then its production and emission is likely to be confined to one gender. Third, since the VNO lumen is mucus filled and located at the base of the nasal cavity it is therefore not directly available to traditional volatile odorants. Relevant stimuli must efficiently diffuse or undergo transport to access the sensory receptors (Meredith and O'Connell, 1979).

Six categories of VNO ligands have now been identified that meet the above predictions: exocrine gland-secreting peptides (ESPs), major histocompatibility complex (MHC) peptide ligands, major urinary proteins (MUPs), volatile small molecules, sulfated steroids, and formyl-peptides. These known ligands fall into three groups. ESPs, MHCs and MUPs are all peptides or small proteins that have undergone species-specific gene duplications in rodents (Kimoto et al., 2007; Logan et al., 2008). The majority of these protein ligands have been shown to activate V2R expressing neurons (Chamero et al., 2007; Kimoto et al., 2007; Leinders-Zufall et al., 2004). VNO-stimulating volatile small molecules and sulfated steroids (also small molecules) are commonly emitted by many animal species and largely function to signal gender- or state-specific internal physiology (Nodari et al., 2008; Novotny et al., 1990; Novotny et al., 1985; Novotny et al., 1999b). The majority of these small molecules are detected by V1R expressing neurons (Leinders-Zufall et al., 2000; Meeks et al., 2010). Formylated peptides are produced by bacteria and mitochondria. These ligands activate FPR receptors (Liberles et al., 2009; Rivière et al., 2009).

The 38 mouse ESPs are secreted from glandular tissues including lacrimal, Harderian, and submaxillary (Kimoto et al., 2005). They are differentially expressed across development and between genders (Kimoto et al., 2007, Ferrero et al., 2013), potentially providing a wealth of state-specific cues to guide social behavior. Detailed study of one ESP, ESP1, found sex-specific expression in male tears (Kimoto

et al., 2005). When detected by females, ESP1 specifically activates a single V2R whose action is necessary to stimulate female mating behavior: lordosis (Haga et al., 2010). Another recently identified ESP (ESP22) acts as a juvenile semiochemical that blocks sexual behaviour (Ferrero et al., 2013).

MHC class I peptides, which function in self-recognition in the immune system, have also been shown to function as VNO sensory stimuli (Leinders-Zufall et al., 2004). They are detected by V2R-expressing neurons in the VNO as well as currently undefined neurons in the main olfactory epithelium (Leinders-Zufall et al., 2004, 2009; Spehr et al., 2006a). MHC peptides are thought to be excreted in urine throughout the life of both males and females, providing a stable representation of individuality. Indeed, they have been shown to be required for a female to imprint the memory of her mating partner (Leinders-Zufall et al., 2004).

Mouse MUPs are a family of 21 species-specific genes (Logan et al., 2008; Mudge et al., 2008). They are differentially regulated by thyroxine, growth hormone, and testosterone (Knopf et al., 1983; Szoka and Paigen, 1978) and therefore exhibit age- and gender-specific expression. MUPs are primarily synthesized in the liver and excreted in urine, but they are also expressed by several secretory tissues including the submaxillary, lacrimal, and mammary glands (Finlayson et al., 1965; Shaw et al., 1983). MUPs fold into a  $\beta$ -barrel structure creating an internal ligand binding pocket (Flower, 1996). This structure efficiently binds small molecules found in urine which themselves activate VNO neurons (Sharrow et al., 2002; Timm et al., 2001). MUPs have been proposed to function as pheromone carrier proteins serving to transmit the small volatile ligands found in urine into the mucus-filled VNO, and as stabilizers of these volatile ligands to extend their signaling potency by delaying their release after excretion into the environment (Beynon and Hurst, 2003, 2004; Hurst et al., 1998). Of the 21 MUP genes in the mouse genome, each individual only expresses 4–12 urine MUPs (Hurst et al., 2001; Robertson et al., 1996, 1997). This personally-tailored protein excretion has been proposed to differentially stabilize small molecules in order to facilitate individual recognition (Armstrong et al., 2005; Cheetham et al., 2009; Hurst and Beynon, 2004; Hurst et al., 2001). In addition, MUPs alone, without the associated small molecule ligands, have been shown to stimulate V2R-expressing neurons (Chamero et al., 2007; Papes et al., 2010). Their detection promotes gender-specific behavior, including territorial aggression when detected by other males and attraction when detected by females (Chamero et al., 2007; Roberts et al., 2010), as well as gender-neutral behavior, acting to facilitate conditioned place preference (Roberts et al., 2012). While strain-specific MUPs additionally constitute a context-dependent combinatorial code that

governs multiple social behaviors in mice (Kaur et al., 2014), MUP orthologs emitted from heterospecifics are sufficient to signal VNO-mediated innate fear (Papes et al., 2010).

To identify gender-specific bioactive ligands, subtractive gas chromatography–mass spectrometry (GCMS) methods were used to screen for compounds enriched in urine from intact males compared to androgen-negative castrated male urine. This approach identified several volatile VNO-activating ligands including isoamylamine (IAA), isobutylamine (IBA), 3,4-dehydro-exo-brevicomin (DHB), 2-sec-butyl-4,5-dihydrothiazole (SBT), 6-hydroxy-6-methyl-3-heptanone (HMH), and  $\alpha/\beta$ -farnesene (Nishimura et al., 1989; Novotny et al., 1999b; Schwende et al., 1986). All of these small molecules bind MUPs which likely act as carriers to transport them into the VNO lumen (Novotny et al., 2007). Unbound, they have all been shown to directly activate V1R expressing neurons, some at as little as  $10^{-11}$  M concentration (Boschat et al., 2002; Leinders-Zufall et al., 2000). SBT,  $\alpha/\beta$ -farnesene, and HMH are excreted in male urine and have been shown to promote female puberty acceleration (Jemiolo et al., 1986; Novotny et al., 1999a; Novotny et al., 1999b, although see Flanagan et al., 2011) while DHB and 2-heptanone are emitted by females to delay estrus or puberty (Jemiolo et al., 1989; Jemiolo et al., 1986; Novotny et al., 1999b). DHB,  $\alpha/\beta$ -farnesene, and 2-heptanone have been shown to direct social behavior in several evolutionarily diverse species, including insects (Goodwin et al., 2006; Papachristoforou et al., 2012; Schulz et al., 2003; Silk et al., 2010).

Biochemically fractionating urine and assaying corresponding VNO neural response led to the purification of sulfated steroids as a potentially large family of VNO ligands whose activity could account for eighty-percent of the total activity of female urine (Nodari et al., 2008). The ligands primarily activate apical (V1R-expressing) neurons (Isogai et al., 2011; Celsi et al., 2012). Steroid hormones are sulfated to facilitate their clearance and therefore reflect the dynamic physiological state of an individual (Hanson et al., 2004). These ligands include androstan-, androsten-, cholestan-, estratrien-, pregnan-, and pregnen-families of sulfated steroids which collectively have the potential to transmit many qualities about an individual's physiological state (Nodari et al., 2008). A blend of three sulfated steroids are said to act as a migratory pheromone in the lamprey, however it is unknown if sulfated steroids function individually or as a blend in the mouse (Fine and Sorensen, 2008; Sorensen et al., 2005).

The identification of FPRs as exclusively expressed in VNO sensory neurons initiated the discovery of formylated-peptides and inflammation-related ligands as chemosensory cues (Liberles et al., 2009; Rivière et al., 2009). Currently, little is known about the function of these

diverse ligands, but they are likely to signal the pathogenic state of individuals (Arakawa et al., 2011). The mouse VNO expresses approximately over 250 different sensory receptors (V1Rs, V2Rs, and FPRs) and the known stimuli have been shown to be detected by a single, highly-tuned receptor (Haga et al., 2010; Leinders-Zufall et al., 2000; Nodari et al., 2008). If each receptor functions to detect a single salient cue then the majority of VNO ligands are still largely unknown.

## 51.4 CIRCUITS AND INFORMATION PROCESSING

Relative to other sensory systems, little is known about either the anatomy or function of VNO-responsive neural circuits. In mammals, sensory information is primarily processed in the cortex by neurons that enable associative learning and a plastic response to stimuli, both within and across individuals. In contrast, the behavioral response to semiochemicals is relatively invariant and highly conserved among individuals. Aligning with these behavioral observations, the circuits activated by the VNO are not traditional cortical structures. Instead, they primarily activate processing networks in the limbic system which utilize more hardwired mechanisms as compared to the cortex (Meredith, 1991; Scalia and Winans, 1975). Further, the circuits activated by VNO stimuli are thought to be relatively “simple” consisting of three primary processing relays between sensory input and output command. The processing centers include the accessory olfactory bulb (AOB), amygdala, and hypothalamus (Figure 51.2) (Lo and Anderson, 2011). Recent knowledge, however, is revealing that the circuit processing of VNO stimuli is likely to be more complex than was previously assumed, as it is influenced by both modulator and feedback mechanisms that enables variable, state specific responses, to VNO stimuli. Further identification and study of VNO stimulated circuits will be necessary to determine how the chemical environment is transformed into a biologically meaningful code that generates emotional behavior and neuroendocrine changes.

### 51.4.1 The Accessory Olfactory Bulb

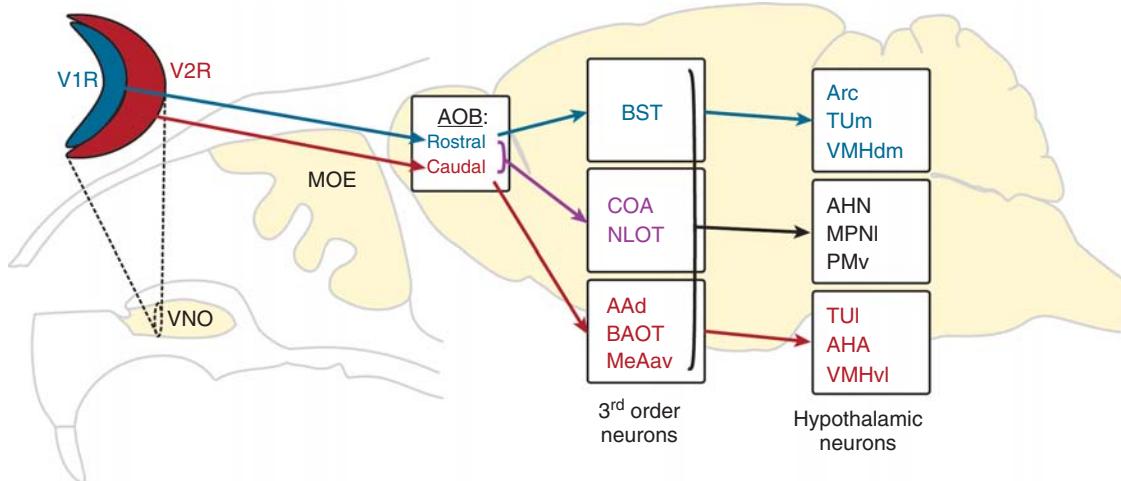

Forming the vomeronasal nerve, VSN axon bundles pass through the cribriform plate and target a specialized region at the dorsal/caudal end of the olfactory bulb; the accessory olfactory bulb (AOB; Fig. 51.2). Each of the functional subsets of VSNs remains segregated in two distinct regions of the AOB (Chamero et al., 2012). V1R expressing neurons co-express OCAM and synapse on OCAM-negative expressing mitral cells located in the rostral half of the

AOB, while the V2R expressing cells lack discernible OCAM expression and synapse with OCAM-positive second-order output neurons, mitral cells, found in the caudal half of the AOB (Jia and Halpern, 1996; Mori et al., 2000). VSNs expressing a single type of VR converge with dendrites of mitral cells in 6–10 glomeruli, distributed in broad regions of the AOB (Del Punta et al., 2002b). Some glomeruli are exclusively innervated by neurons expressing the same VR (Del Punta et al., 2002b), while others coalesce with different, but likely closely related, VSNs (Wagner et al., 2006). This glomerular organization of VSN-to-mitral cell connectivity in the AOB likely serves to integrate incoming sensory information (Belluscio et al., 1999; Rodriguez et al., 1999).

The mechanisms underlying VSN axonal pathfinding to select AOB glomeruli are not well understood. Clearly, both the formation of an AOB glomerular map and VSN survival depend on VR expression (Belluscio et al., 1999). In addition, three of the four prominent and highly conserved families of attractive and / or repulsive axon guidance cues – netrins, semaphorins, ephrins, and slits (Bashaw and Klein, 2010; Yu and Bargmann, 2001) – have been implicated VSN axon navigation. Attractive interaction between EphA6 receptor tyrosine kinases on mitral cell dendrites and cell surface-associated ephrin-A5 ligands on V1R-expressing VSNs mediate axon guidance to the anterior AOB, a mechanism opposite to the frequently observed repulsive interactions between Eph receptors and ligands (Knöll et al., 2001). Chemorepulsive mechanisms, however, also function in segregated VSN pathfinding. Secreted semaphorins act on neuropilin-2 (Npn-2) receptors expressed in apical VSNs (Cloutier et al., 2002) and are required for axon fasciculation and segregation, whereas another secreted chemorepellent, Slit-1, activates Robo-2 receptors that mediate basal VSN axon targeting to the posterior half of the AOB (Prince et al., 2009). Notably, Npn-2 and V1Rs play distinct and complementary roles in promoting AOB wiring as the phenotypic defects in *Npn-2<sup>-/-</sup>* mice and animals lacking individual *V1rs* do not match (Cloutier et al., 2002).

In mice and rats, a morphologically distinct AOB primordium is first detected at E15 and E16, respectively (Knöll et al., 2001; Marchand and Bélanger, 1991) and prenatal formation of the AOB vomeronasal nerve layer has been reported (Knöll et al., 2001). The critical period for fine-tuning of AOB wiring and for formation of well-defined glomeruli, however, occurs after axonal coalescence during the first four to six postnatal days (Hovis et al., 2012; Salazar et al., 2006). During this period, development of precise connectivity appears strongly modulated by early VSN activity (Hovis et al., 2012).

As pointed out by Dulac and Wagner, the basic biology of the AOB is almost unexplored and any functional analogy with neurons / circuits of the main olfactory

**Figure 51.2** Circuits implicated in processing VNO stimuli. Ligands activate a subset of sensory neurons in either the apical, blue, or basal, red, zone of the VNO. The axons from each zone project to glomeruli in spatially distinct regions of the AOB. Some second order mitral cells maintain the apical/basal dichotomy as they project to amygdalar regions, red and blue text, while other amygdalar regions receive information from both zones of the AOB, purple text. The amygdala acts as an information processing hub, which can alter activity throughout the brain, however the hypothalamus has been shown to be a necessary third order target. Regions within the hypothalamus including the Arc, TU, VMH, and AHA maintain the apical and basal segregation established at the periphery suggesting a functional dichotomy within these nuclei. AA, anterior amygdala; AHA, amygdalo-hippocampal area; AHN, anterior hypothalamic nucleus; AOB, accessory olfactory bulb; Arc, arcuate nucleus; BAOT, bed nucleus of the accessory olfactory tract; BST, bed nuclei stria terminalis; COA, cortical nucleus amygdala; MeA, medial amygdala; MPN, medial preoptic nucleus; NLOT, nucleus lateral olfactory tract; PM, pre mammillary nucleus; TU, tuberal nucleus hypothalamus; VMH, ventromedial hypothalamus; VNO, vomeronasal organ; d, dorsal; m, medial; a, anterior; v, ventral; l, lateral. (See plate section for color version.)

bulb is mostly speculative (Dulac and Wagner, 2006). As a result, premature extrapolation of anatomical organization and physiological principles from the main to the accessory bulb has seriously hampered an unbiased assessment of AOB neurobiology. Some fundamental differences between both regions were already pointed out in 1901 by Ramon y Cajal (Larriva-Sahd, 2008): (1) the AOB glomerular layer is relatively thick and composed of smaller and less defined confluent glomeruli; (2) AOB projecting neurons share some morphological analogies to the main bulb's mitral / tufted (M/T) cells, but their somata are rarely mitral shaped; and (3) the AOB shows only a rudimentary external plexiform layer. Indeed, AOB glomeruli are surrounded by only a few periglomerular cells, tightly clustered, and highly variable in size (10–30  $\mu\text{m}$  diameter (Tirindelli et al., 2009)). Since “conventional” plexiform layers are largely missing (Salazar et al., 2006), Larriva-Sahd suggested to refer to an external (ECL) and internal (ICL) cellular layer separated by the complex fiber bundles of the lateral olfactory tract (LOT) which conducts axons from both main and accessory bulb projection neurons (Larriva-Sahd, 2008). In each glomerulus, a few hundred VSN axons terminate and release the excitatory neurotransmitter glutamate upon stimulation (Dudley and Moss, 1995). Two basic models for M/T cell glomerular connectivity have been proposed; homo- and heterotypic connectivity. According to the homotypic wiring scheme,

M/T cell primary dendrites exclusively target glomeruli that are activated by VSN populations that share the same chemoreceptor identity (Del Punta et al., 2002b; Hovis et al., 2012). By contrast, the heterotypic connectivity model predicts that M/T cells connect specifically to glomeruli innervated by neurons expressing receptors of the same subfamily (Wagner et al., 2006), leading to a glomerular map of multiple subfamily-dependent domains (Dulac and Wagner, 2006).

M/T cells in the AOB lack an extensive lateral dendritic tree. Instead, they elaborate extensively branched apical / primary dendrites that terminate as multiple tufts in as many as twelve different glomeruli within the homonymous AOB half (Ben-Shaul et al., 2010; Meeks et al., 2010; Takami and Graziadei, 1991; Urban and Castro, 2005; Wagner et al., 2006). Dendritic tuft size and shape are also polymorphic. Dulac and Wagner described elaborated “ball of yarn” – like tufts, basket-like and bush-like tufts, as well as tufts containing only few fine branches, and tufts with a “dead” end (Dulac and Wagner, 2006). Within such glomerular tufts, local regenerative events – “tuft spikes” – occur independently of somatic spiking, suggesting that M/T cell tufts can accommodate local nonlinear synaptic input integration (Urban and Castro, 2005). Interestingly, both subthreshold and suprathreshold excitation was shown to trigger local dendritic transmitter release from AOB M/T cells (Castro and Urban, 2009).

In addition to local dendritic computation, active back-propagation of sodium spikes from the soma to glomerular tufts can synchronize the activity of “sister” M/T cells that share glomerular projections (Ma and Lowe, 2004). With maximum average firing frequencies <50 Hz, AOB projection neurons are relatively slow, yet divergent in their discharge properties (Zibman et al., 2011). Moreover, both transient and persistent firing responses have been recorded from these neurons (Shpak et al., 2012). As M/T cell axon collaterals contact both adjacent projection neurons as well as interneurons in both the anterior and posterior AOB (Larriba-Sahd, 2008), stimulus-locked as well as sustained firing would be transmitted throughout the AOB.

M/T cells form synapses with inhibitory interneurons both at the glomerular level and along the more proximal parts of their primary dendritic trees (Brennan and Kendrick, 2006). While thoroughly investigated in the main bulb (Price and Powell, 1970; Schoppa and Urban, 2003), the AOB dendrodendritic reciprocal synapse between M/T and granule cells – the main class of AOB interneurons (Keverne and Brennan, 1996) – has received less attention, even though it has been attributed a similarly essential role in information processing (Hayashi et al., 1993; Jia et al., 1999; Taniguchi and Kaba, 2001). Strategically located along the basal segments of M/T cell apical dendrites, AOB dendrodendritic synapses appear to primarily provide GABAergic recursive self-inhibition, rather than spreading lateral inhibition (Luo and Katz, 2004). Such local inhibitory feedback was shown to sharpen M/T cell response selectivity (Hendrickson et al., 2008) and generate  $\gamma$ -frequency field potential oscillations in the AOB (Schoppa, 2006; Sugai et al., 1999). Several groups have suggested that a relatively simple relay-like recursive self-inhibition plays a sensory “gating” role that underlies olfactory learning and memory formation (Brennan and Keverne, 1997; Castro et al., 2007; Hayashi et al., 1993; Kaba et al., 1994).

While local field potential oscillations at  $\gamma$ -frequencies are thought to reflect recursive inhibition at the AOB dendrodendritic synapse, slower oscillations at  $\gamma$ -frequencies have been attributed to feedback interactions with central brain areas (Neville and Haberly, 2003). The AOB receives centrifugal inputs from the amygdala, locus coeruleus, and raphe nucleus (Broadwell and Jacobowitz, 1976; Mohedano-Moriano et al., 2012) as well as the bed nucleus of the stria terminalis the horizontal limb of the diagonal band of Broca (Fan and Luo, 2009; Smith and Araneda, 2010). These feedback afferents enter the AOB via the LOT as well as the bulbar core white matter (Larriba-Sahd, 2008) and they were shown to be critical for olfactory memory formation (Keverne and Brennan, 1996). Initially, attention had focused on both noradrenergic and glutamatergic feedback from the locus coeruleus and corticomedial amygdala, respectively. Based on vaginocervical

stimulation during mating, AOB noradrenaline levels remain increased for ~4 hours (Brennan et al., 1995). During this critical period, noradrenaline release mediates plastic changes in synaptic strength at the dendrodendritic synapse (Brennan and Keverne, 1997; Brennan and Keverne, 2004). Mechanistically, early results pointed to noradrenaline-dependent disinhibition of M/T cells via  $\alpha 2$ -receptor-mediated suppression of granule cells (Brennan, 2004; Otsuka et al., 2001). More recent findings suggest, however, that an  $\alpha 1$ -dependent increase in granule cell GABA release inhibits M/T cell firing (Araneda and Firestein, 2006; Smith et al., 2009). Similarly controversial results were obtained when metabotropic receptor targets of glutamatergic feedback were investigated. The jury is still out on many questions about the exact functional consequences of feedback projections, but it seems clear that afferent centrifugal modulation of AOB processing plays an important physiological role in AOS biology.

### 51.4.2 The Amygdala

Second order neurons project from the AOB to the amygdala, an ancient processing system present in lungfish and tetrapods (Kass, 2007; Medina et al., 2011). The amygdala is highly responsive to unexpected stimuli and therefore signals arousal and attention, especially of biologically relevant signals (Pessoa and Adolphs, 2010; Whalen, 1998). In addition, it is thought to serve as a vigilance system, to determine where incoming sensory information falls on the continuum of positive to negative relevancy to an individual’s fitness or survival, and then signals this assessment to the rest of the brain (LeDoux, 2000, 2012; Pessoa and Adolphs, 2010; Salzman and Fusi, 2010).

The amygdala is composed of a heterogeneous group of approximately ten distinct nuclei. Anatomically, these collective nuclei are highly interconnected with each other, the cortex, and the Hypothalamus-Pituitary-Adrenal, HPA, axis. Together they are positioned to act as a “hub” to coordinate the overall brain state (Newman, 1999; Pessoa and Adolphs, 2010). Amygdalar feedback to the cortex is thought to modulate the “upstream” incoming deluge of sensory information in order to focus attention onto significant information. “Downstream” circuits activate the HPA axis to elicit the hormone and neuroendocrine release associated with emotional behavior. These known characteristics of amygdala information-processing generate underlying features observed during VNO-mediated social and survival behavior.

From the AOB, subsets of second order M/T cells directly project to multiple amygdala nuclei including the MeA, COA, BST, NLOT, BAOT, and the AA (Figure 51.2) (Gutierrez-Castellanos et al., 2010; Fig. 51.2), several of which have been functionally implicated in mediating VNO signaling (Bressler and Baum, 1996; Butler et al.,

2011; Kang et al., 2006; Meredith and Westberry, 2004). Notably, while the M/T neurons stimulated by either V1R or V2R sensory neurons both equally project to most of these amygdalar nuclei (Martinez-Marcos and Halpern, 1999; von Campenhausen and Mori, 2000), anatomical and functional evidence suggest that the V1R/V2R segregation established in the AOB is maintained in the anterior MeA and BST (Figure 51.2) (Mohedano-Moriano et al., 2007, 2008). Specifically, cells from the anterior AOB project to the medial-posterior-medial BST, with no cells from the posterior part projecting to this sub nucleus, and cells from the posterior AOB project to the dorsal AA and deep layers of the BAOT and antero-ventral MeA, with no cells from the anterior AOB projecting to these regions (Mohedano-Moriano et al., 2007; Pardo-Bellver et al., 2012). One clue which may help solve the puzzle of this anatomical distinction may come from functional analysis revealing that sub-nuclei of the MeA are activated by distinct stimuli. Odors from the same species activate both the anterior and posterior MeA while odors from different species have been found to activate only the anterior MeA (Meredith and Westberry, 2004). Consistent with mediating biologically-relevant stimuli, anterior MeA inactivation results in deficits in mating, social memory, and social chemoinvestigative behavior (Ferguson et al., 2001; Kondo, 1992; Kondo and Sachs, 2002; Lehman and Winans, 1982; Lehman et al., 1980; Liu et al., 1997). Most amygdalar neurons are molecularly heterogeneous and little is known about their underlying physiology, however, characterization of the MeA cells show them to have anatomical and physiological properties similar to pyramidal cells in the piriform cortex (Bian et al., 2008). Notably, the MeA output neurons are capable of sustained bursting, a characteristic that may underlie prolonged behavioral responses or neuroendocrine release (Bian et al., 2008).

### 51.4.3 The Hypothalamus

The hypothalamus is thought to be the third, and final, processing module for VNO stimuli prior to circuits that mainly subserve the generation of motor patterns or neuroendocrine release. The hypothalamus is composed of multiple nuclei that function to maintain homeostasis (such as hunger, thirst, temperature, or blood pressure) by releasing hormones to direct the actions of the pituitary (Besser and Mortimer, 1974). It also functions to release the motor patterns that underlie behavioral responses including fear, aggression, mating, and sleep (Adams, 2006; Canteras et al., 1997; LeDoux, 2012; Lin et al., 2011; Motta et al., 2009). Neural activity from the MeA can directly engage the hypothalamus (Adams, 2006; Canteras et al., 1997; Choi et al., 2005; LeDoux, 2012; Lin et al., 2011; Lo and Anderson, 2011; Motta et al., 2009; Pardo-Bellver et al.,

2012; Petrovich et al., 2001). Alternatively, the signal can be further processed by either the BST, a region which is thought to integrate homeostatic and sensory information (Dong et al., 2001; Dumont, 2009) or by the hippocampus, which may serve to prioritize behavioral response to multiple, behaviorally conflicting, VNO stimuli (Petrovich et al., 2001). Notably, the different circuits established by V1R/V2R activity are maintained both anatomically (Mohedano-Moriano et al., 2008; Pardo-Bellver et al., 2012; Petrovich et al., 2001) and functionally in some hypothalamic nuclei (Fig. 51.2) (Bian et al., 2008; Lin et al., 2011).

Neurons in both the amygdala and the hypothalamus express receptors that detect and respond to peptides and other neural modulators. These include steroid hormones (estrogen, testosterone) (Blake and Meredith, 2011; Merchenthaler et al., 2004; Mitra et al., 2003), peptide hormones (NPY, substance P, oxytocin, GNRH, ACTH) (Ferguson et al., 2001; Jennes and Conn, 1994; Van Pett et al., 2000; Wood and Swann, 2005), and small molecule neurotransmitters (dopamine, serotonin) (Fremeau et al., 1991; Lemberger et al., 2007; Schiller et al., 2006). It is known that these receptors enable VNO activated circuits to modulate hard-wired aspects of their response to account for an individual's state (dominance, gender, hunger, and stress levels). However, precisely how neuromodulators alter circuit activity is currently unknown.

It is well established that the behavior elicited by VNO signaling varies depending on the gender of the receiving animal (Baum, 2009; Segovia and Guillamon, 1993; Stowers and Logan, 2010). For example, male-emitted cues elicit aggression when detected by other males but not females. Consistent with these observations, several nuclei within the amygdala and hypothalamus are sexually dimorphic in volume, usually larger in males (based on differences in absolute number, density, and size of individual neurons) (Dulac and Kimchi, 2007; Guillamon and Segovia, 1997; Kawata, 1995). VNO activated circuits have also been demonstrated to be functionally dimorphic (Blake and Meredith, 2011; Halem et al., 2001; Kang et al., 2006; Kimchi et al., 2007; Wu and Shah, 2011). Current studies have begun to determine the molecular mechanisms that underlie gender-dimorphic differences in VNO-activated circuits, though mechanisms remain unknown (Boehm et al., 2005; Gregg et al., 2010; Kimchi et al., 2007; Xu et al., 2012).

## 51.5 EVOLUTION AND DECAY OF THE VNO

The VNO is an evolutionarily ancient system, established prior to taste sensing (Grus and Zhang, 2009). Genetic

analysis of the essential components of VNO signal transduction in living genomes indicates their likely expression in the ancestor of extant vertebrates. *V1rs* and *TrpC2* are expressed in olfactory tissues of the sea lamprey genome indicating they evolved before the divergence of jawless fish and cartilaginous fish. *V2rs* are expressed by the elephant shark and therefore evolved before the divergence of cartilaginous fish and bony vertebrates (Grus and Zhang, 2009). The segregation of these sensory components into a distinct sensory organ, the AOB, occurred with the evolution of tetrapods (Meisami and Bhatnagar, 1998). Expression of VNO signaling elements has been described in all vertebrate lineages except *sirenia*, which has a rudimentary main olfactory system, as well as birds and *cetacea* which also lack main olfactory system (Meisami and Bhatnagar, 1998). Some lineages, such as bats and primates, consist of species that contain a well-developed VNO and other species which lack evidence for VNO function.

Strikingly, the size and anatomy of the VNO and AOB vary dramatically within lineages (Meisami and Bhatnagar, 1998). This variation largely correlates with the magnitudes of the VR gene repertoire (Grus et al., 2005; Young et al., 2010). Indeed, there is a 56-fold variation in *Vr* gene number out of the 37 mammalian species that currently have sufficient genome sequence coverage for analysis. The platypus, mouse, mouse lemur, and rabbit have the largest *V1r* repertoire, each expressing between 160–280 *V1rs* (Grus et al., 2005, 2007; Young et al., 2010); while many diverse genomes contain 60–110 *V1rs* including the other rodents and lagomorphs, bushbaby, treeshrew, shrew, hedgehog, wallaby, and opossum. However, dolphin, little brown bat, and flying fox have no intact *Vrs*, or *TrpC2*, in their genome (Young et al., 2010). Interestingly, although dogs appear to readily sample and utilize olfactory information, their genome only contains 9 *V1rs*. It has been proposed that domestication imposed selective pressure to favor *Vr* inactivating mutations. However, the genome of wild wolves appears similar to the dog indicating that loss of VNO receptors occurred prior to domestication (Young et al., 2010).

While the human genome contains five *V1rs*, they are not likely to function since *TrpC2* underwent inactivating mutations in Old World primates (Liman and Innan, 2003; Zhang and Webb, 2003). This has led to the hypothesis that the evolution of trichromatic vision functioned to eliminate selective pressures on VNO signaling elements (Liman and Innan, 2003). However, analysis of additional primate genomes indicate that *V1r* loss began in the common ancestor of both New and Old World primates, occurring independently of the gain of color vision (Young et al., 2010). Based on known ethological characteristics, gain or loss of *Vrs* has not been found to correlate with body size, nocturnality, diet, sociality, or mating system (Young et al., 2010).

Currently, the selective pressures that result in extreme VR gene duplication or loss remain unknown.

Moreover, the identity of VR expression does not vary predictably across evolution. The known ratio of V1R/V2R receptors is strongly skewed towards the V2Rs in the zebrafish (6/46) and frog (21/330) (Brykczynska et al., 2013). In contrast, most other sequenced genomes are biased to express V1Rs including platypus (283/15), cow (40/0), and mouse (239/121) (Brykczynska et al., 2013; Grus et al., 2007). It has been noted that the strategy of receptor bias switched from V2R to V1R upon water to land habitation, however, more recent analysis of the VR ratios of terrestrial lizard (1/37), and snake (4/116) do not support this hypothesis and the underlying logic of receptor bias remains unknown (Brykczynska et al., 2013; Shi and Zhang, 2007).

In addition to the variance of their absolute numbers, the identity of the *Vr* genes in sequenced genomes has undergone rapid and substantial changes between species (Brykczynska et al., 2013; Grus and Zhang, 2004; Young et al., 2010). Eighty percent of analyzed *V1rs* have a more similar gene in the same genome (paralogs) than in any other species (orthologs) (Young et al., 2010). Even in closely related species such as mouse and rat in which 86–94% of rat genes have mouse orthologs, only 11% of the rat *V1rs* have mouse orthologs (Grus and Zhang, 2004, 2008). Analysis of these changes shows weak purifying selection and random drift, with only about 5% of analyzed *V1rs* having undergone positive selection (Park et al., 2011). Frequent gene duplication and pseudogenization has been found to occur rapidly following divergence of two species (Grus and Zhang, 2004). These characteristics result in a “semi-private” repertoire of species-specific VNO receptors (Young et al., 2010) and support the hypothesis that the VNO functions to detect and convey information about species-relevant ligands.

## 51.6 FUNCTIONAL SIGNIFICANCE OF THE VNO

Since its discovery, the functional relevance of the VNO has posed a mystery. It is not known why most terrestrial vertebrates have at least two distinct olfactory systems; the VNO and the MOE. Species such as humans, that do not possess a functional VNO, demonstrate that the MOE alone is sufficiently sensitive and complex to generate olfactory perceptions and guide behavior. Currently, the functional significance of a secondary olfactory system, the VNO, remains unknown.

Comparison of the two systems shows MOE sensory neurons primarily excite cortical centers, while those from the VNO activate limbic centers (Lo and Anderson, 2011; Stettler and Axel, 2009). This striking difference in the

flow of neural activity led Cajal to first speculate that (the AOB) “is a special center, perhaps differentiated for receiving impressions of some particular kind of olfactory excitation” (Cajal, 1901). Early investigators additionally noted that most terrestrial vertebrates detect and respond to specialized chemosignals that transmit ethologically relevant information among and between species. When considered together, the circuit anatomy of the VNO appeared well suited to mediate such responses. The formal test of this hypothesis was enabled by molecular genetics. Ablation of the primary signal transduction channel of the VNO, *TrpC2*, prevents VNO sensory neurons from responding to many ligand sources. Male *TrpC2*<sup>-/-</sup> mutants have no defects in courting and mating females, which is thought by some to be facilitated by so-called pheromonal cues (see Doty, 2010). However, mutants are unable to initiate territorial aggression or establish dominance hierarchies; behaviors dependent on semiochemicals (Leybold et al., 2002; Stowers et al., 2002). Mutant females show various defects in mating and maternal behavior (Kimchi et al., 2007). Similarly, the MOE can be silenced by genetic ablation of the primary signal transduction channel, *Cnga2* (Brunet et al., 1996). When assayed for putative pheromone-mediated behavior, *Cnga2*<sup>-/-</sup> mutant mice are unable to initiate aggression, both males and females fail to mate, and newborn pups die of dehydration, being unable to detect maternal olfactory cues necessary to initiate suckling (Brunet et al., 1996; Logan et al., 2012; Mandiyan et al., 2005). Together, these studies show that while the VNO is capable of mediating an innate response to ethologically relevant odor cues, the MOE serves this function as well. Therefore, the VNO is not uniquely specialized for chemicals some consider to be “pheromones.”

Another striking difference between the two olfactory systems comes from sequence analysis of VNO receptors. Unlike the MOE, where there are orthologous receptors across divergent species, the receptors of the VNO appear to rapidly evolve between species, creating VNO receptor repertoires that are largely specific to one species (Grus and Zhang, 2004, 2008). It is likely that this customized receptor expression enables each species to recognize chemical cues that are of particular relevance to their survival and fitness.

Stimulation of the mouse VNO can have an immediate “releasing” effect to generate behavior (Bronson 1979, Dulac and Torello, 2003). Detection of cues emitted by strange male mice release aggression and countermarking behavior with a variable latency, on the order of seconds-minutes. Likewise, in the female, VNO stimulation can result in heterosexual attraction and lordosis, a receptive mating posture. In addition, the VNO detects cues emitted by other mice that can act over days to slowly change a recipient’s neuroendocrine physiology (Bronson,

1979, Dulac and Torello, 2003; see, however, Doty, 2010). No so-called priming cues have been described to impact male behavior, but the detection of male-emitted cues may prime a female to synchronize and accelerate the estrus cycle, and advance the onset of estrus in juveniles, while detection of female-emitted cues may prolong diestrus thereby delaying entry into estrus. Females emit volatile chemicals that promote receiving females to slow or even abort the estrus cycle. When colony size is optimal, males emit volatiles that may counter their action, ensuring short estrus cycles and regular fecundity. However, when the colony becomes too large, females in each social group greatly outnumber males and the estrus delaying agents may become effective, slowing the rate of further colony expansion.

The mouse VNO may also play an important role in detecting kairomones, which are ligands emitted by one species that elicit a behavior to advantage the receiver of another species (Ben-Shaul et al. 2010; Isogai et al., 2011; Papes et al., 2010). Indeed, out of 88 receptors found to be stimulated by ethologically relevant odors, only 17 are activated by cues emitted by other mice while 71 have been found to be activated by scents emitted by other species (Isogai et al. 2011). The behavioral significance of the detection of other species cues varies depending on whether the species is a predator, prey, or neutral. The mouse VNO is known to detect cues from likely predators. Upon detection, they function to elicit defensive behaviors such as avoidance and an increase in ACTH stress hormones (Papes et al. 2010, Isogai et al. 2011).

It is tempting to speculate that the chemosignals mediating essential behaviors common to many different species, such as mammalian newborn suckling or the general act of mating, are detected by the dominant MOE system. The VNO, on the other hand, may detect and transmit cues that elicit behaviors that are not common to many species. Instead it may function to promote species specific behavior such as those to facilitate mating, for example urine marking and lordosis, which are sexual behaviors common to the mouse but not essential to successful mating in all vertebrates, or to respond to other species as appropriate predator or prey, such as a mouse’s particular need to avoid a cat. In this hypothesis, the functions of the VNO would vary between species according to their specific ethological needs. Currently, the functional significance of the evolutionarily ancient and genetically costly sensory system remains to be identified.

# Chapter 52

---

## The Septal Organ, Grueneberg Ganglion, and Terminal Nerve

MINGHONG MA, JOERG FLEISCHER, HEINZ BREER, and HEATHER EISTHEN

### 52.1 INTRODUCTION

All vertebrate animals develop complicated chemosensory systems to detect a myriad of chemical cues signaling potential food, mates, and danger. In most non-human animals, the nose – a seemingly unitary organ – contains distinct receptors for multiple chemosensory systems. Besides the main olfactory epithelium (MOE), afferents from the trigeminal nerve (CNV), and the vomeronasal organ (VNO), many mammalian species possess two spatially segregated clusters of sensory cells in the nasal cavity forming the septal organ of Masera (SO) and the Grueneberg ganglion (GG) (Figure 52.1). Each of these chemosensory subsystems detects distinct but overlapping olfactory cues. Interestingly, the SO and GG neurons are polymodal; they convey other sensory modalities mediated by mechanical and thermal stimuli, respectively. The key features of the SO and GG will be discussed in Section 52.2 and 52.3, respectively, including their chemoreceptors, signal transduction cascades, central projections, and functional roles.

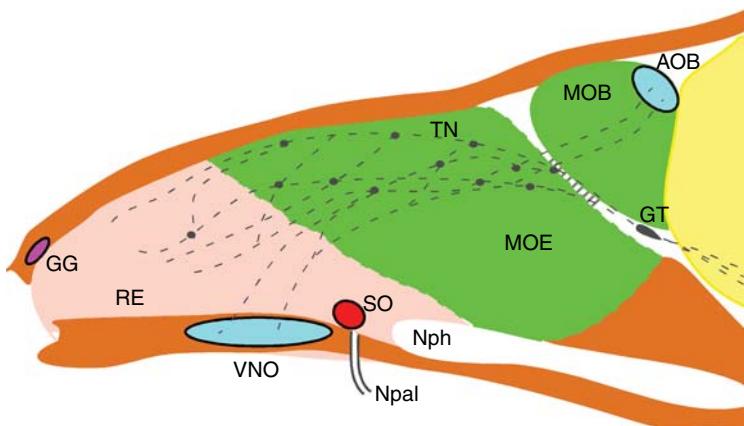

In addition, animals constantly adjust their sensory responses according to their internal status and external environment, partly achieved via centrifugal modulatory pathways. Activity in the olfactory epithelium is modulated by the terminal nerve (TN), which releases peptides, including gonadotropin-releasing hormone (GnRH; Figure 52.1). Section 52.4 of this chapter reviews the modulatory function of the TN system.

### 52.2 THE SEPTAL ORGAN (SO)

The SO is a small island of olfactory epithelium lying bilaterally at the ventral nasal septum near the entrance

of nasopharynx (Figure 52.1). It was first described in newborn mice by Broman (1921) and subsequently characterized in detail by Rodolfo-Masera (1943). The SO has not been demonstrated in primates, including humans, but is found in many mammals, including rabbit, rat, mouse, hamster, deer mouse, guinea pig, opossum, bandicoot, and koala (Rodolfo-Masera, 1943; Adams and McFarland, 1971; Bojsen-Møller, 1975; Katz and Merzel, 1977; Breipohl et al., 1983, 1989; Kratzing, 1984a,b; Taniguchi et al., 1993), but not in cat or ferret (Breipohl et al., 1983; Weiler and Farbman, 2003). The SO resembles the MOE in the cellular composition; it is composed of ciliated olfactory sensory neurons (OSNs), microvillar cells, supporting cells, and Bowman's glands (Graziadei, 1977; Miragall et al., 1984; Kratzing, 1984a,b; Breipohl et al., 1989; Adams, 1992; Taniguchi et al., 1993; Giannetti et al., 1995a).

During development, the SO first appears around embryonic day E16 in both rat and mouse (Giannetti et al., 1995a; Oikawa et al., 2001; Tian and Ma, 2008b). At this stage, the MOE is separated from the respiratory epithelium with a well-defined boundary and some olfactory marker protein (OMP)-positive cells start to cluster in the presumptive SO region. From E18 to postnatal day 7 (P7), OMP-positive OSNs continue to accumulate in the SO, accompanied by the gradual disappearance of the OMP-GFP cells in the transitional zone between the SO and the MOE (Tian and Ma, 2008b). The SO continues to develop postnatally and reaches its peak in size between 2 to 4 months (Weiler and Farbman, 2003). Recent years have witnessed significant advances in our understanding of the molecular and functional organization of this enigmatic organ.

**Figure 52.1** Schematic drawing of the mid-sagittal view of the nasal cavity illustrates multiple chemosensory organs in the rodent nose. MOE = main olfactory epithelium; MOB = main olfactory bulb; VNO = vomeronasal organ; AOB = accessory olfactory bulb; SO = septal organ; RE = respiratory epithelium; GG = Grueneberg ganglion (GG); Npal = nasopalatine duct; Nph = nasopharynx; TN = terminal system; GT = ganglion terminale. The trigeminal system is not shown.

### 52.2.1 Odorant Receptors and Signal Transduction

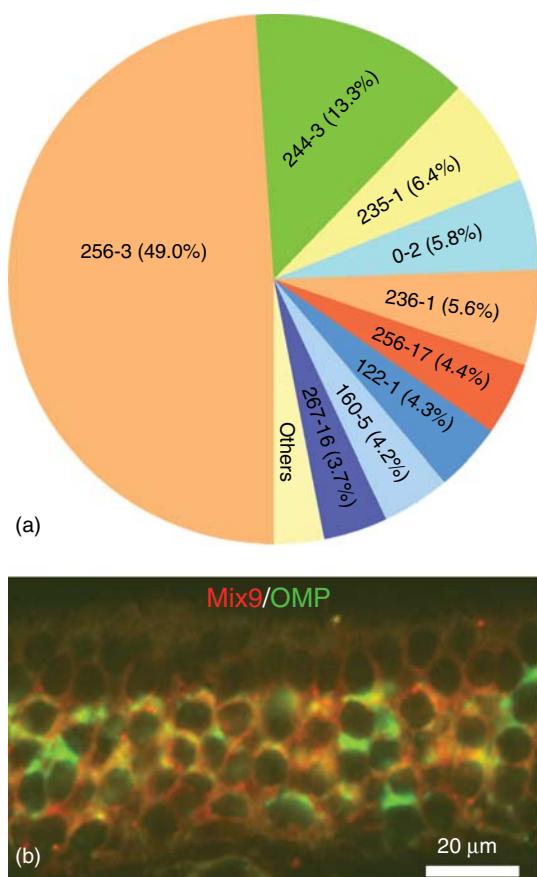

Surprisingly, the septal organ predominantly expresses only a handful of odorant receptors (ORs) out of a repertoire of ~1200 in mouse. Using the cDNA cloning approach, two groups identified more than 120 candidate OR genes from the mouse SO (Kaluza et al., 2004; Tian and Ma, 2004). However, the expression levels of individual OR genes vary dramatically, confirmed by a customized Affymetrix genechip covering all the mouse OR genes (Zhang et al., 2004) and *in situ* hybridization. The most abundant OR, SR1 (also termed MOR256-3 or Olfr124), is expressed in nearly 50% of the SO neurons. Each of the other eight ORs (MOR267-16, 122-1, 160-5, 236-1, 256-17, 0-2, 235-1 and 244-3 from low- to high-abundance) is expressed approximately in 3.7% (MOR267-16) to 13.3% (MOR244-3) of the SO neurons (Figure 52.2A). Together, these nine OR types account for >90% of the SO neurons (Figure 52.2B). All nine abundant septal organ ORs are also expressed in the most ventrolateral zone of the MOE, even though the relative abundance does not match that in the septal organ (Tian and Ma, 2004).

The unusually high density of SR1 neurons in the SO raises the question whether a single cell expresses a single OR type. Double *in situ* hybridization experiments with combined OR probes reiterate the one cell-one receptor tenet with few exceptions (Tian and Ma, 2004). Interestingly, the coexpression frequency of SR1 vs. a mixture of the remaining eight ORs in single neurons is nearly ten times higher in newborn mice (2.0% at P0 vs. 0.2% at P28), suggesting a reduction of the sensory neurons with multiple ORs during postnatal development. In addition, such reduction is prevented by four-week sensory deprivation or impaired apoptosis, indicating that activity induced by sensory inputs plays a role in ensuring the one cell-one receptor rule in a subset of OSNs in the nose (Tian and Ma, 2008a).

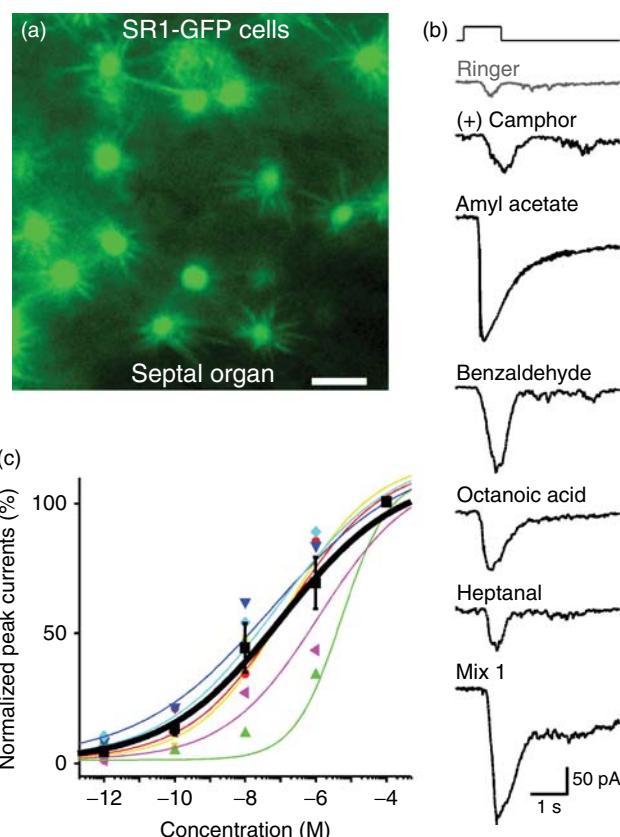

Most SO neurons express the olfactory G protein ( $G_{olf}$ ) and type III adenylyl cyclase (ACIII), revealed by antibody staining (Ma et al., 2003). This suggests that signal transduction in the SO is mediated by the canonical cAMP pathway, which is further supported by patch clamp recordings from individual OSNs in this region. Odorant responses were mimicked by an adenylyl cyclase activator and a phosphodiesterase inhibitor, blocked by an adenylyl cyclase inhibitor, and eliminated in cyclic nucleotide-gated (CNG) channel knockout mice (Ma et al., 2003; Grosmaire et al., 2007). Thus, the SO resembles the MOE in signal transduction, but represents a much simpler system by predominantly expressing a small fraction (~1%) of the OR repertoire.

### 52.2.2 Central Projections

The SO neurons give rise to a few axon bundles that travel across the cribriform plate and terminate in the main olfactory bulb (MOB). In rats, focal injection of horseradish peroxidase (HRP) in the MOB results in labeled cells in the septal organ (Pedersen and Benson, 1986), while injection of HRP in the SO traces the axons to the posterior, ventromedial olfactory bulb with a few densely labeled and many lightly labeled glomeruli (Astic and Saucier, 1988; Giannetti et al., 1992). More recently, these findings were confirmed by placing lipophilic dyes (such as DiI) in the SO (Levai and Strotmann, 2003; Ma et al., 2003). The densely labeled glomeruli (so called “septal” glomeruli) receive inputs mainly (if not exclusively) from the SO, while the lightly labeled glomeruli receive mixed inputs from the SO and the MOE. The projection pattern of the SO is consistent with the fact that this region expresses a few ORs at high densities and many other ORs sparsely. The cortical regions that receive inputs from the mitral/tufted cells innervating the “septal” glomeruli remain to be determined.

**Figure 52.2** The septal organ predominantly expresses nine odorant receptors. (a) The relative contribution of these nine odorant receptors in the septal organ of one-month old mice. The percentage for MOR256-3 (SR1) and MOR244-3 cells was determined by double *in situ* hybridization against the OMP probe and the percentage for other receptor cells was calculated by normalizing their cell densities to that of MOR244-3 cells (Tian & Ma, 2004; 2008b). (b) The mixed probes from these nine odorant receptors labeled >90% of OMP-positive neurons in the septal organ section. Adapted from (Tian and Ma, 2008b). (See plate section for color version.)

**Figure 52.3** SR1 cells in the septal organ respond broadly and over a wide concentration range. (a) The image was taken under fluorescent illumination of the septal organ from an SR1-IRES-tauGFP mouse. Scale bar, 5 μm. (b) A single SR1 cell responded to all five odorants at 1 μM, and to Mix 1 at 1 μM, under voltage-clamp mode. The gray trace (Ringer) was the mechanical response induced by a Ringer puff that was delivered with the same pressure as the odorant puffs. (c) The dose–response curve for amylo acetate was averaged from six SR1 cells. The holding potential was  $-65\text{ mV}$  for all neurons. Each colored line (and the corresponding symbols) represents the data from a single cell, and the thick black line represents the averaged curve from all six neurons. Error bars indicate SEM. Adapted from (Grosmaitre et al., 2009). (See plate section for color version.)

### 52.2.3 Odorant Response Properties

Although the SO primarily covers a small fraction of the OR repertoire, most SO neurons (~70%) are surprisingly responsive to diverse chemicals with different size, shape, and functional groups, as revealed in patch clamp recordings (Grosmaitre et al., 2007; Grosmaitre et al., 2009). These neurons are extremely sensitive to some odorants with a nanomolar threshold and a wide dynamic range covering 3~4 log units of concentration from threshold to saturation (Figure 52.3). This is consistent with a previous EOG study in which the SO was found to respond to many chemicals with a lower threshold than the MOE (Marshall and Maruniak, 1986).

Because SR1 is expressed in 50% of the SO neurons, it is plausible that SR1 confers broad tuning to its host OSNs. This concept is supported by three pieces of evidence. First, all SR1 neurons (genetically labeled for identification, Figure 52.3a), regardless of their location in the SO or in the MOE, are broadly responsive and sensitive (Figure 52.3b,c). Second, genetic deletion of SR1 results in OSNs that are mostly narrowly-tuned to odorants. Third, when expressed in a heterologous cell line, SR1 shows broad response spectrum (Grosmaitre et al., 2009). However, SR1 is not the only broadly-tuned OR in the SO, because more than half of the non-SR1 neurons are also broadly-responsive (Grosmaitre et al., 2009). A recent

study confirms that another SO receptor, MOR256-17, is broadly-tuned in a heterologous system (Li et al., 2012). The SO also contains OSNs that are highly selective. For instance, MOR244-3 (the second most abundant OR in the SO), when expressed in heterologous cells, responds to (methylthio)methanethiol (MTMT), a semiochemical in the male urine that appears to attract female mice. As expected, a significant portion of the non-SR1 neurons in the SO responded to MTMT in patch clamp recordings (Duan et al., 2012). It appears that mammalian ORs and their host OSNs show diverse tuning properties, ranging from highly selective (e.g., MOR244-3) to broadly responsive (e.g., SR1 and MOR256-17).

Situated in the direct air path and packed with broadly-responsive OSNs, the SO may serve as a general odor detector and/or a sensor of the total odor concentration to “alert” the organism, a function originally proposed by Rodolfo-Masera (1943). Nevertheless, the potential alerting role was not verified in a behavioral study with surgical removal of the septal organ (Giannetti et al., 1995b), which could be due to the existence of broadly tuned OSNs in the MOE. An alternative and complementary hypothesis suggests that the septal organ may function as a “mini-nose” in surveying food odors as well as social cues (Breer et al., 2006). The finding that the SO contains MOR244-3 neurons which respond to MTMT supports its role in detecting social cues. It is plausible that this enigmatic organ serves multiple chemosensory roles.

#### 52.2.4 Mechanosensitivity of Olfactory Sensory Neurons

Another novel finding arising from the SO is that many OSNs respond not only to odorants, but also to mechanical stimuli delivered by pressure ejections of odorant-free Ringer’s solution (Grosmaitre et al., 2007). The mechanical responses directly correlate with the pressure intensity and similar mechanosensitivity also exists in a subset of OSNs in the MOE. Several lines of evidence support that odorant receptors are required in mechanosensitivity of mouse OSNs. First, genetic ablation of key signaling proteins in odor transduction completely eliminates mechanical responses in OSNs. Second, mechanosensitivity is associated with certain odorant receptor types. OSNs expressing SR1, I7 or M71 are mechanosensitive while those expressing MOR23 and mOR-EG are not. Third, loss-of-function mutation of the I7 receptor or genetic ablation of the SR1 receptor abolishes or significantly reduces mechanical responses in the host OSNs (Connelly et al., 2015). It remains to be determined whether odorant receptors serve as mechanical sensors as well as odor detectors.

The mechanosensitivity found in the OSNs is particularly interesting because these neurons could provide airflow information during breathing and sniffing, which is known to be required by the olfactory system when actively sampling external stimuli (Buonviso et al., 2006; Schaefer and Margrie, 2007; Wachowiak, 2011). An odorant signal can be interpreted differently, depending on whether it is due to a strong or weak sniff. For instance, when the air flows faster in the nose, such as during a powerful sniff, the mechanical response can enhance the firing probability and frequency of individual OSNs that are weakly stimulated by odorants. Furthermore, the mechanosensitivity of OSNs may drive the synchronization of the olfactory bulb activity (theta-band oscillation) with the breathing cycle, even in the absence of odorants (Grosmaitre et al., 2007). The SO can thus serve as an airflow sensor in addition to its chemosensory roles.

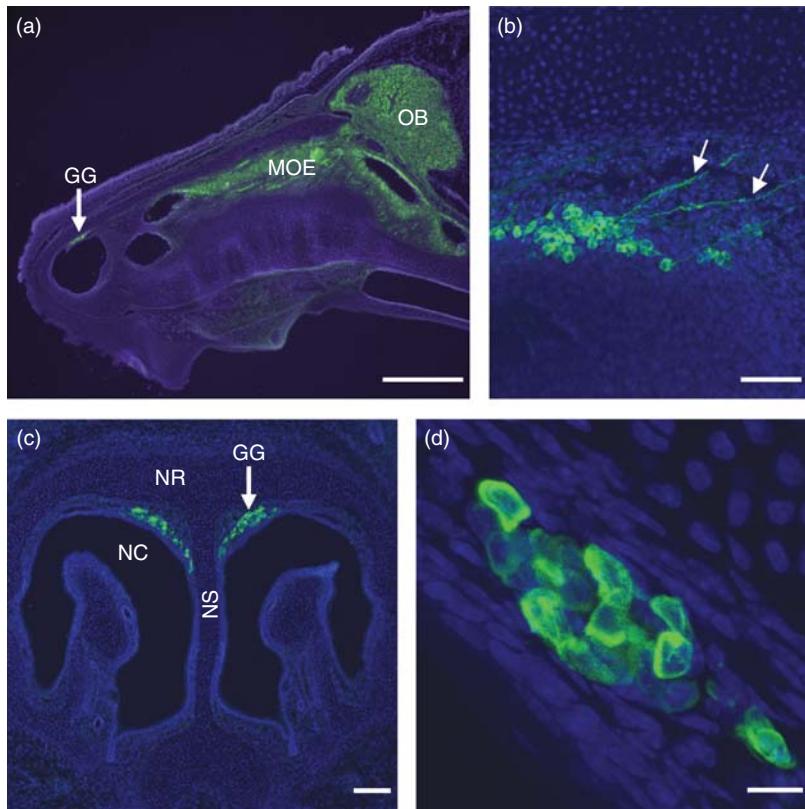

### 52.3 THE GRUENEBERG GANGLION (GG)

Mature sensory neurons in the MOE and VNO are characterized by the expression of olfactory marker protein (OMP). Recently GG neurons were also found to express OMP (Fuss et al., 2005; Koos and Fraser, 2005; Fleischer et al., 2006a; Roppolo et al., 2006; Storan and Key, 2006). The GG, which was named after Hans Grüneberg who first described it (Grüneberg, 1973), has been studied almost exclusively in mice and it is yet unclear whether it exists in other mammals.

#### 52.3.1 Morphology of the GG

In the murine nose, the GG is situated bilaterally in the nasal vestibule, adjacent to the opening of the naris (Figure 52.4a,b). The GG has an extent of a few hundred micrometers along the rostral/caudal axis; it resides between the levels of the orifices of the lateral nasal gland (*glandula nasalis lateralis* or Steno’s gland) and the *glandula nasalis medialis*. It is surrounded by the nasal roof, the septum, and a thin epithelial layer lining the lumen of the nasal cavity (Grüneberg, 1973; Fuss et al., 2005; Koos and Fraser, 2005; Fleischer et al., 2006a; Roppolo et al., 2006; Storan and Key, 2006) (Figure 52.4c).

Two distinct cell types are present in the GG. The first type, hereinafter designated as GG neurons or GG cells, has a round to oval or elliptical shape (Fuss et al., 2005; Koos and Fraser, 2005; Roppolo et al., 2006; Storan and Key, 2006) and expresses OMP (Figure 52.4d) as well as the neuronal marker  $\beta$ III tubulin (Fleischer et al., 2006a; Brechbuhl et al., 2008). Each GG neuron harbors about 30 to 40 cilia with a length of approximately 15  $\mu\text{m}$  and a diameter of about 0.2  $\mu\text{m}$ . The cilia are arranged into

**Figure 52.4** Morphological arrangement of GG neurons. (a) Sagittal section through the head of a neonatal mouse stained with an OMP-specific antibody. At a position far anterior from the main olfactory epithelium (MOE), OMP-expressing cells in the GG are marked by the arrow (OB: olfactory bulb). (b) Higher magnification image of a sagittal section through the very anterior part of the nose harboring the GG. Axons emanating from OMP-positive GG neurons are indicated by arrows. (c) Coronal section through the anterior nasal region of a newborn mouse stained with an OMP antiserum reveals the bilaterally symmetric arrangement of the GG between the nasal septum (NS), the nasal roof (NR) and the nasal cavity (NC). (d) High magnification of a small group of GG neurons stained with an OMP-specific antibody. Sections are counterstained with DAPI or Toto-3. Scale bars: A = 500 µm; B, C = 100 µm; D = 10 µm. (data from Fleischer et al., 2006b; with kind permission of John Wiley and Sons) (See plate section for color version.)

three to four bundles localized to discrete cellular regions. The structure of these cilia is quite exceptional. Their base is located deep in the cell body; consequently, a substantial portion of the cilia is invaginated into the cytoplasm of the soma (Tachibana et al., 1990; Brechbühl et al., 2008). The cytoskeletal structure of the ciliary axoneme is also unusual: the basal body area comprises 9 triplets of microtubules, the proximal portion of the cilia is composed of a (9+0) microtubule doublet and the more distal regions harbor an 8+1 doublet (Brechbühl et al., 2008). GG neurons and their cilia seem to be largely enveloped by so-called satellite or ensheathing cells, which comprise the second type of cells in the GG. The expression of molecular markers such as the glial fibrillary acidic protein (GFAP) suggests that these cells have a glia-like phenotype (Tachibana et al., 1990; Brechbühl et al., 2008). In addition, GG neurons are embedded in connective tissue that is superimposed by a keratinized epithelial layer (Grüneberg, 1973; Fuss et al., 2005; Koos and Fraser, 2005; Fleischer et al., 2006a; Roppolo et al., 2006; Storan and Key, 2006). Thus, in contrast to other OMP-positive neurons in the nose, GG cells apparently lack any direct access to the nasal lumen and are not part of the nasal epithelium.

Throughout pre- and postnatal development, the morphology of the GG undergoes considerable changes. In perinatal stages of mice, GG cells are arranged in smaller

groups or larger clusters surrounded by the connective tissue of the anterior nasal region. This arrangement becomes evident for the first time at embryonic days 15 and 16 (E15/E16). However, the GG neurons are not born in this connective tissue, but appear to originate in stage E14 from a relatively thick epithelium in the anterior nasal region from which they seem to bud off before penetrating the subjacent connective tissue. In juvenile and adult mice, the ganglion-like structure is transformed into a filiform arrangement of the GG neurons (Fleischer et al., 2006a). Moreover, the approximately 800 GG neurons in perinatal stages decline to less than 700 in adults (Fleischer et al., 2007).

Each GG neuron is endowed with a single axon (Figure 52.4B) that projects to the brain (Fuss et al., 2005; Koos and Fraser, 2005; Fleischer et al., 2006a; Roppolo et al., 2006; Storan and Key, 2006). The first GG axons emerge at about E16 (Fuss et al., 2005). Lesion of the axonal process leads to degeneration of GG neurons. In contrast to OMP-positive neurons in other nasal compartments, GG neurons do not regenerate after axotomy. Consistent with this observation, in experiments using the thymidine analogue BrdU, which labels newly generated cells, only very few stained GG cells were found (Roppolo et al., 2006).

### 52.3.2 Spontaneous Electrical Activity of GG Neurons

Based on their spontaneous firing pattern in extracellular recording experiments, GG neurons have been grouped into three categories (Liu et al., 2012). The first group (~38% of the cells) comprises neurons with a continuous discharge of action potentials with firing frequencies of 10 to 25 Hz. The second group (~29% of the cells) is characterized by bursts of action potentials followed by electrical quiescence, i.e., long inter-burst intervals (0.3 to 2 seconds). The third group (~33% of the cells) shows only sporadic firing of actions potentials. The molecular basis and the functional relevance of these three distinct spontaneous firing patterns is yet unknown.

### 52.3.3 Axonal Projection Patterns of GG Neurons

The GG was initially considered to be part of the terminal nerve (TN) (Grüneberg, 1973) (see Section 52.4). The recent finding that GG neurons express OMP favors the view that the GG might, in fact, belong to the olfactory system. In general, OMP-expressing neurons in the nose project their axons to the olfactory bulb (OB) where they synapse on dendritic processes in round structures called glomeruli. The axons of GG neurons coalesce and form a single or a few tracts that run ipsilaterally along the dorsal roof of the nose, penetrate the cribriform plate and approach the MOB. The axon bundles then project along the medial side of the MOB and diverge into two (or sometimes more) smaller bundles that innervate a small group of glomeruli (up to 10) in the posterior region of the MOB (Figure 52.5). These glomeruli are arranged as a chain-like structure surrounding the rostral part of the accessory olfactory bulb (AOB) which resides on the dorsal and posterior region of the MOB.

To reach the relevant glomeruli, one portion of GG fibers takes a dorsal to lateral route, thus innervating glomeruli in the dorsal and in the lateral aspect of the MOB. The other fibers follow a medial to ventral trajectory and innervate glomeruli in these regions of the MOB. Finally, both bundles reach the most ventral region of the MOB (Fuss et al., 2005; Koos and Fraser, 2005; Fleischer et al., 2006a; Roppolo et al., 2006; Storan and Key, 2006; Matsuo et al., 2012). This axonal projection pattern strongly suggests that the GG does not belong to the terminal nerve system but is part of the olfactory system. Further characterization of the glomerular structures innervated by GG fibers revealed that the presynaptic marker synaptotagmin is already present at birth. This finding indicates an early maturation of the GG circuitry and suggests that the GG may already be functional in newborn animals (Matsuo et al., 2012).

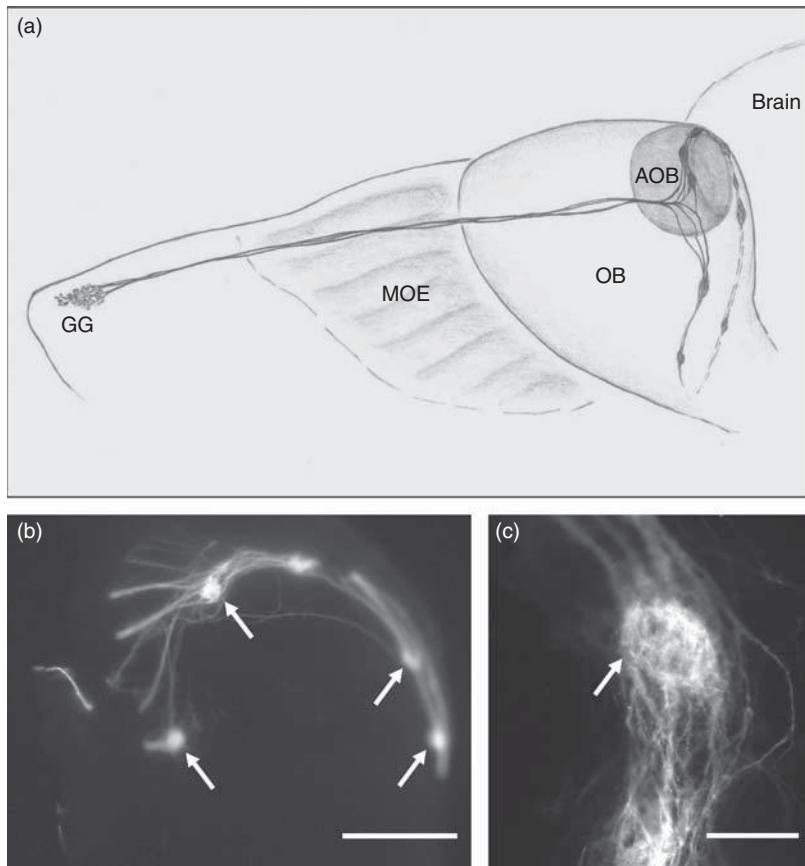

### 52.3.4 Olfactory Signaling Proteins in GG Neurons

Olfactory receptors are necessary to render OSNs responsive to odorants and should be expressed in GG neurons if they also have an olfactory function. Nevertheless, odorant receptors (ORs) are only expressed in very few GG neurons and only at prenatal stages; instead, most GG neurons express the V2r83 receptor (also called Vmn2r1 or V2R2), which belongs to the V2R family of olfactory receptors (Fleischer et al., 2006b) typically expressed in the VNO (Martini et al., 2001). The small subpopulation of V2r83-negative GG neurons expresses members of the trace amine-associated receptors (TAARs); however, only one subtype is expressed in each cell (Fleischer et al., 2007). Thus, similar to OSNs in the MOE (reviewed in Mombaerts, 2004), each GG neuron seems to be endowed with one receptor type only. Expression of V2r83 and TAARs appears to be highest in perinatal stages and diminishes in juveniles and adults (Fleischer et al., 2007).

### 52.3.5 Olfactory Responsiveness of GG Neurons

Since GG neurons share a variety of characteristic features with OSNs in other nasal compartments, including expression of OMP and olfactory receptors as well as axonal projection to the OB, GG neurons might be expected to respond to chemical stimuli. The first evidence for this hypothesis was provided by calcium-imaging experiments indicating that murine GG neurons are activated by so-called alarm pheromones that have been reported to elicit freezing behavior in conspecifics (Brechbuhl et al., 2008). However, the chemical nature of alarm pheromones is so far unknown.

As a more direct approach to identify chemical substances capable of activating GG neurons, a larger array of odorous compounds was tested. Most do not activate GG neurons. By contrast, some pyrazine derivatives strongly activate GG neurons *in vivo*, as monitored by the expression of the activity-dependent gene c-Fos (Mamasuew et al., 2011a). In addition, electrophysiological recordings demonstrate that the GG-activating pyrazine derivatives evoke electrical responses in GG neurons (W. Hanke and J. Fleischer, unpublished data). More detailed analyses revealed that the three pyrazine derivatives 2,3-dimethylpyrazine (2,3-DMP), 2,5-dimethylpyrazine and 2,3,5-trimethylpyrazine are capable of activating GG neurons. Interestingly, even closely related chemical compounds, such as pyrazine, 2-methylpyrazine, 2,3-diethylpyrazine and o-xylene fail to stimulate the GG (Mamasuew et al., 2011a). These findings suggest that GG neurons are activated by only a few distinct compounds. Moreover, only the V2r83-expressing GG neurons respond to given pyrazine derivatives (Mamasuew et al., 2011a).

**Figure 52.5** Axonal projection of GG neurons. (a) Schematic representation of a sagittal section through the head of mouse. Axons emerging from the GG follow a trajectory along the nasal septum and project to the OB. In the posterior region of the OB, at the level of the accessory olfactory bulb (AOB), GG axon bundles separate into two branches to reach the relevant glomeruli in the dorsal, lateral and medial area of the OB. While one branch takes a dorsal trajectory going round the AOB, the other fibers remain on the medial side and project in a ventral direction. (b)-(c) Projection of GG axons in the OB (coronal sections) visualized by staining with the lipophilic tracer DiI (medial is to the left; dorsal is to the top). (b) On their route, GG axons innervate a number of interconnected necklace glomeruli (arrows). (c) High magnification image of a necklace glomerulus (arrow) innervated by GG axons. Scale bars: B = 500 µm; C = 100 µm. (this figure was kindly provided by Sabrina Stebe)

The functional relevance of the GG activation by pyrazine derivatives is so far unclear. Interestingly, strong activation of GG cells by these compounds was only observed in neonates but not in adults (Mamasuew et al., 2011a), suggesting that the responsiveness may have particular implications for pups. Two important natural sources for dimethylpyrazines have been identified. First, dimethylpyrazines are present in the urine of some predators of mice, such as ferrets (Zhang et al., 2005); accordingly, these compounds may have an alerting function. Second, dimethylpyrazines are present in the urine of grouped females that are neither pregnant nor lactating (Jemiolo et al., 1989). In this context, the relevance of these substances for pups is yet unclear.

### 52.3.6 Responsiveness to Coolness

In addition to their chemosensory responsiveness, GG neurons are also activated by cool temperatures (Mamasuew et al., 2008; Schmid et al., 2010). Studies of c-Fos expression *in vivo* suggest that the responsiveness of GG neurons to cool temperatures appears to be more intense in neonates than in adults (Mamasuew et al., 2008).

About 75% of all GG neurons respond to cool stimuli (Mamasuew et al., 2010; Schmid et al., 2010). However,

only the V2r83-expressing GG cells are activated by cool temperatures; the TAAR-positive GG neurons do not respond to coolness (Mamasuew et al., 2008). Thus, the V2r83-positive GG neurons can be considered to be dual sensory cells responding to both chemical and thermal stimuli. Besides the GG, receptor V2r83 is also expressed in a considerable portion of the sensory neurons in the VNO (Martini et al., 2001), but vomeronasal neurons do not respond to cool stimuli (Mamasuew et al., 2008; Schmid et al., 2010).

### 52.3.7 Molecular Signaling Cascades

Recent attempts to characterize the molecular mechanisms underlying the responsiveness of GG neurons to chemical and thermal stimuli have led to the identification of distinct signaling molecules. GG cells abundantly express G proteins, especially the G protein  $\alpha$ -subunits  $G_i$  and  $G_o$  (Fleischer et al., 2006b), both of which are also present in vomeronasal neurons (Berghard and Buck, 1996; Jia and Halpern, 1996). In line with the notion that cyclic nucleotide-gated (CNG) ion channels are crucial for olfactory signaling (Brunet et al., 1996), the CNG channel subunit CNGA3 is expressed in numerous GG neurons (Liu

et al., 2009; Mamasuew et al., 2010). However, CNGA3 is different from the subtype CNGA2, which is typically expressed in OSNs of the MOE. Specifically, CNGA3 is poorly responsive to cyclic adenosine monophosphate (cAMP) but is strongly activated by cyclic guanosine monophosphate (cGMP) (Kaupp and Seifert, 2002), leading to the notion that cGMP may be involved in sensory signaling of GG neurons. This concept was supported by the discovery that the transmembrane guanylyl cyclase subtype GC-G is expressed in the GG. In addition, GG neurons express the cGMP-hydrolyzing phosphodiesterase PDE2A (Fleischer et al., 2009; Liu et al., 2009). In the GG, expression of all these three cGMP-associated signaling elements (CNGA3, GC-G and PDE2A) is confined to the V2r83-positive neurons (Fleischer et al., 2009; Mamasuew et al., 2010; Matsuo et al., 2012). Because only these GG neurons are activated by the above mentioned dimethylpyrazine ligands (Mamasuew et al., 2011a), it is conceivable that cGMP signaling is involved in mediating the responsiveness to these odorants. Indeed, in c-Fos experiments (Mamasuew et al., 2011a) and in electrophysiological approaches (Hanke and Fleischer, unpublished results), responses to odorants were reduced in mice deficient for CNGA3 or GC-G compared to wild-type conspecifics.

The transmembrane guanylyl cyclase GC-G has been reported to be activated by bicarbonate, an observation leading to speculations that the GG might respond to CO<sub>2</sub> (Chao et al., 2010). However, CO<sub>2</sub> failed to activate GG neurons in calcium-imaging (Brechbuhl et al., 2008) as well as in c-Fos (Fleischer and Breer, unpublished results) experiments.

In search for the mechanisms underlying the coolness-evoked GG responses, evidence for a novel thermosensory pathway in mammals has accumulated. The coolness-sensitive TRP channel TRPM8, which is crucial for the responsiveness to coolness in neurons of the dorsal root and trigeminal ganglia (Bautista et al., 2007; Dhaka et al., 2007), is absent from GG neurons (Fleischer et al., 2009). Previous studies have shown that in the nematode *Caenorhabditis elegans*, so-called AWC neurons are capable of responding to both chemical and thermal stimuli, thus resembling GG neurons. Interestingly, in AWC neurons, chemo- and thermosensory transduction requires transmembrane guanylyl cyclases and CNG channels (Coburn and Bargmann, 1996; Komatsu et al., 1996; Inada et al., 2006). Based on these findings, it was hypothesized that the GG neurons may employ a similar transduction pathway to respond to cool temperatures, and c-Fos experiments using mice deficient for CNGA3 or GC-G provide results that support this view (Mamasuew et al., 2010; Fleischer and Breer, unpublished results).

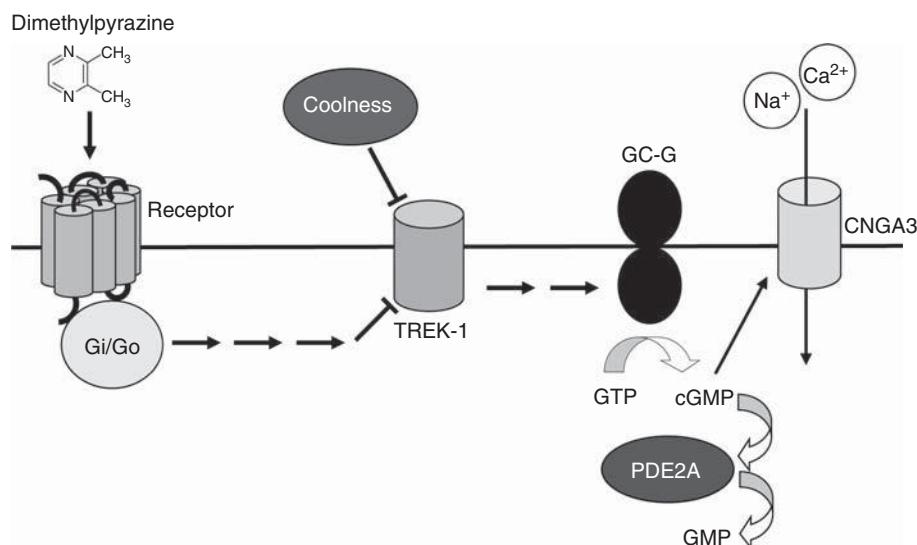

### 52.3.8 Interplay Between Coolness-Induced and Odorant-Induced Responses

Given that cool temperatures and specific odorants activate the same GG neurons via a cGMP pathway, cross-talk between olfactory and thermosensory signal transduction in the GG may occur. Indeed, experiments using c-Fos expression reveal that odor-evoked responses in GG neurons are enhanced at cool temperatures (Mamasuew et al., 2011a). However, odor-evoked but not coolness-induced GG responses attenuate upon long-term exposure, indicating that the relevant transduction mechanisms share some signaling elements but are not identical (Mamasuew et al., 2011b). This notion is also supported by the finding that odor-adapted GG neurons still respond to cool temperatures (Mamasuew et al., 2011b).

The observation that odor-induced activation is abolished at very warm temperatures (35°C) (Fleischer and Breer, unpublished results) suggests that temperature-sensitive ion channels may be also important for chemosensory signaling in the GG. In this context, the thermosensitive potassium channel TREK-1 appears to be an interesting candidate. At cool temperatures, TREK-1 is closed, causing a membrane depolarization; at higher temperatures, TREK-1 is opened and the membrane hyperpolarizes (Maingret et al., 2000). Interestingly, TREK1 is also inhibited by G protein-coupled signaling (Enyedi and Czirjak, 2010). Most recent studies have shown that TREK-1 is expressed in numerous GG neurons (J. Fleischer and H. Breer, unpublished observations). Thus, TREK-1 could function as an important molecular element regarding sensory transduction mechanisms in GG neurons (Figure 52.6).

### 52.3.9 Is the GG Part of the “Necklace” Olfactory System?

GG neurons project their axons to the caudal MOB where they converge in a small number of interconnected glomeruli surrounding the anterior part of the AOB (Fuss et al., 2005; Koos and Fraser, 2005; Roppolo et al., 2006; Storan and Key, 2006). These glomeruli are arrayed like “beads on a string” and have therefore been designated as “necklace” glomeruli (Shinoda et al., 1989). “Necklace” glomeruli are also innervated by axons of the so-called GC-D neurons from the MOE (Juilfs et al., 1997; Leinders-Zufall et al., 2007; Walz et al., 2007). The question whether axons from the GG and the GC-D neurons may project to the same glomeruli was unequivocally answered in a recent study demonstrating that the two axonal populations do not converge (Matsuo et al., 2012). Therefore, the “necklace” system is composed of two different subsets of glomeruli: one exclusively innervated

**Figure 52.6** Putative chemo- and thermosensory signaling pathways in GG neurons. Activation of GG neurons by cool temperatures and given odorants appears to be mediated by cGMP-associated signaling elements, most notably the transmembrane guanylyl cyclase GC-G and the cGMP-activated ion channel CNGA3. It is unknown how these elements are activated by coolness or odorants, respectively. Presumably, cool temperatures directly inhibit the thermosensitive potassium channel TREK-1. Similarly, TREK-1 could be also closed by appropriate odorants via a G protein-mediated cascade. It is yet elusive how inactivation of TREK-1 might affect cGMP signaling in GG neurons. Finally, cGMP could be hydrolyzed by the phosphodiesterase PDE2A.

by neurons from the GG, the other by GC-D neurons from the MOE. The distinct axonal projection pattern of GG neurons and GC-D neurons is also mirrored by the relevance of different guidance factors: while proper targeting of GC-D axonal processes depends on neuropilin-2 (Walz et al., 2007), the GG uses neuropilin-1 to establish accurate wiring (Matsuo et al., 2012).

## 52.4 THE TERMINAL NERVE (TN)

The terminal nerve (TN), which is also termed the nervus terminalis and Cranial Nerve 0 (CN 0), is the most anterior of the vertebrate cranial nerves, extending between the nasal cavity and basal forebrain. It is currently thought to function in modulating activity in the olfactory epithelium and, in teleost fishes, in the retina. We include the TN in this chapter in part because of its role as a centrifugal modulatory olfactory subsystem and in part because the neurons of the TN ganglion develop from the nasal placode, as do those of the olfactory and vomeronasal epithelia (Schwanzel-Fukuda and Pfaff, 1989; Wray et al., 1989).

The TN was first discovered in sharks by Fritsch, who referred to it simply as “a supernumerary nerve” (1878). Pinkus (1894) described the TN in lungfish, leading some subsequent investigators to refer to the TN as “Pinkus’s nerve”. In studies of another lungfish species, Sewertzoff (1902) described part of the nerve that enters the brain

at the level of the preoptic area, leading him to suggest that it be called “nervus praopticus”. Locy (1905) later described the TN in a variety of sharks and rays, and named it the “nervus terminalis” because in these animals the nerve enters the brain through the lamina terminalis. Although the Anglicized version of this name, “terminal nerve”, is now commonly used, alternative names are still found in the older literature and in some newer studies of non-mammalian vertebrates.

### 52.4.1 Anatomy of the Terminal Nerve

The anatomy of the TN has been examined in every class of vertebrates, but most studies have focused on cartilaginous fishes, teleost fishes, and amphibians. These studies indicate some anatomical differences among groups, although the functional consequences are unclear. For example, the centrifugal neurites of the bipolar TN ganglion cells sometimes comprise a separate nerve, but the fibers of the TN sometimes run within the olfactory or vomeronasal nerve. The location of the ganglion cell bodies also varies among species, with somata found in one or more ganglia within the TN proper or along the TN pathway through the olfactory bulb or anterior forebrain. For example, in most cartilaginous fishes, a separate TN runs medial to the olfactory nerve, and includes a visible ganglion located medial and external to the nasal cavity. In some shark species, the TN possesses additional ganglia located along the nerve

itself (Locy, 1905). In contrast, in teleost fishes the TN runs within the olfactory nerve and is not visible externally. In most teleosts the TN ganglion consists of a cluster of neurons located between the olfactory bulb and the ventral telencephalon, with fibers that extend peripherally to both the olfactory epithelium and the retina (Brookover and Jackson, 1911; Rossi et al., 1972; Springer, 1983; Oka et al., 1986). Because of this association with both the olfactory system and retina, the TN ganglion in teleosts is also frequently called the “nucleus olfacto-retinalis” (Munz et al., 1981).

Based largely on its anterior location, the Grueneberg ganglion was thought by its discoverer to be part of the TN system (Grüneberg, 1973). We now know that in mice the TN ganglion lies near the ventrocaudal portion of the MOB, in the subarachnoid space; additional TN ganglion cells are scattered along the path of the TN fibers in the nasal cavity and along the ventral surface of the MOB and AOB (Jennes, 1986) (Figure 52.1). Rostrally, the TN fibers merge with the olfactory fibers and are distributed widely throughout the nasal cavity (Jennes, 1986). Similarly, in adult humans the TN consists of many small bundles in the nasal cavity, coursing with olfactory fibers along septum and with the ethmoid branch of the trigeminal nerve more anteriorly (McCotter, 1915). Inside the braincase, the TN is separate from the olfactory nerve, and in some cases is large enough to be seen with the naked eye (Brookover, 1914; Johnston, 1914). The TN ganglion is medial to the MOB, on the inside surface of the dura mater near the cribriform plate (Brookover, 1914). Proximal to the ganglion, the fibers run over the surface of the gyrus rectus medial to the olfactory peduncles, entering the brain anterior to the optic chiasm (Johnston, 1914).

In many vertebrates, the cells and fibers of the TN contain GnRH (reviewed in Wirsig-Wiechmann et al., 2002). The TN can also be labeled with antisera directed against neuropeptide Y (NPY) and the molluscan cardioexcitatory neuropeptide FMRFamide. These two peptides have a similar C-terminal and many such antisera cross-react. Although the presence of NPY has been established it is not clear whether the TN also contains FMRFamide-like peptides (Chiba, 2000; Mousley et al., 2006). In any case, modern studies often rely on antisera directed against GnRH or FMRFamide to identify or localize TN cells and fibers.

Immunocytochemical data suggest that the TN may not be present in all vertebrates. In some reptiles, either the immunoreactive characteristics of the TN differ from those in other jawed vertebrates, perhaps a way that varies with developmental stage, or the nerve is not present at all developmental stages. For example, among lizards, GnRH-immunoreactive cells and fibers are present

in the TN of adult *Eumeces laticeps* and *Sceloporus undulatus*, but not in adult *Anolis carolinensis* (Rosen et al., 1997). In embryonic and adult *Podarcis sicula*, GnRH-immunoreactive cells and fibers cannot be detected in a nerve, nor in the MOE or MOB (Masucci et al., 1992; D’Aniello et al., 1994). FMRFamide-immunoreactive cells and fibers are present in the TN during development in *Chalcides chalcides*, but not in adults (D’Aniello et al., 2001). Similarly, the TN of the spectacled caiman (*Caiman crocodilus*) displays FMRFamide-like immunoreactivity in embryos but not adults (D’Aniello et al., 1999, 2001). The development of the TN in turtles has been described by Johnston (1913) and Larsell (1917), who were able to visualize the nerve as it courses over the surface of the olfactory nerve due to its several conspicuous ganglia. The histochemical characteristics of the nerve have not been examined in detail in turtles, although FMRFamide-immunoreactive cells and fibers are not present in or around peripheral olfactory structures in adult *Trachemys scripta* (D’Aniello et al., 1999, 2001). On the other hand, a GnRH-immunoreactive TN is present in adult garter snakes (*Thamnophis sirtalis*), with a discrete ganglion at the ventral border between the MOB and rostral telencephalon (Smith et al., 1997). Medina and colleagues (2005) report that Nile crocodiles (*Crocodylus niloticus*) possess a GnRH-immunoreactive TN, but a detailed description of the pathway was not provided.

The presence of a TN in lampreys is also questionable. Based on conventional histology, Heier (1948) first suggested that lampreys lack a TN. Antisera directed against GnRH, NPY, and FMRFamide fail to label any structures reminiscent of the TN in larval or adults of four genera of lampreys (Crim et al., 1979a, b; Meyer et al., 1987; King et al., 1988; Ohtomi et al., 1989; Wright et al., 1994; Tobet et al., 1995; Eisthen and Northcutt, 1996; Chiba, 1999). Consistent with this idea, GnRH neurons in lampreys appear to develop from the diencephalon rather than from the olfactory placode (Tobet et al., 1996). Nevertheless, fibers that project from the nasal sac through olfactory bulb to the ventral forebrain have been labeled with injections of tracers into the nasal sac of larval or adult *Lampetra planeri* and *Ichthyomyzon unicuspis* (Meyer et al., 1987; von Bartheld et al., 1987; Northcutt and Puzdrowski, 1988; von Bartheld and Meyer, 1988). Although this projection was originally interpreted as a TN it may be the extra-bulbar olfactory pathway, the existence of which was unknown at the time these studies were conducted (Eisthen and Northcutt, 1996).

### 52.4.2 Function of the Terminal Nerve

Because the anterior fibers of the TN are found in the nasal cavity and the posterior fibers extend toward the hypothalamic/preoptic area, it was originally thought to serve a sensory function, perhaps related to reproduction (e.g., Rossi et al., 1972; Demski and Northcutt, 1983). Three lines of evidence support the newer idea that the TN serves a neuro-modulatory function: studies have failed to find evidence of sensory activity in the TN; the TN ganglion cells are intrinsically active and release GnRH; and TN peptides modulate activity in the olfactory epithelium and, in teleost fishes, in the retina. We will briefly review these studies below.

Electrophysiological recordings have failed to detect sensory responses in the TN. For example, Bullock and Northcutt (1984) used both hook and suction electrodes to record from the TN in a spiny dogfish (*Squalus acanthias*). The authors detected no response to food, conspecific odorants, or amino acids. They also found no response to mechanical stimuli in the nasal sac or on the body surface nor to auditory, visual, or electrical stimuli. Similarly, another study found that exposure to conspecific sex-related and other odorants did not alter the firing rate of TN ganglion cells in goldfish, *Carassius auratus*. In addition, the TN did not respond to visual, auditory, magnetic, or thermal stimuli (Fujita et al., 1991).

Several researchers have examined the effects of TN lesions on reproductive behaviors and found effects that are subtle and difficult to interpret. For example, lesions of the TN impair initiation of nest-building behavior, but do not abolish reproduction, in male dwarf gouramis, *Colisa lalia* (Yamamoto et al., 1997). In female hamsters (*Mesocricetus auratus*), TN lesions lead to a slight decrease in the latency to exhibit lordosis behavior (Wirsig-Wiechmann, 1997). Male hamsters with TN lesions spent less time investigating female vaginal odors and increased their latency to ejaculate during mating, but lesions had no effect on testosterone surges that result from exposure to female vaginal secretions (Wirsig and Leonard, 1987; Wirsig-Wiechmann, 1993).

The physiological properties of the TN have been the subject of much study in teleost fishes, particularly in dwarf gouramis (reviewed in Oka, 1992, 2002). Electrophysiological experiments demonstrate that the majority of the ganglion cells fire spontaneous action potentials at a constant frequency. Excised TN ganglion cells maintain their pacemaker activity in a dish, demonstrating that the activity is endogenous (Oka, 2002). This rhythmic activity is brought about by the interaction of a tetrodotoxin-resistant persistent sodium current that depolarizes the cell and a persistent potassium current that activates near the resting potential of the cell, initiating repolarization (Oka, 1992, 1996; Abe and Oka, 2000, 2002). The firing frequency of the cells is

modulated by the same form of GnRH that is present in the nerve, causing an initial decrease in firing rate, followed by a later increase (Abe and Oka, 2000, 2002). This modulation of firing rate by GnRH may function to synchronize firing (Abe and Oka, 2000). Experiments with bonnethead sharks (*Sphyrna tiburo*) suggest that tonic activity of TN ganglion cells is not unique to teleosts (White and Meredith, 1987).

Few studies have sought to identify anatomical inputs to the TN, perhaps because it was long thought to serve a sensory function. One detailed tract-tracing study with dwarf gouramis and tilapia (*Oreochromis niloticus*) indicates that in teleost fishes the TN receives input from olfactory areas in the forebrain as well as from the nucleus tegmento-olfactorius, a midbrain region that receives input from the reticular formation as well as visual and somatosensory areas (Yamamoto and Ito, 2000). In contrast, in two species of shark projections to the TN ganglion arise from the medial pallium, septum, and preoptic area, and inputs from primarily olfactory areas of the forebrain were not observed (Yáñez et al., 2011). Activity of TN ganglion cells in bonnethead sharks is modulated by acetylcholine and norepinephrine, which appear to be of central origin (White and Meredith, 1993, 1995). Thus, accumulating evidence suggests that TN ganglion cells are spontaneously active, and that this activity may be regulated by centrifugal inputs that differ among species.

Electrical stimulation of the TN ganglion in Atlantic stingrays (*Dasyatis sabina*) leads to an increase in GnRH levels in cerebrospinal fluid (Moeller and Meredith, 1998). While suggestive, this result does not demonstrate that the TN releases GnRH under normal physiological conditions. More direct evidence comes from studies with dwarf gouramis in which slices of brain containing TN ganglion cells have been shown to release GnRH. Importantly, increasing doses of glutamate increase both the rate of pacemaker potentials in TN ganglion cells and the release of GnRH (Oka, 2002; Ishizaki et al., 2004). This result strongly suggests that spontaneous activity of TN ganglion cells leads to the release of peptides.

If the TN releases peptides, where do the peptides go? The anatomical connection between the terminations of the TN fibers and the nasal sensory epithelia remains obscure because the TN fibers taper and are difficult to identify in electronic micrographs. One study indicates that in mice the TN fibers approach the lamina propria underlying the MOE, although it is not clear whether or not the fibers penetrate into the epithelium (Jennes, 1986). TN fibers also wrap around and take up tracers injected into fenestrated capillaries underneath the MOE, suggesting that the fibers could also release compounds into the microcirculation around the MOE (Jennes, 1986). Finally, some have suggested that TN fibers could release compounds into mucus

overlying the MOE through association with subepithelial glands (e.g., Wirsig-Wiechmann et al., 2002).

If the TN releases peptides in or near the nasal epithelia, peptide receptors are required for a response. Receptors for at least one TN-derived peptide, GnRH, are present in nasal sensory epithelia. Specifically, a radiolabeled GnRH receptor antagonist labels the MOE in tiger salamanders, *Ambystoma tigrinum*, and the VNO in prairie voles, *Microtus ochrogaster* (Wirsig-Wiechmann and Jennes, 1993; Wirsig-Wiechmann and Wiechmann, 2001). An antiserum directed against GnRH receptors labels the MOE in another salamander, the mudpuppy *Necturus maculosus* (Zhang and Delay, 2007). Finally, Southern blots confirm the presence of GnRH receptors in both the MOE and VNO in prairie voles (Wirsig-Wiechmann and Wiechmann, 2001). Thus, if the TN were to release GnRH in or near the nasal sensory epithelia, the peptide would be expected to evoke a response.

Indeed, electrophysiological studies with amphibians demonstrate that TN derived peptides alter both the odorant sensitivity and excitability of OSNs. In mudpuppies, GnRH briefly suppresses then tonically enhances the magnitude of the voltage-dependent, tetrodotoxin (TTX)-sensitive sodium current in OSNs (Eisthen et al., 2000; Zhang and Delay, 2007). This effect depends on both PKA and PKG (Zhang and Delay, 2007), but the GnRH receptor subtype and full biochemical pathway involved have not been identified. Interestingly, the neurons are more responsive to GnRH during the breeding season, suggesting that GnRH may play a role in regulating responses to odorants in a way that promotes reproduction (Eisthen et al., 2000; Zhang and Delay, 2007). Lending further support to the idea that the GnRH-containing fibers of the TN play a role in reproductive behavior, estrogen affects GnRH concentrations in the TN in the African clawed frog *Xenopus laevis* (Wirsig-Wiechmann and Lee, 1999). In addition, GnRH concentrations are higher in courted female rough-skinned newts (*Taricha granulosa*) than in uncourtied conspecifics (Propper and Moore, 1991). Finally, experiments with another aquatic salamander, the axolotl *Ambystoma mexicanum*, demonstrate that GnRH suppresses responses evoked by amino acids, which serve as feeding cues in aquatic vertebrates (Park and Eisthen, 2003). Given that some amphibians cease feeding during the breeding season it is tempting to interpret this result as further evidence of the involvement of TN-derived GnRH in reproduction. Nevertheless, studies with mudpuppies show that even responses to behaviorally meaningless odorants are suppressed by GnRH (Zhang and Delay, 2007).

Although most functional studies of the TN have focused on GnRH, experiments reveal that other TN peptides serve a modulatory function. The TN in axolotls is NPY-immunoreactive. As with GnRH, application of

synthetic axolotl NPY enhances the magnitude of the TTX-sensitive sodium current in OSNs; intriguingly, neurons from food-deprived animals are much more likely to respond to GnRH. Although GnRH suppresses odorant responses evoked by amino acids, NPY enhances them, and the magnitude of the increase is greater in food-deprived animals. These data suggest that TN-derived NPY modulates activity in the MOE with respect to the animal's nutritional state (Mousley et al., 2006). Separate studies with axolotls demonstrate that FMRFamide also modulates both odorant responses and the TTX-sensitive sodium current in OSNs, although it is not yet clear whether the TN contains FMRFamide-related compounds (Park and Eisthen, 2003).

In teleost fishes, an additional branch of the TN innervates the retina, where it likely serves a modulatory function. *In situ* hybridization experiments with the cichlid *Astatotilapia burtoni* indicate that two different subtypes of GnRH receptors are expressed in the amacrine cell layer, probably on interplexiform cells, and in the ganglion cell layer (Grens et al., 2005). Separate studies demonstrate that TN-derived peptides modulate activity of both populations of cells in teleosts. In white perch (*Roccus americana*), GnRH- and FMRFamide-immunoreactive TN fibers synapse on dopaminergic interplexiform cells in the amacrine cell layer (Zucker and Dowling, 1987). GnRH causes release of dopamine from interplexiform cells, reducing the receptive field size and responses to full-field illumination in horizontal cells. FMRFamide alone does not appear to affect activity of horizontal cells, but in some cases suppresses the effects of GnRH (Umino and Dowling, 1991).

In goldfish, GnRH-immunoreactive TN fibers extend into the inner plexiform and amacrine cell layers of the retina. Extracellular recordings from excised retinas demonstrate that GnRH, FMRFamide, and a variety of compounds with some sequence similarity to FMRFamide, such as met-enkephalin, modulate activity of retinal ganglion cells. The effects of these compounds are more pronounced during the winter and spring, again suggesting a relationship between TN activity and reproduction (Walker and Stell, 1986; Stell et al., 1987). Further, the release of FMRFamide-like peptides in the retina can be induced by exposure to light and is temporarily decreased by lesioning the olfactory nerve, presumably eliminating odorant input to the TN ganglion (Fischer and Stell, 1997). *In vivo* experiments with zebrafish (*Danio rerio*) demonstrate that olfactory stimulation with an amino acids enhances light sensitivity and increases firing rate in retinal ganglion cells. This effect appears to be due to TN-stimulated release of dopamine from interplexiform cells (Huang et al., 2005). Finally, exposure of zebrafish to amino acid odorants increases behavioral sensitivity to a looming visual stimulus as well as electroretinogram

responses to a pulse of light. These effects are blocked by administration of a D<sub>2</sub> receptor antagonist or co-injection of 6-hydroxydopamine and pargyline, which selectively eliminates the interplexiform cell population (Maaswinkel and Li, 2003). These data demonstrate that the TN modulates retinal activity in teleosts in response to odorants by stimulating dopamine release from interplexiform cells, altering activity of both horizontal cells and retinal ganglion cells.

Taken together, the available data strongly suggest that the TN functions to modulate activity in the nasal sensory epithelia and, in teleost fishes, in the retina, to maximize sensitivity to stimuli most relevant to the animal's condition. Important questions remain to be answered, including identification of the full suite of peptides found in the TN, the route by which TN peptides travel to olfactory and vomeronasal receptor neurons, and the mechanisms underlying changing responsiveness to TN peptides in OSNs.

## 52.5 CONCLUDING REMARKS

Organization of the peripheral olfactory system is more complicated than previously appreciated. More subsystems may still emerge with new molecular markers and more detailed anatomical and functional analysis. What are the advantages of having multiple chemosensory and modulatory subsystems? First, different receptors expressed in these subsystems can expand the overall detection capacity of the olfactory system for chemicals and other stimuli. Second, critical information can be processed in parallel by multiple subsystems, which send signals to different brain regions for further processing and integration. Third, the chemosensory responses can be modulated based on the internal status and the external environment. These chemosensory systems allow the host organisms to detect the olfactory cues and respond appropriately by adjusting their behaviors, emotions, and hormones. Future studies will elucidate the specific information conveyed by each subsystem and shed light on how the chemosensory information is processed and integrated by the brain.

[<sup>14</sup>C]2-deoxy-D-glucose (2-DG)  
autoradiographic method, 19  
[<sup>18</sup>F] fluorodeoxyglucose method, 19  
1-alcohols, 616  
1-butanol, 309, 382  
1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), 23–4, 423–4, 438, 460, 468, 474  
1-octen-3-ol, 1081  
1,10-dimethyl-9-decalol, 1081  
2,3,7,8-tetrachlorodibenzo-*p*-dioxin, 78, 79  
2,6-dichlorobenzonitrile *see* DCBN  
2,6-dichlorophenyl methylsulfone, 76  
2,6-dichlorothiobenzamide, 80  
2-butanone, 364  
2-deoxyglucose, 268  
2-heptanone, 554  
2-isobutyl-3-[<sup>3</sup>H]methoxypyrazine, 103  
2-ketones, 616  
2-methyl-2-propanethiol, 114  
2-methyl-but-2-enal (2MB2), 317  
2-methylisoborneol (MIB), 1081  
2-phenylethylamine, 115–16  
3-aminobenzamide, 80  
3-drop technique, 753  
3-isobutyl-1-methylxanthine (IBMX), 103  
3-methylcholanthrene, 78, 79  
3-methylindole (3-MI), 69, 77, 77  
3-trifluoromethylpyridine, 76  
3'-5'-cyclic adenosine monophosphate (cAMP), 678  
4-(2,2,3-trimethylcyclopentyl) butanoic acid, 692  
4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK), 69  
4,4'diisothiocyanostilbene-2,2'-disulfonic acid (DIDS), 677

4,8a-dimethyl-decahydronaphthalen-4a-ol (geosmin), 1083  
4-aminobiphenyl, 69  
4-dihydroxybenzoic acid, 667  
5 $\alpha$ -androst-16-en-3-one, 73, 114  
5 $\alpha$ -androstenone, 73–4, 79, 114, 311, 319, 388, **430–1**  
6-hydroxy-6-methyl-3-heptanone, 583  
6-hydroxydopamine (6-OHDA), 460, 468  
6-*n*-propylthiouracil *see* PROP  
7-transmembrane proteins, 533  
7-tridecanone, 574  
8-cup technique, 753  
17 $\alpha$ ,20 $\beta$ -dihydroxy-4-pregnен-3-one, 74  
 $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), 160–1  
 $\alpha$ -defensin, 99–100  
 $\alpha$ -gustducin, 15, 17, 693, 695, 960  
 $\alpha$ -lipoic acid, 392, 904  
 $\alpha$ -naphthoflavone, 79  
 $\alpha$ -synuclein, 198, 414, 424–5, 428, 468, 490–4, 502  
 $\alpha$ -transducin, 693  
 $\beta$ -amyloid, 148, 217–8, 411–2, 468, 490–5, 502, 893  
 $\beta$ -arrestin, 127  
 $\beta$ -catenin, 731  
 $\beta$ -cyclodextrins, methylated, 469  
 $\beta$ -defensins, 99–101, 100, 101  
 $\beta$ -galactosidase, 115, 136  
 $\beta$ -glucopyranosides, 685  
 $\beta$ -ionone, 79, 1081  
 $\beta$ -lactoglobulin, 672  
 $\beta$ -naphthoflavone, 78  
 $\beta$ -phenylethylmethylethylcarbinol, 231  
 $\beta$ , $\beta'$ -iminodipropionitrile (IDPN), 72

accessory olfactory bulb (AOB), 48, 99, 157, 171–3, 306, 592, 593, 608, 617, **618**, 1120, 1121  
accessory olfactory system (AOS), 115, 157, 171, 174, 464, 579, 617, 1113–14  
acesulfame-K, 667, 915, 916  
acetaminophen (APAP), 72, 76, 464  
toxicity, 75  
acetochlor, 78  
acetonitrile, 72  
acetyl salicylic acid, 467  
acetyltransferases, 71  
acoustic neuromas, 891  
acoustic rhinometry, 357–8  
acquired immune deficiency syndrome *see* HIV/AIDS  
acrolein, 1092  
across-fiber pattern theory, 985  
actinomycetes, 1081  
acupuncture, 393, 905  
acute necrotizing ulcerative gingivitis (ANUG) (trench mouth), 894  
acyclovir, 468  
Addison's disease, **378**, 388  
adaptation, olfactory, 248–249  
adaptation, taste, 703  
adenoid hypertrophy, 361, 368  
adenoidectomy, 361, 369, 381  
adenoids, hypertrophied, 381–2  
adenylyl cyclase, 15, 112, 128, 145, 389, 523, 525, 526  
adolescence, olfaction in, 309–11  
adrenocortical insufficiency, *see* Addison's disease  
adrenomedullin, 66  
'adult' stem cells, 135  
*Aedes albopictus*, 533

- Aedes japonicus*, 533  
*Aedes* sp., 532  
*Aethia psittacula* (crested auklet), 570, 573, 574  
 aflatoxin B1, 69  
 ageusia, 780, 888, 896, 902–905  
 aging  
   and medication use, taste dysfunction, 911  
   olfactory function and, 23, 199, 234, 237, 238, 245, 246, 312, 313, 375, 377, 392, 485, 1056  
   taste function and, 642, 797, 804, 963  
 agoenhancers, 667  
*Ailuropoda melanoleuca* (giant panda), 975  
*Ailurus fulgens* (lesser panda), 958  
 air pollution  
   exposure to, 385  
   and olfaction, 489–96, 502  
 air-dilution olfactometers, laboratory-based, 228  
 alachlor, 78, 464  
 alanine, olfactory system in transport of, 463  
 alarm pheromones, 586  
 Albright hereditary osteodystrophy (AHO), 389  
 alcohol, 499–500  
 alcohol abuse, 23, 438, 836  
 alcohol dehydrogenase, 464  
 Alcohol Sniff test, 309  
 alcohols, 569  
 aldehyde dehydrogenases (ALDHs), 68, 70, 464, 486  
 aldehyde oxidase homologue, 371  
 aldehydes, 570  
 algal blooms, 1081–2  
 aliphatic acetic esters, 616  
 alkaline phosphatase, 64, 67  
 allergic rhinitis, 361, 362, 369  
   adrenomedullin in, 66  
 allesthesia, 786, 869  
 allyl N-geranyl carbamate, 675  
 aloin, 671  
 ALS/parkinsonism-dementia Complex of Guam (ALS/PDG), 428  
 aluminum, 499  
   olfactory system in transport of, 459  
   salts, as deodorant, 8  
 Alzheimer's disease (AD), xi, xii, 19, 23, 101, 148, 217, 219, 272, 379, 404–408, 409, 410–12, 463, 472, 492, 549, 1042, 1056  
 alpha-synuclein in, 491  
 aluminum in, 459  
 EEG, 263  
 entorhinal cortex in, 218  
 metals in, 457  
 olfactory bulb volume in, 377  
 olfactory CSERPs, 271  
 olfactory structural imaging in, 286  
 olfactory system as route for pathogens to brain, 456  
   single staircase (SS) procedure in, 230  
   transport in, 473  
*Amblonyx cinereus* (Asian otter), 958  
*Ambystoma* (axolotl), 646  
*Ambystoma mexicanum* (axolotl), 1144  
*Ambystoma tigrinum* (tiger salamander), 1144  
 amides, 570  
 amifostine (EthyolTM), 902, 905  
 amiloride, 631, 665, 916  
 amino acids, transport of, 462–3  
 aminopeptidases, 66, 71  
 amiодароне, 921, 922, 923  
 amitriptyline, 921–2  
 amphibians  
   nasal sac in, 41  
   taste in, 948  
 amygdala, 174, 210, 211, 212, 217, 218, 268, 269, 272, 280, 286, 289, 290, 291, 293, 294, 296–9, 307, 411, 435, 488, 708, 714, 716, 779, 782–3, 785–7, 789, 870, 875, 877–9, 899, 901, 950, 996–7, 1028, 1029, 1035–7, 1120–3  
 amyl acetate, 246, 309, 310, 312, 313, 422, 432, 592, 1135  
 amylase, 627  
 amyloidosis, 893  
 amyotrophic lateral sclerosis (ALS), 23, 101, 412  
 amitriptyline, 902  
 analgesics, administration via nasal cavity, 467  
 androstanedione (AND), 298, 311  
 androstenone, 73–4, 79, 114, 311, 319, 388, 430–1  
 anesthetics, 501  
 aneurysms  
   of anterior communicating bifurcation, 384  
   of internal carotid artery, 384, 385  
 angiotensin-converting enzyme (ACE), 66, 901  
 angiotensin-converting enzyme (ACE) inhibitors, 376, 846  
*Anguilla anguilla* (eel), 462  
 Ankaferd Blood Stopper (ABS), 915  
 ankyrin, 651  
 anoctratin, 2112  
*Anolis carolinensis* (green anole), 973–4, 1142  
 anorexia nervosa, 390, 903  
   chronic disease state cancer, 872  
   estradiol and, 871–2  
   systemic infections and, 872  
   toxicity and, 872  
 anosmia, 8, 12, 843, 1094–5  
 complete, 375  
 congenital, 376, 387–8  
 due to head injury, 13  
 history, 8  
 MRI of, 283, 284  
 nasal trigeminal chemosensitivity in, 1093–4  
 ocular trigeminal chemosensitivity in, 1095–6  
 partial, 375  
 ANP/AFP theory of taste quality coding, 703  
 anterior cingulate cortex, 1032–3  
 anterior cortical nucleus, development of, 307  
 anterior ethmoidectomy, 384  
 anterior olfactory nucleus (AON), 210  
   development of, 307  
 anterior piriform cortex (APC), 289  
   encoded structure, 292  
 anterior rhinomanometer, 355  
*Anthochaera carunculata* (red wattlebird), 965  
 antibiotics, administration via nasal cavity, 467–8  
 antihistamines, in sinus disease, 363  
 antimigraine medicines, 467  
 antivirals, administration via nasal cavity, 467–8  
*Apis mellifera* (honeybee), 531–2, 532  
 apolipoprotein E, 409  
 apomorphine, 867  
 apoptosis, 135  
 appetite, 832  
   brain mechanisms and, 1027  
   suppression, 468–9  
 aquatic vertebrates, olfaction in, 547–58  
   anatomy, 549–53  
   lateral olfactory tract (LOT), 552  
   lateral-medial olfactory tract (LMOT), 552  
   medial-medial olfactory tract(MMOT), 552  
   nares, 549  
   nasal flow, 550–1  
   olfactory bulb, 552–3  
   olfactory chambers, 549  
   olfactory epithelium, 551–2  
   olfactory tracts and connections, 552  
 applications and perspectives, 558  
 behavioral responses, 555  
 fish vs mammalian olfaction, 558  
 functional assessment, 557  
 genetics and physiology, 553–7  
   biotransformation, 556–7  
   OR receptors, 553–4, 554  
   signal transduction, 556  
   TAAR receptors, 556  
   VR receptors, 554–6

- history of study, 548–9  
 terrestrial olfactory adaptation, 557–8  
 aquatic vertebrates, taste in, 947–54  
   central gustatory pathways, 949–50  
   facial and trigeminal nerve complication, 949  
   functional properties of gustatory systems, 950–4  
   molecular basis of gustatory receptors and transduction, 953  
   palatal organs and barbels, 949  
   peripheral gustatory systems, 947–9  
   responses to chemical stimuli, 950–4  
     amino acids, 950–2  
     aversive and/or toxic chemicals, 952–3  
     behavioural implications, 953–4  
     bile acids, 952  
     carbon dioxide/pH, 953  
     quinine, strychnine and tetrodotoxin, 952, 952  
   signal transduction and molecular basis of receptors, 950  
   structural organization, 947–9  
   taste buds, 947–9, 948  
 arginine, 916  
*Argyreus hyperbius*, 936  
*Ariopsis felis*(sea catfish), 553  
 aristolochic acid (AA), 936  
 Arochlor, 1254 79  
*Arothron nigropunctatus* (pufferfish), 550  
 artificial (electronic) noses, 58, 1057  
 asafoetida, 308, 312  
 asbestos, 491  
 ascending method of limits (AML), 230  
 aspartame (APM), 671, 666, 667  
   appetite and, 832  
 assistance neighborhoods, 516  
 associative learning, 297, 1075  
*Astatotilapia burton*, 1144  
*Astynax jordani*, 646  
*Astynax mexicanus*, 646  
*Ateles geoffroyi* (spider monkey), 613  
 atrophic rhinitis syndrome, 369  
*Atta sexdens*, 539  
*Atta* spp., 532  
*Atta vollenweideri*, 532, 539  
 attention-deficit-hyperactivity disorder (ADHD), 438, 463  
 auriculotemporal nerve (ATN), disorders of, 898  
 auto Inducers (AIs), 518  
 autoimmune diseases, olfactory dysfunction in, 391  
 Avicenna, 6  
 avitaminosis, 901  
 axonotmesis, 896  
  
*Bacillus subtilis*, chemotaxis in, 516  
 baclofen, 915  
  
 bacterial chemotaxis, 513–18  
 barbels in aquatic vertebrates, 949  
 barley lectin, 465  
 basal cells, 95–6, 140  
   globose, 137–8, 138  
*Basiliscus basiliscus*, 974  
*Basiliscus vittatus*, 974  
 batrachotoxins, 568  
 bats  
   nasal anatomy in, 41  
   nasal mucosae in, 49  
 bears, olfactory abilities in, 591–2  
 Beck Depression Inventory, 387  
 behavioral functions of olfaction, early, 314–24  
   birth and rapid learning of odors, 315–16, 316  
   fetal chemoreception, 314–15, 315  
   odor communication in nursing niche, 316–20  
     odor of breast milk, 317  
     odor of lactating breast, 316–17  
     olfaction and energy conservation, 319–20  
     transnatal chemosensory continuity, 317–19  
   development of social cognition, 320–4  
   social diversification, 320–4  
     individual recognition, 322–3  
     from social discrimination to social recognition, 320–1  
     social preferences, 323–4  
 Behcet's syndrome, 893  
 Bell's palsy, 890, 891, 895–6, 897, 904  
*Belone belone* (garfish), 549, 550, 552  
 benzaldehyde, 1081  
 benzalkonium chloride, 473  
 benzene, 69  
   olfactory system in transport of, 464  
 benzene acetaldehyde, 1081  
 benzo(a)pyrene, 78, 79  
 benzocaine, 905  
 biased random walks, 513  
 Bible, 8  
 bifrontal craniotomy, 384  
 biofilms, 520, 520  
 Biolfa test, 309  
 bipolar disorder, 148, 903  
 bird odors, 565–75  
   chemicals, classification, 567  
   chemicals, functional groups, 571  
   feathers, 566  
   preen gland, 566–8  
   skin, 566  
   sources of chemicals, 566–8  
   stomach oil, 568  
   volatile organic compounds (VOCs), 569–74  
  
 volatility and vapor pressure classification, 569  
 birds, gustation in, 961–70

*Tiliqua scincoides* (eastern blue-tongued lizard), 974  
Time-Intensity Profiling, 1070, *1071*  
*Tinca tinca* (tench), 550  
‘tissue-resident’ stem cells, 135  
tobacco, 246, 500  
  second-hand smoke (SHS) exposure, 500  
  third-hand smoke (THS) exposure, 500  
toluene, 69  
  olfactory system in transport of, 464  
tongue  
  anatomy of, 637–44  
  blood supply to gustatory papillae, 644  
  development of, 651–3, 652  
  disorders of, 893  
  history, 637–8, 640  
  innervation of, 653–4, 739–41, 740  
  necrosis after chemotherapy, 892  
  salivary glands, 643–4  
  solitary chemosensory cells (SCC), 644  
  *see also* papillae  
tongue map, 764  
tonsillectomy, taste dysfunction and, 896  
topiramate, 902  
trace amine-associated receptors (TAARs), 16, 115–16, 553  
*Trachemys scripta* (red-eared slider turtle), 980, 1142  
trans-cinnamaldehyde, 1092  
trans-2-cis-6-nonadienal, 1082  
trans-2-pentanal, 1092  
trans-stilbene oxide, 79  
transcellular transport, 453  
transcranial magnetic stimulation (TMS), 393, 394  
  transcription factor Phox2b, 737–8  
  transcription factors, including Islet 1 and Tlx3, 737  
transcytosis, 453  
Transient Receptor Potential (TRP) family, 1101  
  TRPM5 666, 694, 695  
transient receptor potential polycystic (TRPP) marker proteins, 675  
transit amplifying cell, 135  
transnatal chemosensory continuity, 318  
transneuronal transport, 466  
transport of agents by olfactory system  
  to brain and circulation, 453–64  
  CNS transport, 466  
  consequences of, 473–4  
  mechanisms, 464–6  
  transneuronal transport, 465–6  
  transporters in nasal epithelia, 466  
  uptake, 464–5  
transverse lamina, 42  
traumatic brain injury (TBI), 468  
trazodone, 921  
*Tremarctos ornatus* (spectacled bear), 958  
trench mouth, 894  
triacylglycerols, 834  
*Trichoglossus haematodus* (rainbow lorikeet), 965  
tridecan-2-one, 570  
triethylamine, 252  
trifluoperazine, 902  
trigeminal chemesthesia, 1091–1105  
  chemical mixtures and, 1099–100  
  cut-off effect, along vapors from homologous chemical series, 1098–109  
  molecular receptors for, 1092–3  
trigeminal event-related potentials (tERP), 1094  
trigeminal nerve, 305–6, *306, 655*  
  development of, 306  
  disorders of, 898  
trigeminal neuralgia, 780, 898  
trimethylamine, 310, 312  
*Triturus* (newt), 646  
tropotaxis, 549  
Trypan blue, olfactory system in transport of, 462  
tuberculosis, 897  
tufted cells (TCs), 157, 163  
tumors  
  corpus callosum, 385  
  intranasal and intracranial, 384  
*Tupaia glis* (tree shrews), 45, 46, 54  
turbinals, 43  
  anatomical and physiological roles of, 46–7  
  in mammals, 41–2  
  phylogenetic variation, 50  
  mucosal properties, 50–1  
turbinate hypertrophy, 360  
turbanectomy, 360  
turbanoplasty, 363, 369  
*Turdus migratorius* (American robin), 966  
Turner's syndrome, 388, 903  
turtles, taste in, 974  
two-alternative forced choice method (2-AFC), 753, 1073–4

- two-bottle taste test, 22  
 tympanoplasty, taste dysfunction and, 896  
 typhoid, 1079  
 tyrosine hydroxylase, 468
- UDP glucuronosyltransferase (UDPGT or UGT), 68, 70, 464, 486  
 umami, 17, 525, 626, 631, 648, **649**, 665  
 birds and, 967–8  
 neuroimaging and, 1037  
 orofacial expressions in infants, 799  
 preference in infants, 798  
 saliva and, 631  
 taste receptor, 634  
 touch sensation and, 1009  
 transduction, 693–4  
 umami, taste modulators, 672–5  
 agoenhancers as, 673–4, 674  
 antagonists as, 674–5  
 glycoconjugated peptides as, 674  
 N-geranyl cyclopropylcarboxamide (NGCC) as, 674–5  
 pure PAMs as, 672–3, 673  
 uncertainty principle, 272  
 uncinctomy, 384  
 unconditioned responses (URs), 865  
 unconditioned stimulus (UCS), 289  
 unconditioned stimulus (US), 865, 875–9  
 unity assumption, 1008  
 University of Pennsylvania Smell Identification Test (UPSIT), 237, 238, 241, **244**, 245, 247, 309, 381, 383, 385–391, **404–8**, 409–14, **415–22**, 429, **430–3**, 434–8, 493, 496, 502, 1086  
 upper respiratory infections, 380–1  
 smell loss and, 378  
 urea bitterness suppression, 672  
 urine washing, 611  
 urocortin peptide, 473  
 urodilatin, 116  
 uroguanylin, 116
- vaccines, administration via nasal cavity, 469  
 vagus nerve, 654–5  
 disorders of, 898  
 valeric acid (VA), 264  
 vallate papillae, 639, 640, 641, 642, 651  
 value adding, 1053  
*Vanessa indica*, 936  
 vascular dementia, 437–8  
 vascular parkinsonism (VP), 428  
 vasculature dementia (VaSD), EEG, 263  
 vasoactive intestinal peptide (VIP), 66, 468, 650  
 vasopressin, 468  
 Venezuelan equine encephalitis virus, 462  
 venlafaxine, 904  
 ventral septal glands, 48  
 Vernet's syndrome, 897–8  
 vesicular stomatitis virus (VSV), 487, 462  
*Vibrio cholerae*  
 cyclic di-GMP in, 517  
 biofilm matrix synthesis by cyclic di-GMP in, 516, 517  
*Vibrio fischeri*, quorum sensing in, 518  
*Vibrio harveyi*  
 quorum sensing in, 518–19, 519  
 autoinducers in, 518  
 viral-related smell dysfunction  
 olfactory bulb volume in, 377  
 viruses, transport of, 461–2  
 visual analog scale (VAS), 758  
 visual-to-taste association learning, 1035  
 vitamin A, 392  
 vitamin B complex, 392, 393  
 vitamin B12 derivatives, administration via nasal cavity, 469  
 vitamin D deficiency, 849  
 volatile organic compounds (VOCs)  
 in humans, trigeminal sensitivity to, 1098–1105  
 in birds, 569, 571, 574  
 analytical techniques, 570–2  
 coatings for, 572, **573**  
 solid phase microextraction (SPME), 572–3, 572, 574  
 solvent extraction, 572  
 stir bar sorptive extraction (SBSE) (Twister), 573, 574  
 volumetric brain mapping (VBM), 286  
 vomer bone, 39  
 vomeromodulin, 66  
 vomeronasal glands, 48  
 vomeronasal organ (VNO), 16, 17, 20–2, 40, 42–4, 47–8, 56–8, 69, 95, 100–101, 110, 115, 157, 171–74, 298, 305–6, 464, 547, 553–6, 593, 617–8, 972–4, 1113–25  
 accessory olfactory bulb, 48, 99, 157, 171–3, 306, 592–3, 608, 617, **618**, 1120–1  
 amygdala, 1122–3  
 circuits and information processing, 1120–3, **1121**  
 evolution and decay of, 1123–4  
 functional significance and, 1124–5  
 hypothalamus, 1123  
 pheromones and, 298  
 in primates, 617–18  
 removal, 22
- signaling cascades, 1117–18  
 signaling mechanisms, 1114–17  
 structure and function, 1113, **1114**  
 vomeronasal chemosensory cues, 1118–22  
 vomeronasal sensory neurons (VSNs), 1113  
 physiology and signaling cascades, 1117–18  
 signaling mechanisms, 1114–17  
 vomeronasal chemoreceptors, 1114–17  
 vomeronasal systems, human, development of, 305–6, 306  
 Von Ebner's Gland Complex (CVP/VEG), development of, 732–3  
 von Ebner's glands, 626, 628
- water, drinking, 1079–87  
 description of taste and odor, 1080–1  
 global impact of algae in, 1081–2  
 methyl tertiary butyl ether (MTBE) in, 1083–6  
 public acceptability of flavor, 1082
- wavelet analysis, 272  
 Weber-Fechner law, 1081  
 Weber's glands, 644  
 Weber's law, 231  
 Wegener's granulomatosis, 896  
 Wernicke-Korsakoff syndrome, 499  
 Westermarck effect, 324  
 wheatgerm agglutinin (WGA), 461  
 WGA conjugated to horseradish peroxidase (WGA-HRP), 461, 466  
 Wheel Smell Identification Test, 309  
 wine industry, 1058–9  
 wisdom tooth extraction, 897  
 witchcraft, 5  
 Wnt planar cell polarity (PCP) pathway, 733  
 Wnt/β-catenin, 733  
 working memory, 297, 338–40  
 World Trade Center (9/11), olfaction and, 496, 502  
 WS-3 (n-ethyl-p-menthane-3-carboxamide), 917  
 Wsp chemosensory pathway, **517**
- X-linked Recessive Dystonia-parkinsonism, also termed 'Lubag', I, 428  
 xenobiotics, 453, 485–8  
 metabolism, olfactory, modification of, 78–81  
*Xenopus*, 557, 952  
*Xenopus laevis* (African clawed frog), 1144  
 xerostomia, 626, 850, 891, 892, 901, 904  
 xylene, olfactory system in transport of, 464

- Y-maze, 548, 557  
yes/no identification tests, 237  
yoga, 905
- Z-4-decenal, 574  
(Z)-5-tetradecen-1-ol, 114  
*Zalophus californianus* (California sea lion), 958
- Zicam (zinc gluconate), 461, 499  
zidovudine (AZT;  
3'-azido-2',3'-dideoxythymidine), 467  
zinc, 499  
nanoparticles, 101–4, 104  
olfactory system in transport of, 461  
zinc deficiency, 846, 849, 901
- zinc-enriched neurons (ZENs), 101  
zinc gluconate, 905  
zinc sulfate, 392, 902  
ziziphins, 669  
zoniporide, 676  
*Zonotrichia albicollis* (white-throated sparrow), 968
